Several factors should be considered when choosing a method of birth control. Chief among these are *effectiveness*, *safety*, and *personal preference*. As indicated in [Table 61-1](#), the most effective methods are etonogestrel subdermal implants [Implanon], intramuscular medroxyprogesterone acetate [Depo-Provera], sterilization, and IUDs. Three other methods—OCs, the contraceptive ring [NuvaRing], and the contraceptive patch [Ortho Evra]—are close behind. The remaining methods—condoms, the sponge, diaphragm, cervical cap, spermicides, and periodic abstinence—must be used in a near-perfect fashion to afford any reasonable level of protection.

When factoring safety into the selection equation, several guidelines apply. Combination OCs should be avoided by women with certain cardiovascular disorders (see below), as well as by women over 35 years old who smoke. For women in these categories, an alternative method (eg, diaphragm, progestin-only pill, or IUD) is preferable. Although OCs are effective and relatively convenient, they can also cause many side effects. Accordingly, women who consider the benefit/risk ratio unfavorable should be ad

737

Figure 61-1 **Percentage use for birth control methods, United States, 2002.** *Note:* The segment labeled “other methods” refers to Norplant (no longer used), Lunelle, contraceptive patches, spermicides, cervical caps, female condoms, and other techniques.

Data from the Centers for Disease Control and Prevention.

vised about alternative contraceptive techniques. Women who are not in a mutually monogamous relationship, and hence are at risk for a sexually transmitted disease (STD), should not use an IUD.

Personal preference is a major factor in providing the motivation needed for consistent implementation of a birth control method. Because even the best form of contraception will be less effective if improperly practiced, the importance of personal preference cannot be overemphasized. Practitioners should take pains to educate patients about the contraceptive methods available so that selection and use can be based on understanding.

Additional factors that bear on selecting a birth control method include family planning goals, age, frequency of sexual intercourse, and the individual's capacity for adherence. If family planning goals have already been met, sterilization of either the male or female partner may be desirable. For women who engage in coitus frequently, OCs or a long-term method (eg, Implanon, Depo-Provera, IUD) are reasonable choices. Conversely, when sexual activity is limited, use of a spermicide, condom, or diaphragm may be more appropriate. Since barrier methods combined with spermicides can offer some protection against venereal disease (as well as providing contraception), these combinations may be of special benefit to individuals who have multiple partners. If adherence is a problem (as it can be with OCs, condoms, and diaphragms), use of a long-term method (eg, vaginal contraceptive ring, IUD, Implanon, Depo-Provera) can confer more reliable protection.

62.3 ORAL CONTRACEPTIVES

62.3.1 Classification

There are two main categories of OCs: (1) those that contain both an estrogen and a progestin, known as *combination OCs*, and (2) those that contain only a progestin, known as “minipills” or *progestin-only OCs*. Of the two groups, combination OCs are by far the more widely used.

Combination OCs have three major subgroups: *monophasic*, *biphasic*, and *triphasic*. In a monophasic regimen, the daily estrogen and progestin dosages remain constant throughout the cycle of use. In a biphasic regimen, the estrogen dosage remains constant, but the progestin dosage is increased during the second half of the cycle. In triphasic regimens, the monthly cycle is divided into three different dosages. In most triphasic regimens, the progestin dosage changes for each phase of the cycle; in two regimens, the estrogen dosage varies too.

62.3.2 Combination Oral Contraceptives

Since their introduction in the late 1950s, combination OCs have become one of our most widely prescribed families of drugs. These drugs are highly effective and very safe, although side effects are common.

62.3.2.1 Chemistry

Combination OCs consist of an estrogen plus a progestin. Only two estrogens are employed: ethinyl estradiol and mestranol, which is converted to ethinyl estradiol in the body. In contrast, several progestins are employed. First-generation progestins include norethindrone, levonorgestrel, and ethynodiol diacetate. Second-generation progestins, developed to decrease androgenicity and more closely mimic progesterone, include norgestrel, desogestrel, and norgestimate. A novel progestin—drospirenone—is an analog of spironolactone ([Table 61-2](#)).

62.3.2.2 Mechanism of Action

Combination OCs decrease fertility in several ways. The principal effect is *inhibition of ovulation*. In addition, OCs promote thickening of the cervical mucus, thereby creating a barrier to passage of sperm. Also, OCs can modify the endometrium, making it less favorable for implantation.

62.3.2.3 Effectiveness

As indicated in [Table 61-1](#), OCs are highly effective. With perfect use, the failure rate is only 0.1%. And even with typical use, the failure rate is only 3%. Among women who are *overweight*, efficacy is somewhat reduced. Possible reasons include decreased blood levels of the hormones, sequestration in adipose tissue, and altered metabolism. However, even though efficacy of OCs is slightly reduced in overweight women, these drugs are still more reliable than most of the alternatives.

62.3.2.4 Adverse Effects

Combination OCs can cause a variety of adverse effects. However, although many types of effects may occur, severe effects are rare. Hence, when compared with the serious risks associated with pregnancy and childbirth, the risks of OCs are low. Nonetheless, because OCs are usually taken by women who are healthy, and because OCs represent a potential health hazard (albeit small), we must take steps to minimize risk. To this end, a full medical history should be obtained. If the history reveals an *absolute* contraindication to OC use ([Table 61-3](#)), OCs should not be prescribed. In women with *relative* contraindications, OCs should be used with caution. Should candidates for OCs undergo a thorough physical examination? Possibly, but the need is questionable.

- a The cycle for Loestrin 24 Fe is 24 active tablets followed by 4 ferrous fumarate tablets.
- b The cycle for YAZ is 24 active tablets followed by 4 inert tablets.
- c Ovcon-35 is the only chewable OC available (it may also be swallowed whole).
- d The cycle for Seasonale is 84 active tablets followed by 7 inert tablets.
- e The cycle for Seasonique and LoSeasonique is 84 active tablets followed by 7 low-estrogen tablets (10 mcg ethinyl estradiol).
- f Lybrel is taken continuously, without interruption.

62.3.2.4.1

Thromboembolic Disorders.

Combination OCs have been associated with venous thromboembolism (VTE), arterial thromboembolism, pulmonary embolism, myocardial infarction, and thrombotic stroke. These thrombotic disorders are caused by the *estrogen* in combination OCs, not by the progestin. Thrombosis results at least in part from an increase in circulating levels of clotting factors. Thrombosis is not due to atherosclerosis.

In contrast to older OCs, the OCs available today carry a very low risk of VTE. When combination OCs first became available, they contained *high* doses of estrogens (eg, 100 mcg ethinyl estradiol). As a result, they carried a significant risk of thrombotic disorders. Because today's OCs contain *low* doses of estrogens—no more than 50 mcg ethinyl estradiol and

usually less—the risk of thrombosis among users is only slightly greater than among nonusers.

The risk of thromboembolic phenomena from OCs is increased in the presence of risk factors, especially *heavy smoking, a history of thromboembolism, and thrombophilias* (genetic disorders that predispose to thrombosis). Additional risk factors include diabetes, hypertension, cerebral vascular disease, coronary artery disease, and surgery in which immobilization increases the risk of postoperative thrombosis.

In the past, OCs were not recommended for women over the age of 35. Why? Because earlier studies indicated an increase in the risk of myocardial infarction for this group. However, re-analysis showed that the risk was limited to older women who smoked. With today's low-estrogen OCs, nonsmokers may continue usage until menopause, with no greater risk of MI than among younger women.

Several measures can help minimize thromboembolic phenomena. First, the estrogen dose in OCs should be no greater than required for contraceptive efficacy. Second, OCs should not be prescribed for heavy smokers, women with a history of thromboembolism, or women with other risk factors for thrombosis. Third, OCs should be discontinued at least 4 weeks prior to surgery in which postoperative thrombosis might be expected. Lastly, women should be informed about the symptoms of thrombosis and thromboembolism (eg, leg tenderness or pain, sudden chest pain, shortness of breath, severe headache, sudden visual disturbance) and instructed to consult the prescriber if these occur.

740

741

TABLE 61-3 Absolute and Relative Contraindications to the Use of Combined OCs

Absolute Contraindications
Thrombophlebitis, thromboembolic disorders, cerebral vascular disease, coronary occlusion
A past history of these conditions or a condition that predisposes to these disorders
Abnormal liver function
Known or suspected breast cancer
Undiagnosed abnormal vaginal bleeding
Known or suspected pregnancy
Smokers over the age of 35
Relative Contraindications
Hypertension
Cardiac disease
Diabetes
History of cholestatic jaundice of pregnancy
Gallbladder disease
Uterine leiomyoma
Epilepsy
Migraine

What about the cardiovascular risk for *former* OC users? Data from the Women's Health Initiative suggest that use of OCs in the past may *protect* against cardiovascular disease. Among women with a history of OC use, there was an 8% decrease in the overall incidence of cardiovascular disease, including a reduced risk of angina, myocardial infarction, peripheral vascular disease, transient ischemic attacks, and elevation of cholesterol.

62.3.2.4.2

Cancer.

Oral contraceptives present no known risk of cancer—with the important exception of promoting breast cancer growth. The effects of OCs on cancers of the ovaries, endometrium, cervix, and breast have been studied extensively. Effects on three of these cancers are clear:

OCs *protect* against ovarian and endometrial cancer, and have *no impact* (positive or negative) on cervical cancer, which is caused by human papillomaviruses.

What about breast cancer? Until recently, the question was unresolved: some older studies found a link between OC use and breast cancer; others did not. Now we seem to have a definitive answer: OCs do *not* increase the risk of breast cancer for most women. This conclusion is based on data from the Women's Contraceptive and Reproductive Experience (Women's CARE) study, published in 2002. This major study, involving over 9000 women, found no association between present or past use of OCs and the development of breast cancer. This conclusion applied not only to study participants as a whole, but also to women in the following subgroups:

- Those who used OCs with high estrogen content
- Those who used OCs for a prolonged time
- Those who began OC use during adolescence
- Those with a first-degree relative with breast cancer

These results should reassure women who are OC users.

However, although this study shows that OCs do not increase risk for most women, the results of another large recent study show that OCs *do* increase risk for some women, specifically, women who have the *BRCA1* gene mutation. Even without taking OCs, these women have a very high—50% to 80%—lifetime risk of breast cancer. OCs increase this risk by one-third. The same study found that OCs do *not* increase risk in women with the *BRCA2* mutation.

It is important to note that, although OCs do not *cause* breast cancer, estrogens can promote the growth of *existing* breast carcinoma. Accordingly, women with this disease should not take OCs.

62.3.2.4.3

Hypertension.

Combination OCs can cause hypertension, but the risk with today's low-estrogen preparations is very low. How do OCs raise blood pressure? By increasing blood levels of two compounds: angiotensin (a potent vasoconstrictor) and aldosterone (a hormone that promotes salt and water retention). If hypertension develops, and if OCs are determined to be the cause, two options are open: (1) discontinue the OC or (2) continue the OC and manage the hypertension with drugs.

62.3.2.4.4 Abnormal Uterine Bleeding.

By altering the endometrium, OCs may decrease or eliminate menstrual flow. In addition, breakthrough bleeding and spotting may occur, especially with the use of extended-cycle OCs (eg, Seasonique, Seasonale). Spotting and bleeding can also occur with monthly-cycle OCs, most often during the first 3 months when low-estrogen OCs are used. If a period is missed while taking monthly-cycle OCs, the possibility of pregnancy should be assessed. Following discontinuation of OCs, normal menstruation usually resumes, although the first period may be delayed. Women with a pretreatment history of irregular menses will return to their previous pattern when OCs are discontinued.

62.3.2.4.5 Use in Pregnancy and Lactation.

OCs have no therapeutic role during pregnancy, and hence are *contraindicated for use by pregnant women*. Pregnancy should be ruled out prior to starting OC therapy, and, if pregnancy should occur despite OC use, dosing should stop immediately. Woman should be assured, however, that inadvertent use of OCs during early pregnancy poses no risk of fetal harm. Because OCs have no role in pregnancy—and *not* because they are harmful—these drugs are classified in Pregnancy Risk Category X.

Combination OCs enter breast milk and reduce milk production, especially in the early stages of lactation. In contrast, progestin-only OCs have little or no effect on milk production, and hence are preferred for contraception during lactation, at least early on. (Later, when the milk supply is well established, and especially with the addition of solids to the infant's diet, combination OCs may again be used.)

62.3.2.4.6 Stroke in Women with Migraine.

When used by women who experience migraine headaches, OCs may increase the risk of thrombotic stroke. However, the absolute increase is low: only 8 cases per 100,000 women at age 20, and rising to 80 cases per 100,000 women at age 40. Because the risk is low, OCs are generally considered safe for women with migraine, provided they are under age 35, don't smoke, and are healthy, and provided their headaches are not preceded by visual changes known as an aura (migraine with aura has a greater risk of stroke than migraine without aura).

Migraine and its management are discussed at length in [Chapter 30](#).

62.3.2.4.7 Benign Hepatic Adenoma.

Hepatic adenoma is a rare complication seen in women who use OCs that contain mestranol. These highly vascular, nonmalignant tumors are usually picked up as incidental findings on a

computed tomography scan or magnetic resonance imaging. If hepatic adenoma is diagnosed, discontinuing OCs usually results in spontaneous tumor regression.

62.3.2.4.8 Glucose Intolerance.

Oral contraceptives can elevate plasma glucose levels. This diabetogenic effect is caused by the *progestin* in OCs. Glucose intolerance is most likely in patients who are already diabetic or have experienced gestational diabetes. Because hypoglycemic agents (eg, insulin) can control glucose elevations induced by OCs, the presence of diabetes does not preclude OC use. Prediabetic women should be monitored for development of hyperglycemia. Glucose intolerance may occur less with OCs that contain second-generation progestins, such as *desogestrel* or *norgestimate*.

62.3.2.4.9 Other Adverse Effects.

Rarely, OCs may precipitate *gallbladder disease* in women who already have gallstones or a history of gallbladder disease. OCs can occasionally cause *ocular injury* (eg, retinal vascular occlusion, retinal edema, optic neuropathy). Accordingly, if visual changes occur, OCs should be discontinued until the underlying cause is diagnosed. Rarely, OCs cause *melasma*, characterized by dark brown patches on the face.

62.3.2.5 Noncontraceptive Benefits of OCs

OCs decrease the risk of several disorders, including ovarian cancer, endometrial cancer, ovarian cysts, pelvic inflammatory disease (PID), benign breast disease, iron deficiency anemia, and acne. In addition, OCs favorably affect menstrual symptoms: cramps are reduced, menstrual flow is lighter and of shorter duration, and menses are more predictable. In women with premenstrual syndrome or premenstrual dysphoric disorder, OCs can reduce symptom intensity. In some women with menstrually associated migraine, OCs can reduce migraine frequency. Surprisingly, OCs may even benefit women with rheumatoid arthritis.

62.3.2.6 Drug Interactions

62.3.2.6.1 Drugs and Herbs That Reduce the Effects of OCs.

Products that induce hepatic cytochrome P450 can accelerate OC metabolism, and can thereby reduce OC effects. Products that induce P450 include *rifampin* (used for tuberculosis), *ritonavir* (used for HIV infection), several *antiepileptic agents* (carbamazepine, phenobarbital, phenytoin, and primidone), and *St. John's wort* (an herb used widely for depression). Women taking OCs in combination with any of these agents should be alert for indications of reduced

OC blood levels, such as breakthrough bleeding or spotting. If these signs appear, it may be necessary to either (1) increase the estrogen dosage of the OC, (2) combine the OC with a second form of birth control (eg, condom), or (3) switch to an alternative form of birth control.

62.3.2.6.2 Drugs Whose Effects Are Reduced by OCs.

OCs can decrease the benefits of warfarin and hypoglycemic agents. By increasing levels of clotting factors, OCs can decrease the effectiveness of *warfarin*, an anticoagulant. By increasing levels of glucose, OCs can counteract the benefits of insulin and other hypoglycemic agents used in diabetes. Accordingly, when combined with OCs, warfarin and hypoglycemic agents may require increased dosage.

62.3.2.6.3 Drugs Whose Effects Are Increased by OCs.

OCs can impair the hepatic metabolism of several agents, including *theophylline*, *tricyclic antidepressants*, *diazepam*, and *chlorthalidone*. Because of reduced clearance, these drugs may accumulate to dangerous levels. If signs of toxicity appear, dosage of these drugs should be reduced.

62.3.2.7 Composition

The combination OCs currently available are listed in [Table 61-2](#). As shown, practically all products contain the same estrogen: *ethinyl estradiol*. (A few older products contain mestranol, which undergoes conversion to ethinyl estradiol in the body.) In contrast, several progestins are employed, including *norethindrone*, *levonorgestrel*, *norgestimate*, *desogestrel*, and *drospirenone*. The preparations in [Table 61-2](#) are listed in order of increasing estrogen content. The OCs with lower estrogen are safer. As a rule, high-estrogen OCs are reserved for women who are taking drugs that induce P450.

62.3.2.7.1 Yasmin and YAZ.

Two combination OCs—Yasmin and YAZ—contain ethinyl estradiol and *drospirenone*, a unique compound that has both progestational and antialdosterone actions. This new compound is a structural analog of spironolactone, a potassium-sparing diuretic that blocks receptors for aldosterone. Drospirenone was developed in an effort to reduce fluid retention caused by the estrogen component in combination OCs. (Estrogens promote fluid retention by activating the renin-angiotensin-aldosterone system. Drospirenone reduces fluid retention by blocking aldosterone receptors, thereby preventing retention of sodium and water. As a result, Yasmin and YAZ may cause less bloating, weight gain, and hypertension than other

combination OCs.) The principal concern with drospirenone is *hyperkalemia* secondary to renal retention of potassium. Accordingly, the drug is inappropriate for women with conditions that predispose to hyperkalemia (eg, renal insufficiency, adrenal insufficiency, liver disease). Furthermore, it should be used with caution in women taking other drugs that can elevate serum potassium. Important among these are angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, potassium-sparing diuretics, potassium supplements, and nonsteroidal anti-inflammatory drugs (when taken daily). If women taking these drugs are given Yasmin or YAZ, potassium levels should be checked during the first cycle of use.

62.3.2.8 Dosing Regimens

Combination OCs are dosed in a cyclic pattern. With most products, each cycle is *28 days long* (see [Table 61-2](#)). However, with three newer products, the cycle is *extended*. The 28-day regimens are subdivided into three groups: *monophasic*, *biphasic*, and *triphasic*. The biphasic and triphasic preparations reflect efforts to more closely simulate ovarian production of estrogens and progestins. However, these preparations offer little if any advantage over monophasic OCs.

62.3.2.8.1 28-Day-Cycle OCs.

With two exceptions,^{*} these products are taken in a sequence consisting of 21 days of an active pill followed by 7 days on which either (1) no pill is taken, (2) an inert pill is taken, or (3) an iron-containing pill is taken. The sequence is begun on either (1) the first day of the menstrual cycle or (2) the first Sunday after the onset of menses. With the first option, protection is conferred immediately, and hence no backup contraception is needed. With a Sunday start, which is done to have menses occur on weekdays rather than the weekend, protection may not be immediate, and hence a condom should be used during the first cycle. 742

With both options, each dose should be taken at the same time every day (eg, with a meal or at bedtime). Successive dosing cycles should commence every 28 days, even if there is breakthrough bleeding or spotting. 743

^{*} With two products—Loestrin 24 Fe and YAZ—active pills are taken for 24 days, rather than 21. The purpose is to decrease bleeding, and to decrease the chance of ovulation (by shortening the pill-free period from 7 days down to 4 days).

62.3.2.8.2 Extended-Cycle and Continuous Regimens.

Many specialists recommend taking combination OCs for an extended time rather than following the traditional 28-day cycle. Why? Because doing so decreases episodes of

withdrawal bleeding with its associated menstrual pain, premenstrual symptoms, headaches, and other problems. Prolonged use of OCs is possible because these drugs suppress endometrial thickening, and hence monthly bleeding is not required to slough off hypertrophied tissue. At this time, only four products—*Seasonale*, *Seasonique*, *LoSeasonique*, and *Lybrel*—are packaged and marketed for prolonged use. The following regimens are employed:

- *Seasonale*—active pills for 84 days, then no pills for 7 days
- *Seasonique* and *LoSeasonique*—active pills for 84 days, then low-dose estrogen pills for 7 days
- *Lybrel*—active pills are taken continuously, with no scheduled interruption

Hence, with *Seasonale*, *Seasonique*, and *LoSeasonique*, withdrawal bleeding occurs just 4 times a year, instead of 13 as with conventional cycles. With *Lybrel*, withdrawal bleeding occurs only when dosing is finally stopped. However, although these products decrease episodes of *scheduled* bleeding, *breakthrough bleeding* can be more common. It is important to note that there is nothing special about the estrogen/progestin combination used in these extended-cycle products. This means we could get the same results with other combination OCs, provided they are *monophasic*. To achieve an extended schedule, the user would simply purchase four packets of a 28-day product (each of which contains 21 active pills), and then take the active pills for 84 days straight.

62.3.2.8.3 Adjusting the Regimen to Reduce Side Effects.

With most women, therapy is initiated with an OC containing 30 to 35 mcg of ethinyl estradiol. If significant nausea occurs, it can be managed by dosing at bedtime or, if needed, switching to an OC with less estrogen. Using less estrogen can also reduce breast discomfort. During the first 3 months of use, spotting and breakthrough bleeding are common, and usually resolve on their own. If they don't, they can be managed by increasing the estrogen dosage, or by using a product that contains a different progestin. When substituting one combination OC for another, the change is best made at the beginning of a new cycle.

62.3.2.8.4 What to Do in the Event of Missed Doses.

The chances of ovulation (and hence pregnancy) from missing one OC dose are small. However, the risk of pregnancy becomes progressively larger with each successive omission. If only one dose is missed, that dose should be taken together with the next scheduled dose. If two doses are missed, two doses should be taken per day on the following 2 days. If three

doses are missed, a new cycle should be initiated, starting 7 days after the last pill was taken. An additional form of birth control should be used during the first 2 weeks of the new cycle.

62.3.3 Progestin-Only Oral Contraceptives

Progestin-only OCs, also known as “minipills,” contain a progestin (either norethindrone or norgestrel) but no estrogen. Because they lack estrogen, minipills do not cause thromboembolic disorders, headaches, nausea, and most of the other adverse effects associated with combination OCs. Unfortunately, although slightly safer than combination OCs, the progestin-only preparations are less effective and are more likely to cause irregular bleeding (breakthrough bleeding, spotting, amenorrhea, inconsistent cycle length, variations in the volume and duration of monthly flow). Irregular bleeding is the major drawback of these products and the principal reason that women discontinue them. Available products are listed in [Table 61-2](#).

Contraceptive effects of the minipill result largely from altering cervical secretions. Under the influence of progestins, cervical glands produce a thick, sticky mucus that acts as a barrier to penetration by sperm. Progestins also modify the endometrium, making it less favorable for nidation. Compared with combination OCs, minipills are weak inhibitors of ovulation, and hence this mechanism contributes little to their effects. Unlike combination OCs, whose administration is cyclic, progestin-only OCs are taken continuously. Use is initiated on day 1 of the menstrual cycle and one pill is taken daily thereafter. A backup contraceptive method should be used for the first 7 days. Each pill should be taken at the same time each day.

In the event of missed dosage, the following guidelines apply. If 1 pill is missed, it should be taken as soon as remembered, and backup contraception should be used for at least 2 days. If two pills are missed, the regimen should be restarted, and backup contraception should be used for at least 2 days. In addition, if two or more pills are missed and no menstrual bleeding occurs, a pregnancy test should be done.

62.4 COMBINATION CONTRACEPTIVES WITH NOVEL DELIVERY SYSTEMS

Two combination contraceptives—a transdermal patch and a vaginal ring—have the same mechanism as combination OCs, but they deliver hormones in novel ways. Like combination OCs, both of the new contraceptives contain two hormones—an estrogen and a progestin—that undergo absorption into the systemic circulation, and prevent pregnancy primarily by suppressing ovulation. What's different is how the hormones are delivered: With the patch, the hormones are absorbed through the skin, and with the vaginal ring, the hormones are absorbed through the vaginal mucosa. Otherwise, the pharmacology of the new contraceptives is essentially identical to that of combination OCs.

62.4.1 Transdermal Contraceptive Patch

In 2001, the FDA approved *Ortho Evra*, the first transdermal contraceptive patch. As noted, the new product has the same mechanism as combination OCs. The patch and combination OCs are equivalent with respect to contraceptive efficacy and the incidence of breakthrough bleeding and spotting. The principal difference between them lies with their dosing schedules: Whereas combination OCs must be taken every day, the patch is applied just once a week. As a result, the patch is more convenient than OCs, and hence adherence is better.

The Ortho Evra patch contains 750 mcg of *ethinyl estradiol* (the estrogen found in most combination OCs) and 6 mg of *norelgestromin* (the active metabolite of norgestimate, a progestin found in some OCs). Each day, the patch releases 20 mcg of ethinyl estradiol and 150 mcg of norelgestromin. Following release, these hormones penetrate the skin, enter capillaries, and undergo distribution throughout the body. Plasma levels plateau 2 days after the first patch is applied.

Application of the patch, which is 1.75 inches square (about the size of a matchbook), is done once a week for 3 weeks, followed by 1 week off (to permit normal menstruation). Patches are applied to the lower abdomen, buttocks, upper outer arm, or upper torso (front or back)—but not to the breasts, or to skin that is red, cut, or irritated. To enhance adhesion, the skin should be clean and dry, and free of lotions, creams, or oils.

743

744

How effective is the patch? In clinical trials, the pregnancy rate was about 1 for every 100 woman-years of patch use. However, among women who weighed 90 kg (198 lbs) or more, the pregnancy rate was significantly higher, suggesting the patch may not be appropriate for women in this weight group.

When should patch use begin? For women not currently using OCs, the first patch should be applied during the first 24 hours of the menstrual period. For women switching from OCs, the first patch should be applied on the first day of withdrawal bleeding.

In clinical trials, 4.6% of patches became partially or completely detached. When this occurs, the patch should be reattached or replaced. If the patch has been off less than 24 hours, backup contraception is unnecessary. However, if the patch has been off more than 24 hours, a new cycle should be started, accompanied by backup contraception during the first 7 days.

The most common adverse effects are breast discomfort, headache, local irritation, nausea, and menstrual cramps. Compared with Triphasil (a combination OC), the patch produces a higher incidence of breast discomfort (18.7% vs. 5.8%) and dysmenorrhea (13.3% vs. 9.6%).

Contraindications and drug interactions are the same as for combination OCs.

Does the patch cause more venous thromboembolism (VTE) than OCs do? Possibly. Three epidemiologic studies have examined the question. In two of these studies, the risk of VTE in women using the patch was double the risk in women using combination OCs. However, in the third study, there was no difference in risk. Of note, women who use the patch are exposed to 60% more estrogen than women who use an OC containing 35 mcg of estrogen. The higher estrogen exposure could increase the risk of VTE.

62.4.2 Vaginal Contraceptive Ring

In 2001, the FDA also approved *NuvaRing*, a hormonal contraceptive device designed for vaginal insertion. Like combination OCs, the ring contains an estrogen/progestin combination that prevents pregnancy largely by suppressing ovulation. Adverse effects, drug interactions, warnings, and contraindications for the ring are the same as for combination OCs. The ring is made of transparent, flexible material and looks like a very skinny doughnut, with an overall diameter of 2.1 inches and a cross-sectional diameter of one-eighth inch. Insertion is done by the user.

The NuvaRing contains 2.7 mg of *ethinyl estradiol* and 11.7 mg of *etonogestrel* (the active metabolite of desogestrel, a progestin found in some OCs). Each day, the ring releases 15 mcg of ethinyl estradiol and 120 mcg of etonogestrel. Following release, the hormones penetrate the vaginal mucosa, undergo absorption into the blood, and then are distributed throughout the body. Contraception results from systemic effects—not from local effects in the vagina.

One ring is inserted once each month, left in place for 3 weeks, and then removed; a new ring is inserted 1 week later. During the ring-free week, withdrawal bleeding occurs. The new ring should be inserted on schedule, even if bleeding is still ongoing. If a ring is expelled before 3 weeks have passed, it can be washed off in warm water (not hot water) and reinserted. If the expelled ring cannot be reused, a new one should be inserted. If more than 3 hours elapse between ring expulsion and reinsertion, contraceptive effects may be diminished, and hence backup contraception should be used for 7 days.

Initiating ring use is done as follows:

- For women not currently using contraception, ring use should start anytime during days 1 through 5 of the menstrual cycle, even if bleeding is ongoing; backup contraception should be used during the first 7 days.
- For women switching from combination OCs, ring use should start within 7 days of taking the last active OC; no backup contraception is needed.

- For women switching from progestin-only OCs, ring use should start on the same day the last pill is taken, which can be any day of the month; backup contraception should be used during the first 7 days.
- For women switching from Implanon, ring use should start on the same day that the implant is removed; backup contraception should be used during the first 7 days.
- For women switching from a progestin-containing IUD, ring use should start on the same day the IUD is removed; backup contraception should be used during the first 7 days.
- For women switching from IM progestin injections, ring use should start on the day of the next scheduled injection; backup contraception should be used during the first 7 days.

In clinical trials, the most common adverse effects were vaginitis, headaches, upper respiratory infection, leukorrhea, sinusitis, weight gain, and nausea. Common reasons for discontinuing the ring included foreign body sensations, coital problems, ring expulsion, vaginal symptoms, headache, and emotional lability. The risk of serious adverse effects—thrombosis, embolism, and hypertension—is the same as with combination OCs.

62.5 LONG-ACTING CONTRACEPTIVES

62.5.1 Subdermal Etonogestrel Implants

A subdermal system [Implanon] for delivery of etonogestrel is available for long-term, reversible contraception. As indicated in [Table 61-1](#), Implanon is among the most effective contraceptives available. An older subdermal system, known as Norplant, was removed from the market.

62.5.1.1 Description.

Implanon consists of a single 4-cm rod that contains 68 mg of etonogestrel, a synthetic progestin. The rod is implanted subdermally in the groove between the biceps and triceps in the nondominant arm. Etonogestrel then diffuses slowly and continuously, providing blood levels sufficient for contraception for 3 years, after which the rod is removed. If continued contraception is desired, a new rod is implanted.

62.5.1.2 Mechanism of Action.

Etonogestrel suppresses ovulation and thickens cervical mucus. In addition, it causes the endometrium to become involuted and hence hostile to implantation.

62.5.1.3 Pharmacokinetics.

Daily release of etonogestrel is 60 to 70 mcg initially and gradually declines to 25 to 30 mcg over 3 years. Absorbed drug is slowly metabolized by the liver. After the rod is removed, etonogestrel is undetectable within 5 to 7 days.

62.5.1.4 Drug Interactions.

Agents that induce hepatic enzymes—such as barbiturates, phenytoin, rifampin, carbamazepine, topiramate, HIV protease inhibitors, and St. John's wort—may reduce the efficacy of Implanon. Accordingly, Implanon should not be used by women taking these drugs.

62.5.1.5 Adverse Effect: Irregular Bleeding.

In women using Implanon, bleeding episodes are irregular and unpredictable. In clinical trials, amenorrhea occurred in 22% of women; infrequent bleeding (less than 3 bleeding or spotting episodes in 90 days) occurred in 34% of women; frequent bleeding (more than 5 bleeding or spotting episodes in 90 days) occurred in 7% of women, and prolonged bleeding (more than 14 days of bleeding in 90 days) occurred in 18% of women. Despite effects on bleeding, levels of hemoglobin were unaffected over 3 years. The general pattern of irregular and unpredictable bleeding does not change while using Implanon. Bleeding irregularities are the leading reason for discontinuing Implanon.

62.5.1.6 Use with Breast-feeding.

Implanon is safe to use during breast-feeding. Very little is excreted into breast milk. In a controlled clinical trial, there were no significant effects on the physical or psychomotor development of infants. Also, Implanon had no effect on the production or quality of milk.

62.5.2 Depot Medroxyprogesterone Acetate

Depot medroxyprogesterone acetate (DMPA), injected IM or subQ, protects against pregnancy for 3 months or longer. Three mechanisms are involved: (1) suppression of ovulation, (2) thickening of the cervical mucus, and (3) alteration of the endometrium such that implantation is unlikely.

When injections are discontinued, return of fertility is delayed. The average delay is 9 months.

744

745

Two DMPA formulations are available. One is injected IM [Depo-Provera] and the other subQ [Depo-subQ Provera 104]. Dosages are 150 mg and 104 mg, respectively, injected once every 3 months. Both products are indicated for contraception. The subQ product is approved for endometriosis as well (see [Chapter 62](#)).

Most adverse effects are like those seen with other progestin-only contraceptives. Menstrual disturbances are common; menstruation may be irregular at first and then, after 6 to 12 months, may cease entirely. Mild weight gain (about 3.5 pounds) is likely during the first year. Women may also experience abdominal bloating, headache, depression, and decreased libido. However, it is unclear that DMPA is the cause. Although DMPA has produced uterine and mammary cancers in animals, a large-scale study has shown no increase in the risk of cervical, ovarian, or breast cancer in women—and the risk of endometrial cancer is actually reduced.

DMPA poses a risk of reversible bone loss, but this risk does not outweigh the benefits of treatment. During the first 1 to 2 years of DMPA use, bone mineral density (BMD) declines rapidly, at a rate of 1% to 2% per year. However, after this time, the rate of bone loss slows down. Importantly, when DMPA is discontinued, BMD returns to pretreatment levels, typically within 30 months. Whether the reduction in BMD increases fracture risk is unknown. While this story was still evolving, the FDA, in 2004, revised the label for DMPA to include a black-box warning that recommends against using the drug for more than 2 years. However, in the light of data gathered since 2004, this warning appears unwarranted. Accordingly, in 2008, an ACOG committee counseled that practitioners should not let concerns about bone loss deter them from prescribing DMPA or cause them to limit prescriptions to 2 years. In addition, the committee recommended against routine testing of BMD in women on DMPA. When counseling patients about this issue, practitioners should point out that any risk of fracture with DMPA is theoretical, whereas the risks associated with pregnancy are very real.

62.5.3 Depot Medroxyprogesterone Acetate plus Estradiol Cypionate

The combination of DMPA plus estradiol, marketed as *Lunelle*, is the first injectable contraceptive to contain a progestin *plus* an estrogen. Dosing is done every 28 to 30 days, and, because of the estrogen component, users experience monthly withdrawal bleeds. Although approved for use here, *Lunelle* was voluntarily withdrawn from the U.S. market in 2005. It remains a popular contraceptive in Latin America.

Lunelle is supplied in 0.5-mL, single-dose vials that contain 25 mg of DMPA and 5 mg of estradiol cypionate. The combination is injected IM (by a healthcare professional) every 28 to 30 days. If more than 33 days have elapsed since the last dose, pregnancy should be ruled out before resuming treatment. Dosing is begun during the first 5 days of the menstrual cycle or within 2 days of discontinuing OCs. Contraceptive effects are present during the first cycle. Women who want to use the drug following pregnancy should begin treatment no sooner than 4 weeks postpartum (in the absence of breast-feeding) or 6 weeks postpartum (in the presence of breast-feeding).

Lunelle and Depo-Provera are similar in some respects and different in others. Both products have the same mechanism of action (they work primarily by suppressing ovulation) and both have high contraceptive efficacy (more than 99%). In other respects, the products differ significantly.

Because each dose of Lunelle contains less DMPA than each dose of Depo-Provera, Lunelle must be administered more often (once a month compared with every 3 months). When treatment is discontinued, fertility returns in 2 to 4 months with Lunelle, versus about 9 to 12 months with Depo-Provera. Because Lunelle has estrogen, most women (75%) using the drug have monthly withdrawal bleeding, whereas, with Depo-Provera, menses becomes irregular and may eventually stop. Since Lunelle contains estrogen and a progestin, it has the same risks as the combined oral contraceptive.

62.5.4 Intrauterine Devices

IUDs are among the most reliable forms of reversible birth control (see [Table 61-1](#)). In addition, the IUDs available today are very safe when used by appropriate clients (see below). Worldwide, over 85 million women use these devices. However, despite their safety and efficacy, IUDs are not popular in the United States: Among women who use birth control, only 2% choose an IUD. Nonuse of IUDs is largely the legacy of the Dalkon Shield, a poorly designed IUD associated with a high rate of pelvic infection.

Two IUDs are currently available: (1) the *copper T 380A* [ParaGard] and (2) the *levonorgestrel-releasing intrauterine system* [Mirena]. As indicated in [Table 61-1](#), both are highly effective. IUDs are placed within 7 days of the onset of menses, and a replacement can be inserted during any phase of the menstrual cycle. ParaGard can remain in place for 10 years and Mirena for 5 years. How do these devices prevent conception? Both IUDs, which are T shaped, produce a harmless local inflammatory response that is spermicidal. ParaGard, whose active ingredient is copper, may also inhibit implantation. Mirena, whose active ingredient is levonorgestrel, also causes endometrial involution and thickening of the cervical mucus. Neither device prevents ovulation.

With proper counseling and client selection, both IUDs are very safe. The principal risk is pelvic inflammatory disease (PID) secondary to a sexually transmitted disease (STD). Accordingly, IUDs should be used only by women with a low risk for STDs—that is, by women who are monogamous, and who are confident that their partners are monogamous too. The risk for PID is highest in the first 20 days after insertion, with a rate of 9.7 cases per 1000 woman-years of use. One month after insertion, the risk declines to only 1.4 cases per 1000 woman-years of use.

Both IUDs can cause cramping and alteration of menses. Cramping is most intense upon IUD insertion, and can be minimized by applying a topical anesthetic (2% lignocaine intracervical gel)

or by premedicating with ibuprofen. With ParaGard, monthly bleeding is increased. With Mirena, light spotting and amenorrhea are common.

In addition to providing long-term contraception, ParaGard can be used for emergency contraception (by placing the device within 5 days of unprotected intercourse). In one study, the pregnancy rate with postcoital placement was only 0.2%.

62.6 SPERMICIDES

Spermicides are chemical surfactants that kill sperm by destroying their cell membrane. These drugs are available in the form of a foam, gel, jelly, suppositories, vaginal film, and contraceptive sponge. All formulations can be purchased without a prescription. When used alone, spermicides are only moderately effective (see [Table 61-1](#)). Combined use with a diaphragm or condom increases efficacy. As indicated in [Table 61-4](#), spermicidal preparations contain either *nonoxynol 9* or *octoxynol 9*.

Spermicides are generally devoid of serious side effects. Studies show no relationship between spermicides and birth defects. However, there is some evidence that nonoxynol 9 may *increase* the risk of HIV transmission. The apparent mechanism is promotion of vaginal, cervical, anal, and rectal lesions that facilitate HIV penetration to cells. Allergic reactions (to the drug or vehicle) occur in some women.

Correct use is required for contraceptive efficacy. The spermicide must be applied prior to coitus, but no more than 1 hour in advance (when used alone). Containers for foam preparations must be shaken thoroughly before each use to ensure dispersal of the spermicide. Suppositories should be inserted at least 10 to 15 minutes before intercourse to allow time for dissolution. Spermicides should be reapplied each time intercourse is anticipated. Douching should be postponed for at least 6 hours following coitus.

The contraceptive sponge [Today Sponge] is a soft, porous, polyurethane disk impregnated with 1000 mg of nonoxynol 9. When inserted to cover the cervix, it protects against conception by (1) releasing spermicide, (2) absorbing seminal fluid, and (3) blocking penetration of sperm. Unlike other spermicide products, which must be re-applied before each act of intercourse, a single sponge is effective for 24 hours, regardless of how often coitus takes place. After 24 hours, the sponge should be removed. The rate of unintended pregnancy with the sponge is high: 16% among typical *nulliparous* users, and 32% among *parous* users. The most common adverse effects are vaginal irritation and dryness. The Today Sponge was voluntarily withdrawn in 1995 and then reintroduced in 2005.

745

TABLE 61-4 Spermicides

Formulation	Active Ingredient	Trade Name
Foam	Nonoxynol 9 (12.5%)	Delfen Contraceptive
Jelly	Nonoxynol 9 (3%)	Gynol II Extra Strength Contraceptive*
Gel	Nonoxynol 9 (4%)	Conceptrol Disposable Contraceptive
	Nonoxynol 9 (3.5%)	Advantage 24*
	Nonoxynol 9 (2.2%)	K-Y Plus*
	Nonoxynol 9 (2%)	Gynol II Contraceptive,* Shur Seal*
	Octoxynol 9 (1%)	Ortho-Gynol Contraceptive*
Suppository	Nonoxynol 9 (2.27%)	Encare
	Nonoxynol 9 (100 mg)	Semicid
Sponge	Nonoxynol 9 (1000 mg)	Today Sponge
Vaginal Film	Nonoxynol 9 (28%)	VCF

* Intended for use only in combination with a vaginal diaphragm.

62.7 BARRIER DEVICES

Barrier devices—male condoms, female condoms, diaphragms, and the cervical cap—are nonpharmacologic options for birth control. Of the barrier devices available, condoms for men are by far the most commonly employed.

62.7.1 Condoms for Men.

The condom is a thin sheath, made of latex, polyurethane, or lamb's intestine, that fits snugly over the penis, and hence traps ejaculate released during intercourse. As indicated in [Figure 61-1](#), condoms are the fourth most common form of birth control. The typical-use failure rate is 15%.

In the United States, most condoms are made of latex, which is impermeable to bacteria and viruses. Hence, in addition to protecting against pregnancy, latex condoms offer protection against STDs. There is good evidence that condom use protects against HIV, chlamydia, trichomonas, and gonorrhea, and probably against infection with HPVs (human papillomaviruses). Protection against syphilis, chancroid, and genital herpes is less certain. Lubricants that contain mineral oil can rapidly decrease the barrier strength of latex—by as much as 90%—and therefore should be avoided. Allergy to latex can develop in men and women, especially with repeated exposure.

Like latex condoms, polyurethane condoms offer some protection against STDs. In addition, they are thinner than latex condoms, possibly stronger, and don't cause allergies. However, the failure rate with polyurethane is higher than with latex.

In contrast to latex and polyurethane condoms, condoms made from lamb intestine are permeable to viruses, and hence do not protect against viral STDs.

62.7.2 Condom for Women.

The *Reality* female condom is a loose-fitting, tubular polyurethane pouch that has flexible rings at both ends. The ring at the closed end anchors the pouch over the cervix. The ring at the open end, which is larger than the ring at the closed end, is placed over the labia and serves as an external anchor. The Reality condom is prelubricated, available without prescription, cannot be combined with a male condom, and should be used just once and then discarded. Like male condoms, the female condom provides some protection against STDs. At this time, the female condom is the only safe and effective woman-initiated method for protecting against HIV infection. The pregnancy failure rate with typical use is 21%.

In 2009, the FDA approved a second-generation female condom (FC2), manufactured by the same company that makes the Reality condom. The FC2 differs from the Reality condom in two ways. First, it is made from a proprietary nitrile polymer (rather than polyurethane). Second, it is easier to make, and hence costs about 30% less.

62.7.3 Diaphragm.

The diaphragm is a soft rubber cap with a metal spring to reinforce its rim. The device must be fitted by a healthcare provider, and the user must be taught how to insert and remove the device. When in place over the cervical os, the diaphragm holds spermicidal jelly or cream against the cervix and blocks access of sperm to the cervix. Spermicide must be reapplied externally with repeated intercourse. The diaphragm can be inserted as long as 6 hours prior to intercourse, and must remain in place for at least 6 hours after. Because of the risk of toxic shock syndrome, the diaphragm should not remain in place more than 24 hours. With typical use, the failure rate is about 18%.

62.7.4 Cervical Cap.

The *Prentif Cavity-Rim Cervical Cap* is a small, pliant, cup-shaped device that fits snugly over the cervix. Suction holds it in place. The device must be fitted by a healthcare provider, and the user must be taught how to insert it. Because only four sizes are available, some women cannot be fitted. Like the diaphragm, the cap is filled with spermicidal cream or jelly prior to use, and can be

inserted up to 6 hours before intercourse. There is no need to apply additional spermicide with repeated intercourse. The cap should remain in place for at least 8 hours after intercourse, and probably no longer than 48 hours (although the manufacturer says it can stay in place 48 hours). The typical-use failure rate is about 18%.

62.8 DRUGS FOR MEDICAL ABORTION

62.8.1 Mifepristone (RU 486) with Misoprostol

Mifepristone (RU 486) [Mifeprex] is a synthetic steroid that blocks receptors for progesterone and glucocorticoids. In the United States, the drug has one approved indication: termination of early intrauterine pregnancy; cotreatment with misoprostol is usually required. Investigational uses include breast cancer, ovarian cancer, meningiomas, Cushing's syndrome, uterine fibroids, and endometriosis. In addition, mifepristone is the most effective drug known for emergency contraception, although it is not used routinely for this purpose ([Box 61-1](#)). Mifepristone was approved for use in the United States on September 20, 2000.

Mifepristone, followed by misoprostol, is a safe and effective alternative to surgery for termination of early pregnancy. Together, these drugs terminate pregnancy in about 95% of women. Principal adverse effects are abdominal pain and vaginal bleeding, which are unavoidable aspects of abortion. There is also a small risk of infection. In contrast to surgical abortion, which is generally unavailable before 8 weeks of gestation, abortion with mifepristone is performed early—within 7 weeks of conception.

62.8.1.1 Mechanism of Action.

Mifepristone promotes abortion through blockade of progesterone receptors. Although mifepristone also blocks receptors for glucocorticoids, this action does not contribute to abortion. In the pregnant uterus, the drug has three effects. First, blockade of progesterone receptors leads to decidual breakdown and detachment of the conceptus. Second, mifepristone promotes cervical softening and dilation. Third, mifepristone increases uterine production of prostaglandins and renders the myometrium more responsive to the contractile actions of these prostaglandins. All three effects lead to expulsion of the conceptus. If mifepristone alone fails to induce abortion, the patient is given 400 mcg of oral misoprostol, a synthetic prostaglandin that reinforces uterine contractions induced by mifepristone. The pharmacology of misoprostol is discussed separately below.

62.8.1.2 Clinical Trials.

In a study conducted in France, the abortion success rate with mifepristone/misoprostol was nearly 99%. Success was defined as termination of pregnancy with complete expulsion of the conceptus. All women in the study had amenorrhea for less than 50 days prior to receiving mifepristone. Dosing was done as follows: Each patient received a 600-mg oral dose of mifepristone and, if abortion had not occurred within 48 hours, each was given a 400-mcg dose of oral misoprostol; a second dose of misoprostol (200 mcg) was offered if abortion had not occurred by 4 hours after the first dose. Only 5.5% of the pregnancies terminated prior to dosing with misoprostol; with the addition of misoprostol, either one or two doses, the cumulative success rate was 98.7%. In the majority of patients (69%), abortion occurred within 4 hours of the first misoprostol dose.

746

62.8.1.2.1 BOX 61-1 Special Interest Topic

747

62.8.1.2.1.1 EMERGENCY CONTRACEPTION

Emergency contraception (EC) is defined as contraception that is implemented *after* intercourse. Women can use EC to prevent pregnancy following unprotected intercourse, which can result from sexual assault, contraceptive failure (eg, broken condom), or occasional lack of forethought. Safe and effective methods of EC have been available for decades. However, products marketed specifically for EC were introduced only recently.

The data on unintended pregnancy are staggering. In the United States, nearly 50% of women ages 15 to 44 report having had at least one unintended pregnancy. Among teenagers, 88% of pregnancies are unintended. Of the 6 million pregnancies that occur each year, about 3.5 million are accidental. Every year, unintended pregnancies lead to 1.4 million abortions and 1.1 million births that women did not want—at least not yet. Clearly, if EC were used widely, most abortions and unwanted births could be avoided.

EC can be accomplished in two basic ways. Use of an *emergency contraceptive pill* (ECP), also known as a *morning-after pill*, or insertion of a copper-TIUD. ECP use is by far most common.

62.8.1.2.1.... Plan B

In the United States, Plan B is the most widely used ECP. The product consists of two high-dose (0.75-mg) tablets of *levonorgestrel*, a progestin found in several combination OCs. The package insert calls for taking 1 tablet within 72 hours of intercourse, and the

second 12 hours later. However, although early implementation is best, Plan B and other ECPs can still be effective when started up to 5 days after intercourse. Success is indicated by onset of menstrual bleeding in about 21 days.

Plan B reduces the odds of pregnancy by 89%, which is better than it may seem. In the absence of Plan B, the pregnancy rate from a single act of unprotected intercourse is about 8% (ie, 8 women in 100 would become pregnant). However, among women using Plan B, only 1 in 100 is likely to become pregnant—a reduction of 89%.

How does Plan B work? Primarily by delaying or stopping ovulation. Inhibition of fertilization and/or implantation may also contribute.

The major side effects of Plan B are nausea (23%) and vomiting (6%). These can be reduced by taking an antiemetic (eg, prochlorperazine) 1 hour before the first dose.

Does Plan B cause abortion? NO. Plan B will not terminate an existing pregnancy (nor will it hurt the fetus if pregnancy is present). Recall that pregnancy is defined as implantation of a fertilized egg, and that implantation occurs 5 to 7 days after ovulation. Since Plan B acts prior to implantation (primarily by inhibiting ovulation, and partly by inhibiting fertilization and implantation), it cannot be considered an abortifacient.

How can you get Plan B? For woman age 17 and older, Plan B is now available over the counter. No prescription is required. However, you do need a government-issued ID to prove your age, and a licensed pharmacist must dispense the drug. For women who are not yet 17, Plan B is still available, but a prescription is required. Prescriptions can be obtained from private physicians, clinics run by Planned Parenthood, and student health departments at colleges and universities.

It's a good idea to keep Plan B on hand “just in case.” Remember, the drug work best when taken right after intercourse. By purchasing Plan B in advance, you can avoid delay.

62.8.1.2.1....

Alternatives to Plan B

The *Yuzpe regimen*, first described in 1974 by Professor A. Alfred Yuzpe, consists of two doses of an OC that contains an estrogen (ethinyl estradiol) plus a progestin (levonorgestrel or norgestrel). As with Plan B, the first dose should be taken within 72 hours of unprotected intercourse, and the second dose 12 hours later. Pregnancy is prevented by interfering with ovulation, fertilization, and implantation. Like Plan B, this regimen will not cause abortion. Compared with Plan B, this regimen is less effective (75% vs. 89%) and causes more nausea (50% vs. 23%) and vomiting (19% vs.

6%). Combination OCs that can be used for EC are presented in the table below. However, because Plan B is more effective, better tolerated, and readily available, these drugs are used infrequently.

EMERGENCY CONTRACEPTIVE PILLS*

Trade Name	Pills/Dose*
Progestin-Only Regimens	
Plan B†	1 white
Ovrette	20 yellow
Yuzpe Regimen	
Ogestrel	2 white
Ovral	2 white
Cryselle	4 white
Levlen	4 orange
Levora	4 white
Lo/Ovral	4 orange
Low-Ogestrel	4 white
Nordette	4 orange
Portia	4 pink
Seasonale	4 pink
Tri-Levlen	4 yellow
Triphasil	4 yellow
Trivora	4 pink
Alesse	5 pink
Aviane	5 orange
Lessina	5 pink
Levlite	5 pink
Lutera	5 white

* For all ECPs, formal protocols call for two doses, the first taken within 72 hours of intercourse, and the second 12 hours later. However, starting within 120 hours of intercourse can still be effective. Also, for the progestin-only regimens—Plan B and Ovrette—taking both doses at once is effective.

† Plan B is the only product packaged and marketed specifically for EC. All the rest are ordinary OCs that can be used for EC if needed (color indicates which pills in multipill pack are to be taken.)

Ovrette is a *progestin-only OC* similar to Plan B. The principal difference is dosing: Since 1 *Ovrette* pill contains only 0.075 mg of progestin (norgestrel), each dose for EC would require 20 pills, compared with just 1 pill of Plan B. Otherwise, the products are nearly identical.

One drug—*mifepristone*—can prevent pregnancy *or* cause abortion, depending on when it is taken. If *mifepristone* is taken within 5 days of unprotected intercourse, it will prevent pregnancy from occurring, and hence can be considered an ECP. However, if *mifepristone* is taken after this time, it may terminate pregnancy that has already begun, and hence can be considered an abortifacient. When used as an ECP, *mifepristone* is 100% effective. The drug is available in the United States, but is not approved for EC.

Insertion of a *copper IUD* within 5 days of unprotected intercourse can prevent pregnancy in most women. The method is more than 99.9% effective, allowing less than 1 pregnancy for every 1000 IUD recipients. IUD insertion has the additional benefit of providing ongoing contraception for up to 10 years. Although using an IUD for EC is highly effective, the technique does have drawbacks: the IUD is expensive, not all women are candidates, and obtaining one quickly may be a problem.

747

In the United States, success with *mifepristone/misoprostol* has also been good—although not quite as good as in France. In 1999, American researchers reported that the abortion rate with *mifepristone/misoprostol* declined with increasing duration of gestation. Success was greatest (92%) when gestation was 49 days or less, falling to 83% during days 50 to 56 of gestation, and to 77% during days 57 to 63. The dosages employed were the same as in the French study. Why the success rate was lower than in the French study is unknown.

748

There is good evidence that *intravaginal misoprostol* is more effective and better tolerated than oral *misoprostol*. In one study, women received 600 mg of oral *mifepristone*, followed by 800 mcg of *misoprostol*, either PO or intravaginally. Following intravaginal *misoprostol*, 95% of conceptuses were expelled without the need for surgery, compared with only 87% following oral *misoprostol*. With intravaginal administration, abortion occurred within 4 hours in 93% of patients, compared with 78% of patients receiving oral *misoprostol*. The incidence of nausea and vomiting with intravaginal administration was significantly lower than with oral administration. Intravaginal *misoprostol*—but not oral *misoprostol*—has been associated with

very rare cases of severe sepsis, one heart attack, and one death (from hemorrhage) following a ruptured ectopic pregnancy. However, a causal relationship between these events and mifepristone/misoprostol has not been established.

62.8.1.3 Adverse Effects.

The most common side effects are bleeding (100%), cramping (80%), nausea (60%), vomiting (26%), diarrhea (20%), and headache (31%). The most serious adverse effects are severe bleeding and sepsis.

Successful abortion necessarily causes abdominal pain (cramping) and bleeding. Nearly all women experience these effects. About 80% of patients experience transient cramping, beginning 1 hour after taking misoprostol; most women require an opioid analgesic for relief. Bleeding and spotting typically last 9 to 16 days. However, in some women, bleeding persists for 30 days or more. About 1% of women experience severe bleeding; treatment measures include curettage, uterotonic drugs (eg, methylergonovine, ergonovine), and infusion of fluids, blood, or both.

Mifepristone/misoprostol has been associated with a few cases of serious bacterial infection, including very rare cases of fatal septic shock. Accordingly, patients and physicians should be alert for typical signs of sepsis (sustained fever of 100.4°F or higher, severe abdominal pain, pelvic tenderness). However, in two confirmed cases of sepsis caused by *Clostridium sordellii*, these signs were absent. Instead, the patients presented with nausea, vomiting, and diarrhea, without fever or abdominal pain. In patients with typical or atypical presentation, the possibility of infection should be evaluated immediately.

The bleeding caused by mifepristone/misoprostol could mask bleeding due to a ruptured ectopic pregnancy. Accordingly, before mifepristone/misoprostol is used, ectopic pregnancy must be ruled out. This is best done by a routine ultrasound examination.

Misoprostol (but not mifepristone), a proven teratogen, can cause Möbius' syndrome, a rare fetal anomaly. Hence if the mifepristone/misoprostol fails to induce abortion, a surgical abortion should be considered.

62.8.1.4 Contraindications.

Major contraindications to mifepristone/misoprostol are ectopic pregnancy, hemorrhagic disorders, or use of anticoagulant drugs. Because mifepristone blocks receptors for glucocorticoids, it should not be used in women with adrenal insufficiency and those on long-term glucocorticoid therapy.

62.8.1.5 Preparations, Dosage, and Administration.

Mifepristone [Mifeprex] is supplied in single-dose packets containing three 200-mg tablets. The dosage is either 200 mg or 600 mg taken all at once—followed in 2 days by 400 mcg of oral misoprostol (if mifepristone did not induce complete abortion by itself). Mifepristone is available only through qualified physicians; it is not sold in pharmacies.

62.8.1.6 FDA-Approved Protocol for Abortion.

Under the FDA-approved protocol, induction of abortion with mifepristone/misoprostol requires *three visits to a qualified physician*. In order to dispense mifepristone, a physician must be qualified to determine pregnancy duration and to diagnose ectopic pregnancy. In addition, the physician must either (1) be able to perform surgical abortion (in the event mifepristone/misoprostol fails) as well as curettage (in the event of severe bleeding), or (2) have a commitment from a colleague to perform these procedures.

62.8.1.6.1 Day 1.

Mifepristone (600 mg) is taken—but only after several conditions have been met. The physician must rule out ectopic pregnancy and must ensure that the pregnancy is indeed early (defined as pregnancy in which no more than 49 days have elapsed since the beginning of the last menstrual period). If necessary, ultrasound should be performed to confirm that pregnancy is intrauterine and not beyond the 49-day limit. Also, the patient must read a Medication Guide supplied by the manufacturer, and both the patient and physician must sign a Patient Agreement Form stating that the patient understands the benefits and risks of the procedure and has decided to end the pregnancy. Finally, the patient must be given clear instruction on whom to call and what to do in the event of an emergency.

62.8.1.6.2 Day 3.

Two days after taking mifepristone, the patient returns to the physician, who performs a physical examination or ultrasound scan to determine if abortion has occurred. If abortion has not occurred, the patient takes misoprostol (400 mcg).

62.8.1.6.3 Day 14.

About 14 days after taking mifepristone, the patient returns to the physician, who confirms by physical examination or ultrasound scan that pregnancy has been terminated. If the woman is still pregnant, surgical abortion should be considered.

62.8.2 Methotrexate with Misoprostol

Methotrexate, followed by misoprostol, is a safe and effective alternative to surgical termination of early pregnancy. Methotrexate induces abortion because of its toxicity to trophoblastic tissue; misoprostol contributes by promoting uterine contraction. Abortion is accomplished by giving an intramuscular injection of methotrexate (50 mg/m²) followed in 4 to 8 days by 800 mcg of intravaginal misoprostol. If abortion does not occur in 24 hours, dosing with misoprostol is repeated. In one study, 14% of patients required the second dose of misoprostol, but 96% eventually aborted. The procedure is more effective at 49 days of gestation (or less) than between days 50 and 56. Side effects include nausea, vomiting, diarrhea, headache, dizziness, and hot flushes. Acetaminophen plus codeine is usually sufficient to relieve pain. The vast majority of women who have undergone the procedure said they would recommend it.

62.8.3 Prostaglandins: Misoprostol, Carboprost, and Dinoprostone

Prostaglandins are synthesized in all tissues of the body, where they act as local hormones. Unlike true hormones, which travel to distant sites to produce their effects, prostaglandins act on the very tissues in which they are made; degradation of prostaglandins is so rapid that they rarely escape their tissue of origin intact. Although the prostaglandins produce a broad spectrum of physiologic effects, their clinical use is limited. In obstetrics, prostaglandins are indicated for induction of abortion, cervical ripening prior to labor induction, and control of postpartum hemorrhage. Use of prostaglandins for abortion is discussed here. Use for cervical ripening and control of postpartum hemorrhage is discussed in [Chapter 63](#).

748

749

62.8.3.1 Nomenclature.

Nomenclature regarding the prostaglandins can be confusing, and hence deserves comment. Each prostaglandin has three names: a traditional name, an official generic name, and a trade name. Misoprostol, carboprost, and dinoprostone are *generic names*. For carboprost, the traditional name is *15-methyl-prostaglandin F₂ alpha* and the trade name is *Hemabate*. For dinoprostone, the traditional name is *prostaglandin E₂*; trade names are *Prostin E₂*, *Cervidil*, and *Prepidil*. For misoprostol, a synthetic analog of prostaglandin E₁, the trade name is *Cytotec*.

62.8.3.2 Physiologic and Pharmacologic Effects.

62.8.3.2.1 Uterine Stimulation.

Prostaglandins increase the force, frequency, and duration of uterine contractions. In the early months of pregnancy, the uterus is more responsive to prostaglandins than to oxytocin. During the second and third trimesters, prostaglandins can induce contractions of sufficient strength to cause complete evacuation of the uterus.

Like oxytocin, prostaglandins appear to have a physiologic role as promoters of uterine contraction, spontaneous labor, and delivery. Observations supporting this statement include: (1) exogenous prostaglandins can induce uterine contractions that are very similar in frequency and duration to contractions that occur spontaneously; (2) the ability of the uterus to synthesize prostaglandins increases at term; (3) the prostaglandin content of amniotic fluid, umbilical blood, and maternal blood increases at term and during labor; and (4) labor is delayed and prolonged by agents that inhibit prostaglandin synthesis.

62.8.3.2.2 Cervical Softening.

Local application of prostaglandins produces cervical softening. This softening results from breakdown of collagen, and hence mimics the process by which natural cervical ripening occurs. Softening of the cervix is not dependent on uterine stimulation.

62.8.3.3 Therapeutic Uses.

62.8.3.3.1 Abortion.

All three prostaglandins—misoprostol, carboprost, and dinoprost—can be used to induce abortion. Misoprostol (in combination with methotrexate or mifepristone [RU 486]) is used *early* in pregnancy as well as in the *second trimester*. Carboprost and dinoprostone are used in the *second trimester only*. With all three drugs, uterine contractions develop slowly. As a result, about 18 hours must pass between dosing and expulsion of the fetus. Unlike other abortifacients, prostaglandins are not fetocidal, and hence the aborted fetus may show transient signs of life. Following passage of the fetus and placenta, the patient should be examined for possible cervical or uterine laceration.

62.8.3.3.2 Control of Postpartum Hemorrhage.

Carboprost is indicated for control of postpartum hemorrhage. The drug is reserved for bleeding that has been refractory to more conventional agents (oxytocin, ergot alkaloids). In

these situations, carboprost may be lifesaving. Use of carboprost to control postpartum hemorrhage is discussed in [Chapter 63](#).

62.8.3.3.3 Induction of Labor.

Misoprostol has been used to induce labor. The regimen recommended by the American College of Obstetricians and Gynecologists consists of 25 mcg vaginally repeated every 3 to 6 hours as needed.

62.8.3.3.4 Cervical Ripening.

Dinoprostone and *misoprostol* can be used to initiate ripening of the cervix prior to induction of labor. This application is discussed in [Chapter 63](#).

62.8.3.4 Adverse Effects.

Gastrointestinal reactions are extremely common with dinoprostone and result from the ability of prostaglandins to stimulate smooth muscle of the alimentary canal. Vomiting and diarrhea occur in up to 61% of those treated. Nausea also occurs often. These responses can be reduced by pretreatment with antiemetic and antidiarrheal medications.

Intense uterine contractions can result in *cervical or uterine laceration*. The patient should be examined thoroughly for trauma following expulsion of the fetus and placenta.

Fever is seen with dinoprostone. When hyperthermia develops, it is important to distinguish between drug-induced fever and pyrexia resulting from endometritis. With dinoprostone, there is a 10% incidence of headache, shivering, and chills.

62.8.3.5 Precautions and Contraindications.

Prostaglandins are *contraindicated* for women with active disease of the heart, lungs, kidneys, or liver. Carboprost should be avoided in women with a history of asthma or hypertension.

62.8.3.6 Preparations, Dosage, and Administration.

62.8.3.6.1 Dinoprostone.

Dinoprostone [Prepidil, Prostin E2, Cervidil] is available in three formulations: (1) 20-mg vaginal suppositories, (2) 10-mg vaginal inserts, and (3) a 0.5-mg gel. Dinoprostone suppositories [Prostin E2] are used for abortion. The gel [Prepidil] and vaginal inserts [Cervidil] are used for cervical ripening.

For *induction of abortion* (weeks 12 to 20), one 20-mg vaginal suppository is inserted initially, followed by one suppository every 3 to 5 hours as needed.

62.8.3.6.2 Carboprost Tromethamine.

Carboprost tromethamine [Hemabate] is available in solution (250 mcg/mL) for IM administration. For *induction of abortion* (weeks 13 to 20), the dosage is 250 mcg initially followed by 250 mcg every 1.5 to 3.5 hours as needed. For *control of postpartum bleeding*, a single 250-mcg dose is injected.

62.8.3.6.3 Misoprostol.

Misoprostol [Cytotec] is available in 200- and 400-mcg tablets. For induction of abortion in the *first trimester*, misoprostol is used in combination with mifepristone or methotrexate (see above for dosages and routes of administration); dosing options for misoprostol include 400 mcg PO and 800 mcg intravaginally. For induction of abortion in the *second trimester*, the dosage is 200 mcg administered vaginally every 6 to 12 hrs until abortion occurs.

62.8.3.6.3.1

KEY POINTS

- The most effective methods of birth control are etonogestrel subdermal implants [Implanon], intramuscular medroxyprogesterone acetate [Depo-Provera], IUDs, and sterilization. OCs and transdermal patches are a close second.
- Sterilization is the most common form of birth control. OCs and male condoms come next.
- A long-term method of birth control (eg, Implanon, Depo-Provera, IUD) is a good choice when adherence is a problem.
- There are two main categories of OCs: (1) combination OCs, which contain an estrogen plus a progestin, and (2) progestin-only OCs (minipills).
- Almost all combination OCs use the same estrogen: ethinyl estradiol. In contrast, several different progestins are employed.
- Combination OCs act primarily by inhibiting ovulation.
- Although combination OCs can cause a wide variety of adverse effects, serious effects are rare.

- The low-estrogen combination OCs used today pose low risk of thromboembolism—except in smokers and women with thrombophilias.
- When used by nonsmoking women with normal cardiovascular function, OCs produce no greater mortality than other active forms of birth control.
- Combination OCs protect against ovarian and endometrial cancer. They do *not* increase the risk of breast cancer.
- OCs are contraindicated during pregnancy, not because they are dangerous, but because they have no legitimate use during pregnancy. If accidental pregnancy occurs, OCs should be discontinued.
- The efficacy of OCs can be reduced by agents that induce hepatic drug-metabolizing enzymes (eg, rifampin, phenobarbital, St. John's wort).

749

- Because they lack estrogen, progestin-only OCs are safer than combination OCs—but are less effective and cause more menstrual irregularity.
- Progestin-only OCs prevent pregnancy by causing production of thick, sticky mucus (which creates a barrier to migration of sperm) and by suppressing endometrial growth (which discourages nidation).
- Subdermal etonogestrel implants [Implanon] are active for 3 years, and are among the most effective contraceptives available.
- Implanon has the same mechanism as progestin-only pills: production of thick, sticky mucus and involution of the endometrium.
- Injectable medroxyprogesterone acetate [Depo-Provera] is active for 3 months, and is one of the most effective contraceptives available.
- Depo-Provera prevents pregnancy mainly by suppressing ovulation. In addition, it thickens cervical mucus and alters the endometrium such that nidation is discouraged.

750

62.8.3.6.3.2

Summary of Major Nursing Implications*

62.8.3.6.3.2.1

COMBINATION ORAL CONTRACEPTIVES

62.8.3.6.3.2.1.1

Preadministration Assessment

62.8.3.6.3.2.1...

Therapeutic Goal

Prevention of unwanted pregnancy.

62.8.3.6.3.2.1...

Baseline Data

Assess for a history of hypertension, diabetes, thrombophlebitis, thromboembolic disorders, cerebrovascular disease, coronary artery disease, breast carcinoma, estrogen-dependent neoplasm, and benign or malignant liver tumors.

62.8.3.6.3.2.1...

Identifying High-Risk Patients

Absolute contraindications to OC use are thromboembolic disorders, cerebrovascular disease, coronary occlusion, abnormal liver function, known or suspected breast carcinoma, undiagnosed abnormal genital bleeding, known or suspected pregnancy, and smokers older than 35. *Relative contraindications* to OC use are diabetes, hypertension, cardiac disease, history of cholestatic jaundice of pregnancy, gallbladder disease, uterine leiomyoma, epilepsy, and migraine.

Women anticipating elective surgery in which postoperative immobilization increases the risk of thrombosis should stop OCs prior to surgery.

62.8.3.6.3.2.1.2

Implementation: Administration

62.8.3.6.3.2.1...

Dosing Schedule

Provide the client with the following instructions on administration:

- **Initiate dosing on the first day of menses, or the first Sunday after the onset of menses.**
- **For most combination OCs, the approved dosing schedule consists of 21 days of active drug followed by 7 days off (for the 7 “off” days, the manufacturer may provide inert tablets, iron-containing tablets, or no tablets).**

- For *Seasonale* (an extended-cycle OC), the dosing schedule is 84 days of active drug followed by 7 days off.
- For *Seasonique* and *LoSeasonique* (two other extended-cycle OCs), the dosing schedule is 84 days of active drug followed by 7 days of using a low-estrogen pill.
- For all OCs, take pills at the same time each day (eg, with a meal, at bedtime).

62.8.3.6.3.2.1...

Responding to Missed Doses

Provide the client with the following instructions regarding missed doses:

- If only one dose is missed, take the omitted dose together with the next scheduled dose.
- If two doses are missed, take two doses per day on the following 2 days.
- If three doses are missed, initiate a new cycle (starting 7 days after the last pill was taken) and use an additional form of contraception (eg, condom, diaphragm) during the first 2 weeks of the new cycle.

62.8.3.6.3.2.1...

Postpartum Use

Inform the client that OCs can be initiated 2 weeks after delivery if breastfeeding is not intended. (For breastfeeding mothers, the progestin-only minipill can be started immediately postpartum.)

62.8.3.6.3.2.1...

Promoting Adherence

Counsel the client about the importance of taking OCs as prescribed. Encourage the client to read the package insert provided with combination OCs.

62.8.3.6.3.2.1.3	Ongoing Evaluation and Interventions	
62.8.3.6.3.2.1...	Minimizing Adverse Effects	
62.8.3.6.3.2.1...	Thrombotic Disorders	
	Because of their estrogen content, combination OCs slightly increase the risk of thrombosis and thromboembolism. To minimize thrombosis and thromboembolism, (1) use OCs of low estrogen content, (2) avoid OCs in women with known risk factors for thrombotic disorders, and (3) discontinue OCs at least 4 weeks prior to elective surgery in which postoperative thrombosis might be expected. Inform the client about symptoms of thrombosis and thromboembolism (eg, leg tenderness or pain, sudden chest pain, shortness of breath, severe headache, sudden visual disturbance) and instruct her to notify the prescriber if these develop.	750 751
62.8.3.6.3.2.1...	Hypertension	
	Perform periodic determinations of blood pressure. If hypertension is detected, discontinue OCs. Blood pressure usually normalizes. However, for women with chronic hypertension, OCs can be used as long as the blood pressure is normal.	
62.8.3.6.3.2.1...	Abnormal Uterine Bleeding	
	During initial use, combination OCs may cause breakthrough bleeding or spotting. This usually resolves with continued use. Bleeding is less likely with low-estrogen OCs. Instruct the client to notify the prescriber if two consecutive periods are missed; the possibility of pregnancy must be evaluated. Instruct the client to notify the prescriber if bleeding irregularities persist; an alternative OC may be tried. Inform the client that, once OCs are discontinued, menses quickly return to normal.	

62.8.3.6.3.2.1...

Use in Pregnancy and Lactation

OCs are contraindicated during pregnancy, not because they are dangerous, but because they have no therapeutic role. Pregnancy should be ruled out prior to OC use. **Instruct the client to cease OC use if accidental pregnancy should occur.**

Inform the client that OCs can reduce milk production early in lactation. Once the milk supply is established, OC use can be resumed.

62.8.3.6.3.2.1...

Glucose Intolerance

OCs can elevate plasma glucose levels. **Advise clients with diabetes to monitor blood glucose levels closely; dosage of insulin or oral hypoglycemic medication may need to be increased.** Monitor the prediabetic client for hyperglycemia.

62.8.3.6.3.2.1...

Stroke in Women with Migraine

When used by women with migraine, OCs may increase the risk of thrombotic stroke. To minimize risk, OCs should be reserved for migraineurs who are under age 35, don't smoke, are generally healthy, and have migraine without aura.

62.8.3.6.3.2.1...

Hyperkalemia

Yasmin and YAZ pose a risk of hyperkalemia, and hence should not be used by (1) women with conditions that predispose to hyperkalemia (eg, renal insufficiency, adrenal insufficiency, liver disease) and (2) women taking drugs that can increase potassium levels (see below).

62.8.3.6.3.2.1...

Minimizing Adverse Interactions

62.8.3.6.3.2.1...

Agents That Reduce OC Levels

Levels of OCs can be reduced by agents that induce hepatic drug-metabolizing enzymes (eg, phenobarbital, phenytoin, troglitazone, rifampin, ritonavir, St. John's wort). **Advise clients who are taking these agents to be alert for indications of reduced OC levels (eg, breakthrough bleeding, spotting), and to notify the prescriber if these occur.** An increase in OC dosage or use of an alternative method of birth control may be required.

62.8.3.6.3.2.1...

Drugs Whose Effects Are Reduced by OCs

OCs can reduce the effects of some drugs, including *warfarin*, *insulin*, and some *oral hypoglycemics*. When combined with OCs, these drugs may require a greater than normal dosage.

62.8.3.6.3.2.1...

Drugs Whose Effects Are Increased by OCs

OCs can increase blood levels of several drugs, including *theophylline* and *imipramine*. Women using these drugs in combination with OCs should be alert for signs of toxicity; dosage reduction for theophylline or imipramine may be required.

62.8.3.6.3.2.1...

Drugs That Elevate Potassium

Drugs that elevate serum potassium (eg, potassium supplements, potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers) should be avoided by women using Yasmin or YAZ, OCs that promote potassium retention.

62.8.3.6.3.2.2

PROGESTIN-ONLY ORAL CONTRACEPTIVES

62.8.3.6.3.2.2.1

Preadministration Assessment

62.8.3.6.3.2.2...

Therapeutic Goal

Prevention of unwanted pregnancy.

62.8.3.6.3.2.2.2

Implementation: Administration

62.8.3.6.3.2.2...

Dosing Schedule

Instruct the client to initiate the minipill on day 1 of the menstrual cycle and to take one pill every day thereafter. Pills should be taken at the same time each day (eg, with a meal, at bedtime).

62.8.3.6.3.2.2...

Responding to Missed Doses

Provide the client with the following instructions regarding missed doses:

- **If one pill is missed, take it as soon as the omission is remembered. Use a backup form of contraception for 2 days.**

- If two pills are missed, take one pill as soon as the omission is remembered, discard the second pill, and use a backup form of contraception for 2 days.
- If three pills are missed, the minipill should be stopped. Do not resume use until menstruation occurs or until pregnancy has been ruled out.

62.8.3.6.3.2.2.3

Ongoing Evaluation and Interventions

62.8.3.6.3.2.2...

Minimizing Adverse Effects

62.8.3.6.3.2.2...

Menstrual Irregularities

Breakthrough bleeding, spotting, amenorrhea, inconsistent cycle length, and variations in the amount and duration of monthly flow are common and unavoidable. Forewarn the client of these effects.

* Patient education information is highlighted as **blue text**.

⁶³CHAPTER 62 Drug Therapy of Infertility

Infertility (subfertility) is defined as a decrease in the ability to reproduce. This contrasts with sterility, which is the complete absence of reproductive ability. About 10% of couples attempting to have children experience infertility. Failure to conceive may be due to reproductive dysfunction of the male partner, the female partner, or both. When medical treatment is implemented, approximately one-half of infertile couples achieve pregnancy. To date, drug therapy of female infertility has been considerably more successful than drug therapy of male infertility.

In treating infertility, the chances of success are greatly enhanced by accurate diagnosis. A thorough history of both partners is essential, including information on frequency and timing of coitus and use of drugs that might lower fertility. Routine evaluation should include a semen analysis, determination of fallopian tube patency, and assessment of ovulation. If the patient reports regular menstrual cycles, ovulation is presumed, and hence there is no need to determine estrogen and progesterone levels.

In this chapter, we discuss infertility in two stages. First, we discuss the underlying causes of reproductive dysfunction. Second, we discuss the fertility-promoting drugs. As preparation to study these agents, you should review [Chapter 60](#) for information on the menstrual cycle and information on the biosynthesis and physiologic and pharmacologic effects of estrogens and progestins. Pay special attention to the roles of gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH).

^{63.1} INFERTILITY: CAUSES AND TREATMENT STRATEGIES

^{63.1.1} Female Infertility

Female infertility can result from disrupting all phases of the reproductive process. The most critical phases are follicular maturation, ovulation, transport of the ovum through the fallopian tubes, fertilization of the ovum, nidation (implantation), and growth and development of the conceptus. These events can take place only if the ovaries, uterus, hypothalamus, and pituitary are functioning properly. If the activity of any of these structures is disturbed, fertility can be impaired. Causes of female infertility that respond to drug therapy are discussed below.

^{63.1.1.1} Anovulation and Failure of Follicular Maturation

In the absence of adequate hormonal stimulation, ovarian follicles will not ripen and ovulation will not take place. Frequently, these causes of infertility can be corrected with drugs. The agents used to promote follicular maturation and/or ovulation are *clomiphene*, *menotropins*, *follitropins* (eg, urofollitropin), and *human chorionic gonadotropin* (hCG). Clomiphene induces follicular maturation and ovulation by promoting release of FSH and LH from the pituitary; in

some cases, induction of ovulation requires co-treatment with hCG. Menotropins and follitropins are used in conjunction with hCG: Menotropins and follitropins act directly on the ovary to promote follicular development; after follicles have matured, hCG is given to induce ovulation. Because hCG acts on mature follicles to cause ovulation, the drug is used only after follicular maturation has been induced with another agent (menotropins, a follitropin, or clomiphene). The pharmacology of clomiphene, menotropins, follitropins, and hCG is discussed below.

63.1.1.2 Unfavorable Cervical Mucus

In the periovulatory period, the cervical glands normally secrete large volumes of thin, watery mucus. These secretions, which are produced under the influence of estrogen, facilitate passage of sperm through the cervical canal. If the cervical mucus is scant or of inappropriate consistency (thick, sticky), sperm will be unable to pass through to the uterus. Production of unfavorable mucus may occur spontaneously or as a side effect of clomiphene (see below).

Cervical mucus can be restored to its proper volume and consistency by administering estrogen. Two regimens have been employed. In one, ethinyl estradiol is given beginning early in the menstrual cycle (on day 6, 7, or 8) and continued through day 12 or 13; dosages range from 20 to 80 mcg/day. In the other regimen, conjugated estrogens are administered from day 5 through day 15 of the cycle; dosages range from 2.5 to 5 mg/day. When used to counteract the effects of clomiphene on the cervical mucus, estrogens are administered for 10 days beginning 1 day after the last clomiphene dose.

63.1.1.3 Hyperprolactinemia

Elevation of prolactin levels may be caused by a pituitary adenoma or by disturbed regulation of the healthy pituitary. Amenorrhea, galactorrhea, and infertility may all occur in association with excessive prolactin levels. The mechanism by which hyperprolactinemia impairs fertility is

unknown. Hyperprolactinemia can be treated with cabergoline [Dostinex], bromocriptine [Parlodel], and other dopamine agonists.

752

753

63.1.1.4 Endometriosis

Endometriosis is a condition in which endometrial tissue has become implanted in an abnormal location (eg, uterine wall, ovary, extragenital sites). These implants respond to hormonal stimulation in much the same way as the normally situated endometrium. Endometriosis affects about 5.5 million women in the United States and Canada, and is a common cause of infertility. When pregnancies do occur, the rate of spontaneous abortion is high (about 50%).

The mechanism by which endometriosis reduces fertility is not always clear. In some cases, infertility results from ovarian or tubal adhesions that impede transport of the ovum. However, when endometriosis is mild, a visible cause of infertility may be absent.

Endometriosis can be treated with surgery, drugs, or both. Surgery reduces symptoms of endometriosis and increases fertility. In contrast, although drugs can reduce symptoms, they do *not* enhance fertility. The drugs employed most often are *leuprolide* and *nafarelin*, synthetic analogs of gonadotropin-releasing hormone. Oral contraceptives can reduce symptoms of endometriosis, but obviously won't promote fertility.

63.1.1.5 Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a combined endocrine-metabolic disorder characterized by androgen excess and insulin resistance. Symptoms include irregular periods, anovulation, infertility, acne, and hirsutism. About 50% of patients are obese. PCOS increases the risk for diabetes, cardiovascular disease, and cancer of the ovaries and endometrium. The syndrome was first described in a woman whose ovaries were enlarged and covered with multiple fluid-filled cysts. However, the presence of cysts is not required for a positive diagnosis. Hence the disease name can be misleading. PCOS is the most common endocrine disorder in young women, affecting 5% to 10% of women of reproductive age.

PCOS can be treated with lifestyle changes and drugs. The goal is to restore regular menstruation and ovulation, reverse hyperandrogenism (and thereby eliminate acne and hirsutism), and decrease the long-term risk of diabetes, cancer, and heart disease. Treatment options include the following:

- *Weight loss*, through exercise and diet, can reduce insulin and androgen levels, improve insulin sensitivity, restore menstruation and ovulation, and increase pregnancy rates.
- *Clomiphene* [Clomid] is considered a first-line drug for inducing ovulation. It may be used alone or in combination with metformin.
- *Metformin* [Glucophage], a drug for type 2 diabetes, increases insulin sensitivity and decreases insulin levels, which, through an indirect mechanism, lowers androgen levels. The net result is improved glucose tolerance, improved ovulation, and increased pregnancy rates.
- *Glitazones*—rosiglitazone [Avandia] and pioglitazone [Actos]—act like metformin: they can increase insulin sensitivity and decrease insulin and androgen levels. These drugs can

harm the fetus, and hence should not be used by women who are trying to become pregnant.

- *Oral contraceptives* can restore regular periods and reduce acne and hirsutism, but obviously won't improve fertility.
- *Spironolactone* has antiandrogenic actions, and can thereby decrease hirsutism and acne. The drug can harm the fetus, and hence must not be used during pregnancy.

63.1.2 Male Infertility

For about 30% of couples who experience infertility, failure to conceive is due entirely to reproductive dysfunction in the male. Male infertility is due most often to decreased density or motility of sperm, or to semen of abnormal volume or quality. The most obvious manifestation of male infertility is erectile dysfunction (ED). In most cases, infertility in males is not associated with an identifiable endocrine disorder. Unfortunately, with the exception of ED, male infertility is generally unresponsive to drugs.

63.1.2.1 Hypogonadotropic Hypogonadism

A few males may be incapable of spermatogenesis because of insufficient gonadotropin secretion. In these rare cases, drug therapy may help. If the gonadotropin deficiency is only partial, sperm counts can be increased using hCG (alone or in combination with menotropins). If the deficiency is severe, treatment with androgens is required (see [Chapter 64](#)). If therapy with hCG and menotropins is intended, the patient should be informed that treatment will be prolonged (3 to 4 years) and expensive.

63.1.2.2 Erectile Dysfunction

Inability to achieve erection is the most conspicuous cause of male infertility. Sildenafil [Viagra] and other drugs for ED are discussed in [Chapter 65](#).

63.1.2.3 Idiopathic Male Infertility

Idiopathic infertility is defined as infertility for which no cause can be identified. About 25% to 40% of male infertility is idiopathic. Since the cause is unknown, specific drug therapy is impossible. Accordingly, treatment is empiric (trial and error). Several drugs, including androgens, clomiphene, and hCG, have been administered in hopes of improving idiopathic infertility in males. Unfortunately, success rates are low.

63.2 DRUGS USED TO TREAT FEMALE INFERTILITY

63.2.1 Drugs for Controlled Ovarian Stimulation

The term *controlled ovarian stimulation* refers to the use of drugs to facilitate follicular maturation and ovulation. Following ovulation, fertilization can be accomplished either naturally (through sexual intercourse) or through assisted reproduction technology (eg, *in vitro* fertilization). Of the drugs discussed below, six are used to promote follicular maturation, two are used to stimulate ovulation, and two are used to prevent premature stimulation of ovulation by endogenous hormones ([Table 62-1](#)).

63.2.1.1 Clomiphene

63.2.1.1.1 Therapeutic Use.

Clomiphene [Clomid, Milophene, Serophene] is used to promote follicular maturation and ovulation in selected infertile women.

63.2.1.1.2 Mechanism of Fertility Promotion.

Clomiphene blocks receptors for estrogen. Receptor blockade in the hypothalamus and pituitary makes it appear to these structures that estrogen levels are low. In response, the pituitary increases secretion of gonadotropins (LH and FSH), and these hormones then stimulate the ovary, promoting follicular maturation and ovulation. In properly selected patients, the ovulation rate is about 90%. Because of its mechanism, clomiphene can induce ovulation only if the pituitary is capable of producing LH and FSH, and only if the ovaries are capable of responding. Success is impossible in women with primary pituitary or ovarian failure. Accordingly, pituitary and ovarian function should be verified prior to clomiphene therapy. If treatment produces follicular maturation but ovulation fails to occur, it may be possible to induce ovulation by adding hCG to the regimen (see below).

753

754

TABLE 62-1 Drugs for Controlled Ovarian Stimulation

Generic Name	Trade Name	Mechanism of Action
Drugs That Promote Follicular Maturation		
Clomiphene	Clomid, Milophene, Serophene	Clomiphene blocks estrogen receptors in the hypothalamus and pituitary, and thereby causes a compensatory increase in the release of LH and FSH, which then act on the ovary to promote follicular maturation (and possibly ovulation).
Menotropins	Repronex, Menopur	Menotropins is a 50:50 mixture of FSH and LH that acts on the ovary to promote follicular maturation. Treatment is followed by hCG to induce ovulation.
Follitropin alfa	Gonal-F	Follitropins are preparations of FSH that act on the ovary to promote follicular maturation. Treatment is followed by hCG to induce ovulation.
Follitropin beta	Follistim AQ	
Urofollitropin	Bravelle, Fertinex, Metrodin	
Lutropin alfa	Luveris	Lutropin alfa is a recombinant form of LH used in combination with follitropin alfa [Gonal-F] to promote follicular maturation. Treatment is followed by hCG to induce ovulation.
Drugs That Stimulate Ovulation		
Human chorionic gonadotropin (hCG)	Choron 10, Gonic, Novarel, Pregnyl, Profasi	hCG is similar in structure and identical in action to LH. The drug acts on the ovary to induce ovulation.
Choriogonadotropin alfa	Ovidrel	Choriogonadotropin is a recombinant form of hCG that acts on the ovary to induce ovulation.
Drugs That Prevent Premature Ovulation		
Ganirelix	Generic only	These drugs are GnRH antagonists that block endogenous release of LH, and thereby prevent possible premature ovulation in women receiving drugs to promote follicular maturation.
Cetrorelix	Cetrotide	

63.2.1.1.3

Monitoring.

Effects on the ovary can be monitored with serial ultrasound exams. When treatment is successful, the scans will show progressive follicular enlargement, followed by conversion of the follicle to a corpus luteum after ovulation occurs.

63.2.1.1.4 Adverse Effects.

Common side effects include hot flushes (similar to the vasomotor responses of menopause), nausea, abdominal discomfort, bloating, and breast engorgement. Some patients experience visual disturbances (blurred vision, visual flashes), which usually reverse following drug withdrawal. Multiple births (usually twins) occur in 8% to 10% of clomiphene-facilitated pregnancies. Patients should be told of this possibility.

Very rarely, clomiphene can cause ovarian hyperstimulation. Symptoms include low abdominal pain, pressure, weight gain, and swelling. Hyperstimulation can be minimized by avoiding unnecessarily large doses. If undue ovarian enlargement occurs, clomiphene use should cease. The ovaries will then regress to normal size.

Some actions of clomiphene may *interfere* with conception. Luteal-phase defect may be induced, but can be corrected by giving progesterone. Because it has antiestrogenic actions, clomiphene may force the production of scant and viscous cervical mucus; estrogen therapy can render cervical secretions more hospitable to sperm.

Clomiphene should be avoided during pregnancy. Although no human fetal defects have been reported, clomiphene has produced developmental abnormalities in animals.

63.2.1.1.5 Preparations, Dosage, and Administration.

Clomiphene [Clomid, Milophene, Serophene] is supplied in 50-mg oral tablets. The initial course of treatment consists of 50 mg once daily for 5 days. If cyclic menstrual bleeding has been occurring, therapy should begin on the fifth day after the onset of menses. If menstruation has been absent, dosing can start any time (assuming pregnancy has been ruled out). If the first course of treatment fails to induce ovulation, a second 5-day course (using 100 mg/day) may be tried. The second course may begin as early as 30 days after the previous one. Doses may be increased in subsequent courses. However, doses above 100 mg/day are rarely needed. Once a dose that induces ovulation has been established, that dose should be used for a maximum of three cycles. If pregnancy has not occurred, further treatment is unlikely to succeed. When ovulation does occur, it is usually within 5 to 10 days after the last clomiphene dose; patients should be instructed to have coitus at least every other day during this interval.

754

63.2.1.2 Menotropins

Menotropins [Repronex, Menopur]—also known as human menopausal gonadotropin, or hMG—consists of equal amounts of LH and FSH activity. Commercial menotropins is prepared by extraction from the urine of postmenopausal women.

63.2.1.2.1 Therapeutic Actions and Uses.

Anovulatory Women. Menotropins, in conjunction with hCG, is used to promote follicular maturation and ovulation in anovulatory patients. Menotropins acts directly on the ovaries to cause maturation of follicles. Once follicles have ripened, hCG is given to induce ovulation.

Menotropins is employed when gonadotropin secretion by the pituitary is insufficient to provide adequate ovarian stimulation. Candidates must have ovaries capable of responding to FSH and LH; menotropins is of no help in women with primary ovarian failure. Among properly selected patients, the rate of ovulation approaches 100%. It should be noted that therapy with menotropins is extremely expensive.

63.2.1.2.1.1 Ovulatory Women.

Menotropins can be used to induce development of multiple follicles in ovulatory women participating in an *in vitro* fertilization program.

63.2.1.2.1.2 Men.

Menotropins has been used off-label to promote spermatogenesis in males with primary or secondary hypogonadotropic hypogonadism.

63.2.1.2.2 Adverse Effects.

The most serious adverse response is *ovarian hyperstimulation syndrome*, a condition characterized by sudden enlargement of the ovaries. Mild to moderate ovarian enlargement is common, occurring in about 20% of patients. This condition is benign and resolves spontaneously after discontinuing drug use. Of greater concern is ovarian enlargement that occurs rapidly and that may be accompanied by ascites, pleural effusion, and considerable pain. If this manifestation of ovarian stimulation occurs, menotropins should be withdrawn and the patient hospitalized. Treatment is usually supportive (bed rest, analgesics, fluid and electrolyte replacement). Paracentesis can be used to remove some excess ascitic fluid. If rupture of ovarian cysts occurs, surgery may be required to stop bleeding. Enlargement of the ovaries is most likely during the first 2 weeks of treatment. To ensure early detection, the

patient should be examined at least every other day while taking menotropins, and for 2 weeks after stopping. Ovarian stimulation can be minimized by keeping the dosage as low as possible.

Pregnancies facilitated by menotropins often result in *multiple births*: 15% of pregnancies result in twins, and 5% of pregnancies result in three or more babies.

63.2.1.2.3 Monitoring Therapy.

Ovarian responses to menotropins must be monitored to determine timing of hCG administration and to minimize the risk of ovarian enlargement. Responses can be followed by ultrasonography of the developing follicles and by measuring serum estrogen. When ultrasonography indicates that follicles have enlarged to 16 to 20 mm and when serum estrogen is 200 pg/mL per maturing follicle, then menotropins administration should cease and hCG should be injected.

63.2.1.2.4 Preparations, Dosage, and Administration.

Menotropins [Repronex, Menopur] is supplied as a powder or pellet to be reconstituted immediately prior to use. Ampules of menotropins contain either (1) 75 international units (IU) of FSH activity plus 75 IU of LH activity or (2) 150 IU of FSH activity plus 150 IU of LH activity. Repronex is administered IM; Menopur is administered subQ.

Menotropins is used sequentially with hCG: After follicular maturation has been induced with menotropins, hCG is injected to promote ovulation. For the initial cycle, the contents of 1 menotropins ampule are injected daily for 9 to 12 days. When estrogen measurements indicate follicular maturation has occurred, menotropins is discontinued; hCG (5000 to 10,000 USP units) is injected 24 hours after the last menotropins dose. Ovulation occurs 2 to 3 days after injecting hCG. Accordingly, patients should be instructed to have intercourse on the evening before hCG injection and on the following 2 to 3 days. If there is evidence of ovulation but conception does not take place, treatment should be repeated for two more courses using the same menotropins dosage. If treatment remains ineffective, two additional courses may be tried, using twice as much menotropins as previously. If there is still no conception, further treatment is unlikely to help.

63.2.1.3 Follitropins

63.2.1.3.1 Description.

Three follitropins are available: *urofollitropin* [Metrodin, Fertinex, Bravelle], *follitropin alfa* [Gonal-F], and *follitropin beta* [Follistim AQ]. All three are preparations of FSH.

Urofollitropin is a highly purified preparation of FSH extracted from the urine of postmenopausal women. Follitropin alfa and follitropin beta are produced by recombinant DNA technology.

63.2.1.3.2 Use in Women.

The actions, uses, and adverse effects of the follitropins are much like those of menotropins (a 50:50 mixture of FSH and LH). Like menotropins, the follitropins act directly on the ovary to stimulate follicle maturation. All three follitropins are employed to stimulate ovulation in anovulatory women, and to promote production of multiple follicles in ovulatory women participating in an *in vitro* fertilization program. For both indications, the follitropins are used sequentially with hCG: the follitropin is given first to promote follicle maturation; then hCG is given to stimulate ovulation. As with menotropins, multiple births are relatively common. The principal adverse effect of the follitropins is ovarian hyperstimulation syndrome. All of the follitropins are administered subQ; follitropin beta may also be given IM.

63.2.1.3.3 Use in Men.

One agent—*follitropin alfa*—is approved for promoting spermatogenesis in males with primary or secondary hypogonadotropic hypogonadism.

63.2.1.4 Lutropin Alfa

Lutropin alfa [Luveris] is a recombinant form of LH. The drug is approved for combined use with follitropin alfa [Gonal-F] to promote follicular maturation in infertile, hypogonadotropic, hypogonadal women with profound LH deficiency. Following treatment with lutropin alfa/follitropin alfa, hCG is injected to induce ovulation. Adverse effects of the combination include headache, abdominal pain, nausea, breast pain, ovarian enlargement, and ovarian hyperstimulation syndrome.

63.2.1.5 Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is a polypeptide hormone produced by the placenta. hCG is similar in structure and identical in action to luteinizing hormone.

63.2.1.5.1 Therapeutic Use.

hCG is used to promote follicular maturation and ovulation in women who are infertile because of ovulatory failure. The drug causes ovulation by simulating the midcycle LH surge. When hCG is used to promote ovulation, follicular maturation must first be induced with

another agent, usually menopins. hCG can also be used in conjunction with clomiphene when treatment with clomiphene alone has failed to promote ovulation.

63.2.1.5.2 Adverse Effects.

The most severe adverse response to hCG is *ovarian hyperstimulation syndrome*. If this occurs, hospitalization and discontinuation of hCG are indicated. hCG may also provoke *rupture of ovarian cysts* with resultant bleeding into the peritoneal cavity. Additional adverse effects include edema, injection-site pain, and central nervous system disturbances (headache, irritability, restlessness, fatigue).

63.2.1.5.3 Preparations, Dosage, and Administration.

Commercial hCG is prepared by extraction from the urine of pregnant women. hCG is supplied as a powder and must be reconstituted for use. Administration is by IM injection. The usual dose for induction of ovulation is 5000 to 10,000 USP units. Trade names are *Choron 10*, *Gonic*, *Novarel*, *Pregnyl*, and *Profasi*.

Prior to giving hCG, follicular maturation must be induced with another agent (clomiphene, menopins, or a follitropin). When used in conjunction with clomiphene, hCG is administered 7 to 9 days after the last clomiphene dose. When used in conjunction with menopins or a follitropin, hCG is injected 1 day after the last menopins or follitropin dose.

755

756

63.2.1.6 Choriogonadotropin Alfa

Choriogonadotropin alfa [Ovidrel] is a form of hCG produced by recombinant DNA technology. The drug's physicochemical, immunologic, and biologic activities are equivalent to those of naturally occurring hCG, produced by extraction from the urine of pregnant women. However, unlike urinederived hCG, which must be injected IM, choriogonadotropin alfa is injected subQ. As a result, administration is more comfortable (IM injection can be painful). Choriogonadotropin alfa has two indications. First, like natural hCG, the drug is given to *trigger ovulation* in women who are infertile owing to anovulation. Second, the drug is used to *promote late follicular maturation and early luteinization* in women undergoing assisted reproductive technology (eg, *in vitro* fertilization). For both indications, follicular maturation must first be induced with a follicle-stimulating agent (eg, menopins). Choriogonadotropin alfa (250 mcg) is then given as a single subQ injection 1 day after the last dose of the follicle-stimulating agent. Major adverse effects are the same as those of natural hCG: ovarian hyperstimulation syndrome, rupture of ovarian cysts, and multiple births.

63.2.1.7 Gonadotropin-Releasing Hormone Antagonists

Gonadotropin-releasing hormone (GnRH) antagonists are used to prevent a premature surge of endogenous LH in women undergoing controlled ovarian stimulation (with menotropins or follitropin [FSH]). As discussed above, after follicles have matured under the influence of exogenous menotropins or FSH, the patient is given an injection of hCG (LH) to cause ovulation. However, in some women, the natural midcycle LH surge occurs early, causing ovulation before the eggs have fully matured. As a result, the chances of successful conception and implantation are reduced. The GnRH antagonists prevent LH release, and thereby eliminate the chance of premature ovulation.

Two GnRH antagonists are available: *ganirelix* (generic only) and *cetrorelix* [Cetrotide]. Both drugs block GnRH receptors, and thereby prevent GnRH from promoting the production and release of LH from the pituitary. Various dosing schedules are employed. One option for either drug is to give 250 mcg subQ daily, beginning in the early follicular phase and continuing until the day of hCG administration. Injections are made by the patient into the upper thigh or the region around the navel.

63.2.2 Dopamine Agonists for Hyperprolactinemia

Two dopamine agonists—cabergoline and bromocriptine—are approved for hyperprolactinemia. Both drugs are derivatives of ergot, an alkaloid found in plants. Cabergoline is better tolerated than bromocriptine, and dosing is more convenient. Accordingly, cabergoline is preferred.

63.2.2.1 Cabergoline

63.2.2.1.1 Therapeutic Use.

Cabergoline [Dostinex] is used to correct amenorrhea and infertility associated with excessive prolactin secretion. If galactorrhea is present, this consequence of hyperprolactinemia may also be corrected. When the source of excessive prolactin is a pituitary adenoma, cabergoline can induce tumor regression. Effects on prolactin begin within hours of dosing and persist about 14 days. To monitor treatment, prolactin should be measured monthly until the level is normal (below 20 pg/mL).

In addition to its use in hyperprolactinemia, cabergoline is used in Parkinson's disease, although the drug is not approved for this disorder.

63.2.2.1.2 Mechanism of Fertility Promotion.

Cabergoline is a dopamine receptor agonist. By activating dopamine receptors in the anterior pituitary, cabergoline inhibits prolactin secretion. The result is normalization of the menstrual cycle and a return of fertility. The mechanism by which reducing prolactin levels leads to a return of ovulation is unknown.

63.2.2.1.3 Pharmacokinetics.

Administration is oral, and absorption is not affected by food. Plasma levels peak 2 to 3 hours after dosing, but absolute bioavailability is unknown. Cabergoline undergoes extensive hepatic metabolism followed by excretion in the urine and feces. The elimination half-life is prolonged, about 65 hours. In patients with severe hepatic impairment, cabergoline levels may rise.

63.2.2.1.4 Adverse Effects.

The most common adverse effects are nausea (29%), headache (26%), and dizziness (17%). Orthostatic hypotension may occur, but is rare at recommended doses. Adverse effects can be minimized by initiating treatment at low doses. Like other ergot derivatives, cabergoline may pose a risk of valvular heart damage.

63.2.2.1.5 Preparations, Dosage, and Administration.

Cabergoline [Dostinex] is supplied in 0.5-mg tablets. The initial dosage is 0.25 mg twice a week, administered with or without food. Dosage may be increased in 0.25-mg increments to a maximum of 1 mg twice a week. At least 4 weeks should separate each rise in dosage. After prolactin has been maintained at a normal level for at least 6 months, treatment can stop.

63.2.2.2 Bromocriptine

63.2.2.2.1 Actions and Therapeutic Uses.

Like cabergoline, bromocriptine [Parlodel] activates dopamine receptors in the pituitary, and can thereby reduce prolactin secretion. As a result, it can correct amenorrhea, galactorrhea, and infertility. If hyperprolactinemia is caused by a pituitary adenoma, bromocriptine can induce regression of the tumor (in addition to reducing prolactin secretion). Continuous treatment can suppress tumor growth for years. Bromocriptine is also used in Parkinson's disease (see [Chapter 21](#)).

63.2.2.2.2 Adverse Effects.

When bromocriptine is used for infertility, adverse effects are frequent but usually mild. Nausea occurs in 50% of patients. Headache, dizziness, fatigue, and abdominal cramps are also common. Orthostatic hypotension may occur, but is rare at the doses employed. Teratogenic effects have not been reported. Adverse effects can be minimized by taking bromocriptine with meals and initiating treatment at low doses. Like cabergoline and other ergot derivatives, bromocriptine may pose a risk of valvular heart injury.

63.2.2.2.3 Preparations, Dosage, and Administration.

Bromocriptine mesylate [Parlodel] is supplied in 2.5-mg tablets and 5-mg capsules. Dosing is begun at 2.5 mg once a day and then gradually increased to 2.5 mg 2 or 3 times a day. All doses should be administered with food. Normalization of the menstrual cycle may occur rapidly (within a few days) or may require up to 2 months of treatment. As soon as pregnancy is achieved, use of bromocriptine should cease. As a rule, administration should not resume until after delivery. If treatment is not reinstated, hypersecretion of prolactin is almost certain to recur within a year.

63.2.3 Drugs for Endometriosis

63.2.3.1 GnRH Agonists

Leuprolide and nafarelin are synthetic analogs of GnRH. Both drugs are used to treat endometriosis. However, although they can reduce symptoms, they do not increase fertility. In the United States, leuprolide is used more widely than nafarelin.

63.2.3.1.1 Leuprolide.

Therapeutic Uses. Leuprolide [Lupron Depot, Eligard] is a GnRH analog with several approved uses. In addition to endometriosis, the drug is indicated for uterine fibroids, central precocious puberty, and advanced prostate cancer (see [Chapter 102](#)). Discussion here is limited to treatment of endometriosis.

63.2.3.1.1.1 Mechanism of Action.

Like the normal endometrium, ectopic endometrial implants are dependent on ovarian hormones. Leuprolide suppresses endometriosis by indirectly suppressing ovarian hormone production. How? *Initial* doses actually increase hormone production. Why? Because leuprolide, like endogenous GnRH, acts on the pituitary to promote release of FSH and LH,

which in turn act on the ovary to stimulate hormone production. However, in contrast to endogenous GnRH, which has a short half-life and is released in a *pulsatile* fashion, leuprolide has a long half-life and blood levels remain steady. As a result, leuprolide causes continuous activation of pituitary GnRH receptors, which has the paradoxical effect of *suppressing* FSH and LH release, thereby depriving the ovary of the stimulation needed for hormone production. By decreasing production of ovarian hormones, the drug reduces the area of endometriosis and improves symptoms. It must be stressed that leuprolide does not produce cure. Within 6 months after the drug is withdrawn, symptoms return in up to 50% of women who had previously been rendered symptom free.

756

757

63.2.3.1.1.2

Adverse Effects.

Most undesired effects are secondary to estrogen deficiency. Common responses include hot flushes, vaginal dryness, decreased libido, mood changes, and headache. Nasal irritation also occurs (with administration by nasal spray). Leuprolide is teratogenic and must not be used during pregnancy.

The adverse effect of greatest concern is *bone loss*. After 3 to 6 months of treatment, bone mass and mineral content may decrease. To minimize the risk of osteoporosis, the manufacturer recommends that treatment last no more than 6 months.

63.2.3.1.1.3

Preparations, Dosage, and Administration.

For treatment of endometriosis, a depot formulation is used. Dosing consists of either 3.75 mg IM once a month or 11.25 mg every 3 months. As noted, treatment should stop after 6 months.

63.2.3.1.2

Nafarelin.

Like leuprolide, nafarelin [Synarel] is a GnRH analog that can reduce symptoms of endometriosis, but does not improve fertility. Nafarelin has the same mechanism as leuprolide (suppression of LH and FSH release) as well as the same adverse effects (hot flushes, vaginal dryness, amenorrhea, headache, depression, osteoporosis). Nafarelin is supplied as a nasal spray. (The drug cannot be given orally owing to rapid degradation by GI enzymes.) The initial dosage is 200 mcg (1 spray) in the morning and evening. Doses should alternate between nostrils. Treatment should begin between days 2 and 4 of the menstrual cycle.

63.2.3.2 Danazol

63.2.3.2.1 Therapeutic Use.

Danazol, formerly available as Danocrine, can improve symptoms of endometriosis, but does *not* increase fertility. Treatment leads to complete regression of endometrial implants in the majority of patients. However, implants will eventually recur after treatment stops. In addition to the therapy of endometriosis, danazol has been used to treat *angioneurotic edema* and *fibrocystic breast disease*. Since the introduction of nafarelin and leuprolide, use of danazol for endometriosis has sharply declined. Today, the drug is given only when nafarelin and leuprolide are contraindicated.

63.2.3.2.2 Mechanism of Action.

Danazol acts by multiple mechanisms to induce regression of endometrial implants. First, the drug inhibits several of the enzymes needed to synthesize ovarian hormones, and thereby deprives the implant of the hormonal environment it needs for maintenance. Second, danazol suppresses secretion of pituitary gonadotropins (FSH and LH), and thereby further decreases the availability of ovarian hormones. Lastly, danazol may act directly on the implant to block ovarian hormone receptors. All of these actions result in atrophy of ectopic endometrial tissue. The normal endometrium atrophies as well.

63.2.3.2.3 Adverse Effects and Interactions.

Danazol is weakly androgenic and may induce virilization. Potential manifestations include acne, deepening of the voice, and growth of facial hair. These effects usually reverse after treatment stops. Danazol may also cause edema, and therefore should be used with caution in patients with cardiac and renal disorders. Thrombotic events have been reported, including fatal strokes. Liver impairment may also occur, and hence liver function should be assessed at baseline and periodically thereafter. Danazol may intensify the anticoagulant effects of warfarin. Lastly, the drug can masculinize the female fetus, and hence is contraindicated during pregnancy.

63.2.3.2.4 Preparations, Dosage, and Administration.

Danazol is supplied in capsules (50, 100, and 200 mg) for oral use. A dosage of 200 to 300 mg twice daily is usually effective. To ensure that danazol is not taken during pregnancy, therapy should be initiated at the time of menstruation. The usual course of treatment is 3 to 9 months.

63.2.3.2.4.1

KEY POINTS

- Infertility (subfertility) is defined as a decrease in reproductive ability, whereas sterility is a complete absence of reproductive ability.
- Infertility in a couple may result from infertility in the male partner, the female partner, or both.
- Clomiphene is used to promote follicular maturation and ovulation.
- Clomiphene acts by blocking estrogen receptors in the hypothalamus and pituitary, causing a compensatory increase in the release of LH and FSH, which then act on the ovary to promote follicular maturation and ovulation.
- Menotropins is a 50:50 mixture of LH and FSH.
- Menotropins is used sequentially with hCG: menotropins is given to promote follicular maturation, then hCG is given to promote ovulation.
- The most serious adverse effect of menotropins is ovarian hyperstimulation syndrome, characterized by sudden enlargement of the ovaries.
- hCG is given to stimulate ovulation (after another agent, such as menotropins, has been given to promote follicular maturation).
- Like menotropins, hCG can cause ovarian hyperstimulation syndrome.
- Cabergoline is a dopamine agonist used to suppress excessive prolactin release.
- Two GnRH agonists—leuprolide and nafarelin—can promote regression of endometrial implants, but these drugs will not increase fertility.

63.2.3.2.4.2

Summary of Major Nursing Implications*

63.2.3.2.4.2.1

CLOMIPHENE

The implications summarized here apply only to the use of clomiphene for promoting maturation of ovarian follicles and ovulation. (Clomiphene has also been used investigationally to increase fertility in males.)

63.2.3.2.4.2.1.1	Preadministration Assessment	
63.2.3.2.4.2.1...	Therapeutic Goal Promotion of follicular maturation and ovulation in carefully selected patients.	
63.2.3.2.4.2.1...	Baseline Data Take a complete health and gynecologic history, and assess for tubal patency. Ovarian and pituitary function must be confirmed. Pregnancy must be ruled out.	
63.2.3.2.4.2.1...	Identifying High-Risk Patients Clomiphene is <i>contraindicated</i> during pregnancy and in women with liver disease and abnormal uterine bleeding of undetermined origin.	757
63.2.3.2.4.2.1.2	Implementation: Administration	758
63.2.3.2.4.2.1...	Route Oral.	
63.2.3.2.4.2.1...	Administration Schedule If cyclic menstrual bleeding has been occurring, begin therapy 5 days after the onset of menses. If menstruation has been absent, begin any time. The initial course consists of 50-mg doses once daily for 5 days. If ovulation fails to occur, additional courses may be tried, each beginning no sooner than 30 days after the previous course.	
63.2.3.2.4.2.1.3	Implementation: Measures to Enhance Therapeutic Effects	
63.2.3.2.4.2.1...	Timing of Coitus Advise the couple to have coitus at least every other day during the 5- to 10-day period that follows the last clomiphene dose.	
63.2.3.2.4.2.1...	Adjunctive Use of hCG If ovulation fails to occur under the influence of clomiphene alone, injecting hCG 7 to 9 days after the last clomiphene dose may bring success.	

63.2.3.2.4.2.1.4

Ongoing Evaluation and Interventions

63.2.3.2.4.2.1...

Evaluating Therapeutic Effects

Monitor treatment with serial ultrasound exams of the ovary. Success is indicated by progressive follicular enlargement followed by conversion of the follicle to a corpus luteum.

63.2.3.2.4.2.1...

Minimizing Adverse Effects

63.2.3.2.4.2.1...

Ovarian Enlargement.

Instruct the patient to notify the prescriber if pelvic pain occurs (an indication of ovarian enlargement). If ovarian enlargement is diagnosed, clomiphene should be withdrawn, after which ovarian size usually regresses spontaneously.

63.2.3.2.4.2.1...

Reduced Fertility.

Clomiphene may cause luteal-phase defect, which can be corrected with progesterone. Alteration of cervical mucus may occur; estrogens can be used to restore the volume and fluidity of cervical secretions.

63.2.3.2.4.2.1...

Multiple Births.

Inform the couple that multiple births (usually twins) are not uncommon in clomiphene-facilitated pregnancies.

63.2.3.2.4.2.1...

Visual Disturbances.

Forewarn the patient about possible visual disturbances (blurred vision, visual flashes), and instruct her to notify the prescriber if these occur. Visual aberrations usually cease following drug withdrawal.

63.2.3.2.4.2.1...

Other Adverse Effects.

Common side effects include hot flushes (similar to the vasomotor responses of menopause), nausea, abdominal discomfort, bloating, and breast engorgement. **Inform the patient about these effects, and instruct her to notify the prescriber if they are especially disturbing.**

63.2.3.2.4.2.2

MENOTROPINS

The implications summarized here refer only to the use of menotropins (together with hCG) for induction of follicular maturation and ovulation. (Menotropins is also used to treat infertility in males.)

63.2.3.2.4.2.2.1

Preadministration Assessment

63.2.3.2.4.2.2...

Therapeutic Goal

Induction of follicular maturation and ovulation (in conjunction with hCG) in carefully selected patients.

63.2.3.2.4.2.2...

Baseline Data

A thorough gynecologic and endocrinologic evaluation should precede treatment. Ovarian function must be verified. Obtain a baseline value for serum estrogen.

63.2.3.2.4.2.2...

Identifying High-Risk Patients

Menotropins is *contraindicated* in the presence of pregnancy, primary ovarian failure, thyroid dysfunction, adrenal dysfunction, ovarian cysts, and ovarian enlargement (other than that caused by polycystic ovary syndrome).

63.2.3.2.4.2.2.2

Implementation: Administration

63.2.3.2.4.2.2...

Route

Intramuscular.

63.2.3.2.4.2.2...

Administration

Reconstitute powdered menotropins with sterile saline immediately prior to injection.

Menotropins is employed sequentially with hCG. Administer menotropins for 9 to 12 days (to promote follicular maturation). Twenty-four hours after the last dose, inject hCG. Ovulation follows in 2 to 3 days.

Ultrasonography and serum estrogen level are used to assess follicular maturation. Upon follicular maturation, menotropins is discontinued and hCG is injected.

63.2.3.2.4.2.2.3	Implementation: Measures to Enhance Therapeutic Effects	
63.2.3.2.4.2.2...	Timing of Coitus Advise the couple to have intercourse on the evening before hCG injection and on the following 2 to 3 days (ie, during the probable period of ovulation).	
63.2.3.2.4.2.2.4	Ongoing Evaluation and Interventions	
63.2.3.2.4.2.2...	Minimizing Adverse Effects	
63.2.3.2.4.2.2...	Ovarian Hyperstimulation Syndrome. Rapid ovarian enlargement can occur, sometimes associated with pain, ascites, pleural effusion, and shortness of breath. If ovarian enlargement is excessive, discontinue menotropins and hospitalize the patient. Treatment is supportive (bed rest, analgesics, fluid and electrolyte replacement). Paracentesis can be used to remove excess ascitic fluid. If ovarian cysts rupture, surgery may be required to stop bleeding. To ensure early detection of ovarian enlargement, the patient should be examined at least every other day during menotropins use, and for 2 weeks after dosing stops.	758
63.2.3.2.4.2.2...	Other Adverse Effects. Inform the couple that multiple births are relatively common in menotropins-facilitated pregnancies.	759
63.2.3.2.4.2.3	HUMAN CHORIONIC GONADOTROPIN The implications summarized here apply only to the use of hCG in the treatment of female infertility.	
63.2.3.2.4.2.3.1	Preadministration Assessment	
63.2.3.2.4.2.3...	Therapeutic Goal Induction of ovulation in women who are infertile because of anovulation. Pretreatment with menotropins, urofollitropin, or clomiphene is required.	

63.2.3.2.4.2.3.2

Implementation: Administration

63.2.3.2.4.2.3...

Route

Intramuscular.

63.2.3.2.4.2.3...

Administration

hCG must be used in conjunction with menotropins, a follitropin, or clomiphene. When used with menotropins or a follitropin, hCG is injected 1 day after the last menotropins dose. When used with clomiphene, hCG is administered 7 to 9 days after the last clomiphene dose.

63.2.3.2.4.2.3.3

Ongoing Evaluation and Interventions

63.2.3.2.4.2.3...

Minimizing Adverse Effects

63.2.3.2.4.2.3...

Ovarian Hyperstimulation Syndrome.

See *Minimizing Adverse Effects* for menotropins.

63.2.3.2.4.2.4

CABERGOLINE

63.2.3.2.4.2.4.1

Preadministration Assessment

63.2.3.2.4.2.4...

Therapeutic Goal

Treatment of female infertility occurring secondary to hyperprolactinemia.

63.2.3.2.4.2.4...

Identifying High-Risk Patients

Cabergoline should be used with *caution* in patients with severe hepatic insufficiency.

63.2.3.2.4.2.4.2

Implementation: Administration

63.2.3.2.4.2.4...

Route

Oral.

63.2.3.2.4.2.4...

Administration

Instruct patients to take cabergoline twice a week, with or without food.

Treatment can stop after prolactin levels have been maintained in the normal range (below 20 pg/mL) for at least 6 months.

63.2.3.2.4.2.4.3

Ongoing Evaluation and Interventions

63.2.3.2.4.2.4...

Minimizing Adverse Effects

63.2.3.2.4.2.4...

Nausea, Headache, and Dizziness.

Initiating treatment at low doses may help minimize these effects.

* Patient education information is highlighted as **blue text**.

⁶⁴CHAPTER 63 Drugs That Affect Uterine Function

In this chapter, our principal focus is on drugs that stimulate or suppress uterine contractions. In addition, we discuss two drugs that promote cervical ripening. Drugs that stimulate uterine contraction are known as *oxytocics*. Drugs that suppress contraction are known as *tocolytics*. Oxytocic agents have three applications: (1) induction or augmentation of labor, (2) control of postpartum bleeding, and (3) induction of abortion. The tocolytic drugs have only one major use: suppression of preterm labor. Drugs that promote cervical ripening are used to soften the cervix prior to induction of labor.

^{64.1} UTERINE RELAXANTS (TOCOLYTICS) AND THEIR USE IN PRETERM LABOR

Premature birth, defined as birth before 37 weeks' gestation, is the leading cause of infant morbidity and neonatal mortality. In the United States, about 12.5% of all live births (500,000 annually) are premature. These preterm births account for 75% of neonatal mortality and 50% of congenital neurologic deficits. The most common complication of premature birth is *neonatal respiratory distress syndrome*. Risk factors for preterm delivery include a previous preterm delivery, multifetal pregnancy, cervical or uterine abnormalities, and intrauterine infection. The annual cost of preterm births is estimated at \$26 billion—about \$52,000 per infant.

Because of the morbidity and mortality associated with premature birth, uterine relaxants (tocolytic drugs) are used to suppress preterm labor, and thereby delay delivery. These drugs can suppress labor *briefly*, but not long term. On average, delivery is postponed by only 48 hours. Hence, birth still takes place prior to term. If tocolytics don't permit pregnancy to reach term, what are they good for? The answer: Almost nothing—if they are used *alone*. However, when tocolytics are combined with glucocorticoids, which accelerate fetal lung development (see [Chapter 106](#)), the outcome can be improved: Infants experience less respiratory distress syndrome, intraventricular hemorrhage, and mortality. Tocolytics also buy time to treat infection, if present. Unfortunately, tocolytic drugs can pose a risk to the fetus. Accordingly, the ultimate goal of treatment is to extend fetal time in the womb, but without causing significant fetal or neonatal harm.

Research discussed in [Box 63-1](#) suggests there may be ways to *prevent* preterm labor—rather than treat it after the fact. Given that tocolytic drugs work only briefly, effective prevention would be welcome indeed.

^{64.1.1} Control of Myometrial Contraction and Mechanisms of Tocolytic Drug Action

Contraction of the myometrium (uterine smooth muscle) is regulated by multiple mediators, including beta-adrenergic agonists, oxytocin, and prostaglandins ([Fig. 63-1](#)). As a result, there are

multiple ways in which drugs can suppress uterine activity. However, although these drugs work through different mechanisms, they all have one thing in common: Ultimately, they all *decrease the availability of phosphorylated light-chain (LC) myosin*, the form of myosin that interacts with actin to cause contraction. As indicated in [Figure 63-1](#), four classes of tocolytic drugs—beta-adrenergic agonists, calcium channel blockers, cyclooxygenase (COX) inhibitors, and oxytocin receptor antagonists—work to reduce the activity of myosin LC kinase, the enzyme that converts myosin to its phosphorylated form. A fifth group—the nitric oxide donors—work to increase the activity of myosin LC phosphatase, the enzyme that removes phosphate from myosin, thereby converting it to its inactive form. Note also that three groups of drugs—COX inhibitors, oxytocin receptor antagonists, and calcium channel blockers—*decrease the release of calcium* from the sarcoplasmic reticulum (SR). As indicated in the figure, calcium combines with calmodulin to form a complex that increases myosin light-chain kinase activity. Hence, in the absence of sufficient free calcium, myosin LC kinase activity declines, causing the phosphorylation of myosin to decline as well.

64.1.2 Specific Tocolytic Drugs

A variety of drugs can suppress preterm labor. Options include beta₂-adrenergic agonists (eg, terbutaline), nifedipine (a calcium channel blocker), and COX inhibitors (eg, indomethacin). All of these drugs appear equally good at suppressing labor, and hence there is no obvious “first-choice” agent among them. Accordingly, selection is based primarily on side effects, which

760

Figure 63-1 Control of myometrial contraction and the actions of tocolytic drugs. The figure shows five pathways that regulate availability of myosin LC phosphate (myosin LC PO_4), the form of myosin needed for contractile interaction with actin. Note that two enzymes—myosin LC kinase and myosin LC phosphatase—play central roles. Four classes of tocolytic drugs work to reduce the activity of myosin LC kinase, and thereby reduce production of myosin LC phosphate. A fifth class—the nitric oxide donors—increases the activity of myosin LC phosphatase, and thereby stimulates conversion of myosin LC phosphate into its inactive (dephosphorylated) form. Note also the important role played by calcium in controlling the activity of myosin LC kinase. (AA = arachidonic acid, ATP = adenosine triphosphate, cAMP = cyclic adenosine monophosphate, CCBs = calcium channel blockers, cGMP = cyclic guanosine monophosphate, COX = cyclooxygenase, GTP = guanosine triphosphate, LC = light chain, IP_3 = inositol triphosphate, NO = nitric oxide, PG = prostaglandin, PIP_3 = phosphatidylinositol triphosphate, PO_4 = phosphate, SR = sarcoplasmic reticulum.)

are summarized in [Table 63-1](#). Interestingly, of the drugs that have been employed to suppress preterm labor, only one agent—ritodrine—has ever been approved by the Food and Drug Administration (FDA) for this use.

64.1.2.1 Beta₂-Adrenergic Agonists

Two beta₂-adrenergic agonists—ritodrine and terbutaline—have been used widely to suppress preterm labor. Both drugs are effective, but adverse effects on the mother are a concern.

64.1.2.1.1 Ritodrine.

Ritodrine (no longer available in the United States) is classified as a beta₂-selective adrenergic agonist. By activating beta₂ receptors in the uterus, ritodrine increases production of cyclic AMP (cAMP), a mediator that leads to suppression of myosin light-chain kinase activity. The result is a decrease in both the intensity and frequency of contractions. Unfortunately, although ritodrine is effective, it poses a significant risk to the mother. Adverse effects result from activating beta₁ receptors as well as beta₂ receptors. (Although ritodrine is classified as beta₂ selective, it also activates beta₁ receptors, albeit less readily than beta₂ receptors.) Adverse effects of greatest concern are pulmonary edema, hypotension, and hyperglycemia in the mother, and tachycardia in both the mother and fetus.

64.1.2.1.2 Terbutaline.

Terbutaline [Brethine] is a beta₂-selective adrenergic agonist similar to ritodrine in actions and adverse effects. The drug's principal indication is asthma (see [Chapter 75](#)). In addition, terbutaline has been used to delay preterm labor, although it is not approved by the FDA for this use. The drug is given IV or subQ for up to 48 hours.

761

64.1.2.1.2.1 BOX 63-1 Special Interest Topic

762

64.1.2.1.2.1.1 SURE, DRUGS CAN **DELAY** PRETERM LABOR, BUT CAN THEY **PREVENT** IT?

We can arrest preterm labor (albeit briefly) with tocolytics, but is there any way we can *prevent* it? Recent studies suggest that the answer is “Yes”—at least for some women. Two drug interventions look promising: progesterone and antibiotics.

The beneficial effects of progesterone on preterm delivery were demonstrated by Meis et al.¹ Their study enrolled 463 pregnant women at high risk of preterm delivery

(because they had preterm deliveries in the past). After random assignment to placebo or treatment groups, one-third of the women were given weekly IM injections of placebo, and two-thirds were given weekly IM injections of 17-alpha-hydroxyprogesterone caproate (17P), a weakly active, naturally occurring progesterone. Injections began at 16 to 20 weeks of gestation and continued until delivery or until 36 weeks of gestation. The result? The rate of preterm delivery was 54.9% in the placebo group, but only 36.3% in the progesterone group—a highly significant reduction. In addition, progesterone reduced the risk of low birth weight and several other complications. Progesterone-induced birth defects were not observed. Although these results are both impressive and encouraging, important questions remain:

- Are there any long-term risks to the child? (Experience with diethylstilbestrol, an estrogen that can cause vaginal cancer in women exposed to it *in utero*, is a warning for caution.)
- Do these results apply to women at risk of preterm delivery for reasons other than having a history of the problem?
- Are other progestational agents also effective?
- Why did 17P only work in some women? (Preterm delivery still occurred in more than one-third of the women who were treated.)

Despite these questions, the study remains important, having shown that preterm delivery can be prevented, at least in some women. Recently, the American College of Obstetricians and Gynecologists endorsed the use of 17P to prevent preterm birth in women who experienced spontaneous preterm delivery prior to 37 weeks' gestation.

Two randomized, double-blind, placebo-controlled trials^{2,3} have shown that, in women with bacterial vaginosis, antibiotic therapy can reduce the incidence of preterm labor. Why were these studies conducted? Because there is an association between abnormal genital tract flora and preterm delivery, suggesting that normalizing genital tract flora might reduce risk.

In the first study, involving 409 pregnant women with abnormal genital tract flora (suggesting bacterial vaginosis), subjects were given a 3-day course of either 2% clindamycin vaginal cream or a placebo vaginal cream, beginning at 13 to 20 weeks of gestation. If abnormal flora were still present 3 weeks later, subjects received a longer (7-day) course of clindamycin or placebo. The result? Preterm delivery occurred in 10% of the placebo group, compared with only 4% of the clindamycin group.

In the second study, involving 494 pregnant women with abnormal genital tract flora, subjects were given a single, 5-day oral course of either clindamycin (300 mg twice daily) or placebo. Dosing was done during weeks 12 to 22 of pregnancy. Preterm delivery occurred in 16% of placebo recipients, but only 5% of clindamycin recipients.

Taken together, these antibiotic studies suggest a simple method for preventing some preterm deliveries: early screening for and treatment of asymptomatic bacterial vaginosis.

64.1.2.2 Nifedipine, a Calcium Channel Blocker

Nifedipine [Procardia, Adalat, Nifedical] can suppress preterm labor for at least 48 hours. Efficacy equals that of ritodrine—and safety is superior. How does nifedipine work? By blocking calcium channels, the drug inhibits entry of calcium into myometrial cells. As a result, release of calcium from the SR is reduced, and hence the activity of myosin light-chain kinase is reduced as well. Maternal side effects, which are rare, include transient tachycardia, facial flushing, headache, dizziness, and nausea. Hypotension may occur in hypovolemic patients. There is some concern that nifedipine may compromise uteroplacental blood flow. In animal studies, calcium channel blockers have caused acidosis, hypoxemia, and hypercapnia in the newborn. To suppress preterm labor, an initial loading dose (30 mg sublingual) is followed by maintenance doses (10 or 20 mg PO) every 4 to 6 hours. The basic pharmacology of calcium channel blockers is discussed in [Chapter 44](#).

64.1.2.3 Indomethacin, a Cyclooxygenase Inhibitor

Indomethacin [Indocin] is a second-line tocolytic agent generally reserved for women who go into labor extremely early. The drug is as effective as ritodrine, but carries a higher risk of neonatal complications. Indomethacin suppresses labor by inhibiting synthesis of prostaglandins, local hormones that promote uterine contraction by increasing release of calcium from the SR. Adverse neonatal outcomes include prolonged renal insufficiency, bronchopulmonary dysplasia, necrotizing enterocolitis, and periventricular leukomalacia (white matter injury caused by reduced blood flow in the brain). In addition, indomethacin can cause *in utero* closure of the ductus arteriosus. Adverse maternal effects include nausea, gastric irritation, interstitial nephritis, and, rarely, increased postpartum bleeding. Tocolytic treatment is initiated with a loading dose (50 or 100 mg, usually rectal) followed by maintenance doses (25 to 50 mg PO) given every 4 to 8 hours for 2 to 3 days.

762

763

TABLE 63-1 Adverse Effects of Tocolytic Drugs

Major Adverse Effects		
Drug	Maternal	Fetal/Neonatal
Terbutaline, a beta ₂ -agonist	Pulmonary edema, tachycardia, palpitations, chest pain, myocardial ischemia, hypotension, tremors, hypokalemia, hyperglycemia	Fetal tachycardia, hypotension, ileus, hyperinsulinemia with hypoglycemia, hyperbilirubinemia, hypocalcemia
Nifedipine, a calcium channel blocker	Tachycardia, hypotension, hepatotoxicity	Hypotension
Indomethacin, a cyclooxygenase inhibitor	Nausea, gastric irritation, interstitial nephritis, prolonged postpartum bleeding (rarely)	Prolonged renal insufficiency, bronchopulmonary dysplasia, necrotizing enterocolitis, periventricular leukomalacia, <i>in utero</i> closure of ductus arteriosus
Nitroglycerin, a nitric oxide donor	Hypotension, headache, dizziness, flushing	Hypotension
Atosiban, an oxytocin receptor antagonist	Allergic reactions, injection-site reactions, headache, nausea	Increased rate of fetal or infant death when used before 28 weeks' gestation

64.1.2.4 Nitroglycerin, a Nitric Oxide Donor

Nitroglycerin, administered by transdermal patch, appears similar in efficacy to ritodrine. Benefits derive from release of nitric oxide, which then stimulates production of cyclic GMP (cGMP), a mediator that leads to enhanced activity of myosin light-chain phosphatase. As a result, availability of phosphorylated myosin declines. Major side effects are hypotension and headache in the mother, and hypotension in the infant. Dosing consists of one 10-mg patch applied every 12 hours for up to 48 hours. The basic pharmacology of nitroglycerin is discussed in [Chapter 50](#).

64.1.2.5 Atosiban, an Oxytocin Receptor Antagonist

Atosiban suppresses uterine contractions by blocking oxytocin receptors on the myometrium, resulting in reduced release of calcium from the SR. The drug is licensed in Europe but not the United States. Some experts say the drug works as well as the beta agonists; others disagree. Principal maternal side effects are hypersensitivity reactions and short-lasting headache and nausea. Significant fetal side effects have not been noted. However, when used very early in gestation—before 28 weeks—atosiban appears to increase fetal and neonatal mortality.

64.1.2.6 Magnesium Sulfate

Opinion on the role of magnesium sulfate in preterm labor is changing. Although the drug has been popular in the United States (but not in Europe), there seems to be nothing to recommend its use. Why? First and foremost, the drug doesn't work: magnesium sulfate does not prevent or even delay preterm birth. Second, treatment has been associated with *increased* infant mortality. Hence, although previous editions of this book described magnesium sulfate as “the treatment of choice for suppressing preterm labor,” current data indicate that it shouldn't be used at all.

How does magnesium sulfate suppress contractions? It inhibits release of acetylcholine at neuromuscular junctions (NMJs), both in the uterus and in skeletal muscle. At high doses, the drug can cause profound muscle weakness and respiratory arrest.

Magnesium sulfate can cause a variety of maternal adverse effects. Initial reactions include transient hypotension, flushing, headache, dizziness, lethargy, dry mouth, and a feeling of warmth. High doses may cause hypothermia and paralytic ileus. Pulmonary edema, which can be fatal, is seen in 2% of patients. This complication is managed by discontinuing magnesium and giving a diuretic to accelerate magnesium excretion. Magnesium sulfate is contraindicated in patients with myasthenia gravis (because the disease causes muscle weakness), renal failure

(because magnesium is eliminated entirely by the kidneys), and hypocalcemia (because hypocalcemia intensifies magnesium-induced suppression of neurotransmitter release).

Magnesium readily crosses the placenta and is associated with increased infant mortality. The drug may also cause hypotonia (muscle weakness) and sleepiness in the newborn. Because elimination of magnesium by neonatal kidneys is slow, hypotonia may persist 3 to 4 days. During this time, mechanical assistance of ventilation may be required.

The risk of adverse effects can be reduced by monitoring (1) magnesium levels; (2) renal function (because renal impairment will cause magnesium levels to rise); (3) fluid balance (because fluid retention increases the risk of pulmonary edema); and (4) deep tendon reflexes (because loss of deep tendon reflexes is an early sign that magnesium levels are rising dangerously high).

Dosing consists of an initial IV bolus (4 to 6 gm), followed by IV infusion of 2 to 3 gm/hr for 48 to 72 hours. A controlled infusion pump is needed to minimize toxicity.

In addition to its use in preterm labor, magnesium sulfate is the preferred drug for prevention and treatment of seizures associated with eclampsia and severe preeclampsia (see [Chapter 46](#)).

64.2 UTERINE STIMULANTS (OXYTOCICS)

There are three groups of uterine stimulants: (1) *oxytocin* (in a group by itself), (2) *ergot alkaloids*, and (3) *prostaglandins*. The principal use for oxytocin is induction of labor, and the principal use for the ergot alkaloids is control of postpartum bleeding. The prostaglandins have three obstetric applications: induction of abortion, control of postpartum bleeding, and promotion of cervical ripening. Two of these uses—induction of abortion (discussed in [Chapter 61](#)) and control of postpartum bleeding—are based on the ability of prostaglandins to stimulate uterine contractions; promotion of cervical ripening is unrelated to uterine stimulation. Clinical applications of the oxytocic drugs are summarized in [Table 63-2](#).

64.2.1 Oxytocin

Oxytocin [Pitocin] is a peptide hormone produced by the posterior pituitary. This hormone promotes uterine contraction during parturition and stimulates the milk-ejection reflex. The primary therapeutic use of oxytocin is induction of labor near term, a procedure for which oxytocin is the agent of choice.

64.2.1.1 Physiologic and Pharmacologic Effects

64.2.1.1.1 Uterine Stimulation.

Oxytocin can increase the force, frequency, and duration of uterine contractions. The ability of the uterus to respond to oxytocin depends on the stage of gestation: Early in pregnancy, uterine sensitivity to oxytocin is low; as pregnancy proceeds, the uterus becomes progressively more responsive; and just prior to term, a large and abrupt increase in responsiveness develops. Sensitivity increases over time because the number of oxytocin receptors on uterine smooth muscle increases throughout pregnancy. Although uterine sensitivity to oxytocin is low early in pregnancy, oxytocin can still initiate and enhance contractions at this stage. However, the doses required are much larger than those needed at term.

763

764

TABLE 63-2 Clinical Uses of Uterine Stimulants

Drug Class and Generic Name	Trade Name	Clinical Use		
		Induction of Labor	Control of Postpartum Hemorrhage	Induction of Abortion
Oxytocin	Pitocin	✓	✓	
Ergot alkaloids				
Ergonovine	Ergotrate		✓	
Methylergonovine	Methergine		✓	
Prostaglandins				
Carboprost	Hemabate		✓	✓
Dinoprostone*	Prostin E ₂			✓
Misoprostol*	Cytotec			✓

* Dinoprostone and misoprostol are also used to promote cervical ripening, an application unrelated to uterine stimulation. When used for cervical ripening, dinoprostone is marketed as Cervidil or Prepidil.

Despite the profound effects of oxytocin on uterine contractility, the precise role of oxytocin in spontaneous labor and delivery has not been established. We do know that giving exogenous oxytocin can elicit contractions identical to those seen during spontaneous labor. However, we also know that parturition can take place with virtually no oxytocin present—although labor will be prolonged. Furthermore, during normal labor or during labor induced

artificially (through rupture of the membranes), only modest increases in plasma oxytocin occur. From these observations we can conclude that, although oxytocin is not absolutely required for parturition, the hormone probably acts to facilitate contractions. However, it is not certain that oxytocin is responsible for *initiating* labor.

64.2.1.1.2 Milk Ejection.

Milk is produced by glandular tissue of the breast and is later transferred, via small channels, into large sinuses where it is readily accessible to the suckling infant. Transfer to the sinuses is brought about by the milk-ejection reflex: When the infant sucks on the breast, neuronal stimuli are sent to the posterior pituitary, causing release of oxytocin; oxytocin then causes contraction of the smooth muscle surrounding the small milk channels, thereby forcing milk into the large sinuses. In the absence of oxytocin, milk ejection does not occur.

64.2.1.1.3 Water Retention.

Oxytocin is similar in structure to antidiuretic hormone (ADH), which acts on the kidney to decrease excretion of water. Although less potent than ADH, oxytocin can nonetheless promote renal retention of water.

64.2.1.2 Pharmacokinetics

Oxytocin is administered IV or IM. The plasma half-life is short, ranging from 12 to 17 minutes. Elimination is by hepatic metabolism and renal excretion.

64.2.1.3 Use for Induction of Labor

64.2.1.3.1 Rationale.

Induction of labor is reserved for (1) pregnancy that has continued beyond term (ie, beyond 42 weeks) and (2) pregnancy in which early vaginal delivery is likely to decrease morbidity and mortality for the mother or infant. Post-term pregnancy is the most common reason for induction. Reasons for *early* induction include premature rupture of the membranes, severe maternal infection, diabetes mellitus, placental insufficiency, renal insufficiency, anemia, and preeclampsia at or near term. Labor should be induced only when continued pregnancy constitutes a greater risk to the mother and fetus than does the risk of induction itself. Induction for elective purposes (eg, convenience of the obstetrician) is controversial.

64.2.1.3.2 Preinduction Preparation.

Induction should not be done if the fetal lungs have not matured, or if the cervix is not ripe. Accordingly, prior to induction, if the fetal lungs are still immature, maturation should be hastened with a glucocorticoid (see [Chapter 106](#)). Likewise, if the cervix is not yet ripe, ripening should be induced with dinoprostone or misoprostol (see below). Alternatively, cervical ripening can be induced mechanically (with a cervical dilator) or by membrane stripping (ie, by separating the chorioamnionic membranes from the internal surface of the uterus).

64.2.1.3.3 Precautions and Contraindications.

Improper use of oxytocin can be hazardous. Uterine rupture may occur, posing a risk of death for the mother, the infant, or both. The likelihood of trauma is especially high in cases of cephalopelvic disproportion, fetal malpresentation, placental abnormalities, umbilical prolapse, previous uterine surgery, and fetal distress. Oxytocin is contraindicated in pregnancies with any of these characteristics. In addition, oxytocin is contraindicated in women with active genital herpes. Induction of labor in women of high parity (five or more pregnancies) carries a high risk of uterine rupture, and hence oxytocin must be used with great caution in these patients.

64.2.1.3.4 Adverse Effect: Water Intoxication.

When administered in large doses, oxytocin exerts an antidiuretic effect. If large volumes of fluid have been administered along with oxytocin, retention of water may produce intoxication. However, at the doses employed to induce labor, water intoxication is rare.

64.2.1.3.5 Dosage and Administration.

For induction of labor, oxytocin is administered by intravenous infusion. The flow rate must be carefully controlled with an infusion pump. Solutions should be dilute (eg, 10 milliunits/mL) and infused at an initial rate of no more than 1 to 2 milliunits/min. The infusion rate is then gradually increased (by increments of 1 to 2 milliunits/min every 30 to 60 minutes) until uterine contractions resembling those of spontaneous labor have been produced (ie, contractions every 2 to 3 minutes and lasting 45 to 60 seconds). The infusion rate should rarely exceed 10 milliunits/min.

During oxytocin infusion, constant monitoring is required. The mother should be monitored for blood pressure, pulse rate, and uterine contractility (frequency, duration, and intensity).

The fetus should be monitored for heart rate and rhythm. In the event of significant maternal

or fetal distress, the infusion should be stopped; contractions will diminish rapidly. Complications that usually require interruption of the infusion are (1) elevation of resting uterine pressure above 15 to 20 mm Hg, (2) contractions that persist for more than 1 minute, (3) contractions that occur more often than every 2 to 3 minutes, and (4) pronounced alteration in fetal heart rate or rhythm.

64.2.1.4 Additional Therapeutic Uses

64.2.1.4.1 Augmentation of Labor.

Oxytocin may be employed if labor is dysfunctional. However, patients must be judiciously selected, and dosage must be regulated with special care. As a rule, oxytocic agents should not be used to promote labor that is already in progress, even if labor is proceeding slowly: By intensifying the force of contractions, oxytocin may cause uterine damage (laceration or rupture) or trauma to the infant.

64.2.1.4.2 Postpartum Use.

Oxytocin can be administered IM or IV following placental delivery to control bleeding or hemorrhage and to increase uterine tone.

64.2.1.4.3 Abortion.

Oxytocin has been employed during the second trimester to manage incomplete abortion. Intravenous infusion of 10 units at a rate of 10 to 20 milliunits/min is often effective in emptying the uterus. However, oxytocin is not a method of choice.

64.2.2 Ergot Alkaloids: Ergonovine and Methylergonovine

Ergot is a dried preparation of *Claviceps purpurea*, a fungus that grows on rye plants. The ergot alkaloids are compounds present in ergot. Ergot is capable of inducing powerful uterine contractions, a fact known to midwives for centuries. Analysis of ergot has revealed the presence of several pharmacologically active constituents. Of these, *ergonovine* is the most effective uterine stimulant. A derivative of ergonovine—*methylergonovine*—has been synthesized and produces effects much like those of ergonovine. Because the actions of ergonovine and methylergonovine are very similar, we will consider these agents jointly.

In obstetrics, the ergot alkaloids are used to control postpartum bleeding. However, because they carry a high risk of severe hypertension, they are generally reserved for women who have not responded to safer agents: oxytocin and carboprost tromethamine.

64.2.2.1 Pharmacologic Effects

Ergot alkaloids produce their effects by stimulating a variety of receptors (adrenergic, dopaminergic, serotonergic). These drugs exert their most profound effects on uterine and vascular smooth muscle.

64.2.2.1.1 Effects on the Uterus.

Ergot alkaloids stimulate uterine contraction. In small doses, they produce contractions of moderate strength that alternate with uterine relaxation of normal degree and duration. With large doses, the force and frequency of contractions are greatly increased, and the extent of uterine relaxation is reduced; sustained contraction is not uncommon. Because contractions may be prolonged, *ergot alkaloids are not employed to induce labor*.

64.2.2.1.2 Vascular Effects.

Ergot alkaloids can cause constriction of arterioles and veins. This ability underlies the use of two agents—ergotamine and dihydroergotamine—to treat migraine headache (see [Chapter 30](#)). Vasoconstriction may also contribute to control of postpartum bleeding.

64.2.2.2 Pharmacokinetics

Regardless of the route employed, ergonovine and methylergonovine act rapidly. Uterine contractions begin within 60 seconds of IV injection, and within 10 minutes of oral or IM administration. Effects persist for several hours.

64.2.2.3 Therapeutic Uses

64.2.2.3.1 Postpartum Use.

The ergot alkaloids may be used postpartum and postabortion to increase uterine tone and decrease bleeding. The ability to induce sustained uterine contraction makes them very effective for these purposes. Administration is usually delayed until after delivery of the placenta. The patient should be monitored for blood pressure, pulse rate, and uterine contractility. Cramping occurs as part of the therapeutic response, but may also indicate overdose. Owing to a high risk of severe hypertension, many physicians reserve the ergot alkaloids for patients who have not responded to safer alternatives (ie, oxytocin or carboprost tromethamine).

64.2.2.3.2 Augmentation of Labor.

Because contractions may be both intense and prolonged, ergot alkaloids are not recommended for use during labor. If they are given during labor, excessive uterine tone can cause trauma to the mother, fetus, or both. Placental blood flow may be reduced, resulting in fetal hypoxia and uterine rupture. In addition, cervical laceration may occur.

64.2.2.3.3 Migraine.

Ergot alkaloids relieve migraine in part by constricting dilated cerebral blood vessels. Two preparations are employed: ergotamine and dihydroergotamine. The pharmacology of these drugs and their use in migraine are discussed in [Chapter 30](#) (Drugs for Headache).

64.2.2.4 Adverse Effects

When ergot alkaloids are given orally or IM, significant adverse effects are rare. In contrast, IV administration frequently causes *hypertension*. Hypertension can be severe and may be associated with nausea, vomiting, and headache; convulsions and even death have occurred. Accordingly, IV administration should be reserved for emergencies. Furthermore, patients with pre-existing hypertension should not be given these drugs. Caution should be exercised in patients with cardiovascular, renal, or hepatic disorders.

64.2.2.5 Contraindications

Ergot alkaloids are contraindicated for women who are pregnant, hypertensive, or hypersensitive to these drugs. They are also contraindicated for induction of labor and for use in the presence of threatened or ongoing spontaneous abortion.

64.2.2.6 Preparations, Dosage, and Administration

64.2.2.6.1 Preparations.

Ergonovine maleate [Ergotrate] is available in 0.2-mg tablets. *Methylergonovine maleate* [Methergine] is available in 0.2-mg tablets and in solution (0.2 mg/mL) for IV and IM administration.

64.2.2.6.2 Dosage and Administration.

Parenteral. For parenteral therapy, methylergonovine is usually administered IM; intravenous administration is hazardous and should be reserved for emergency control of postpartum hemorrhage. Treatment is usually initiated only after passage of the placenta. Dosages are as

follows: <i>intramuscular</i> (for control of postpartum bleeding), 0.2 mg initially, repeated every 2	765
hours as needed; <i>intravenous</i> (for control of uterine hemorrhage), 0.2 mg infused over 60	766
seconds or more.	

64.2.2.6.3 Oral.

The dosage for *methylergonovine* (to promote involution of the uterus) is 0.2 mg every 6 to 8 hours for up to 1 week. The dosage for *ergonovine* (for prevention of postpartum or postabortion hemorrhage) is 0.2 to 0.4 mg every 6 to 12 hours until the danger of uterine atony has passed (usually 48 hours).

64.2.3 Carboprost Tromethamine

64.2.3.1 Therapeutic Use

Carboprost tromethamine [Hemabate], also known as 15-methyl prostaglandin F₂ alpha, is a preferred agent for controlling postpartum hemorrhage. The drug suppresses bleeding primarily by causing intense uterine contractions, and partly by causing vasoconstriction. In most cases, bleeding can be stopped with a single 250-mg IM dose. If needed, the same dose can be repeated every 15 to 90 minutes, but the cumulative dosage should not exceed 2 mg. In addition to its postpartum use, carboprost is used to induce abortion (see [Chapter 61](#)).

64.2.3.2 Adverse Effects

As with other prostaglandins, GI reactions are very common. The underlying cause is stimulation of smooth muscle of the gut. Vomiting and diarrhea occur in up to 60% of patients. Nausea is also common. Gastrointestinal reactions can be reduced by pretreatment with antiemetic and antidiarrheal medications.

Fever is common. If body temperature rises, it is important to differentiate between drug-induced fever and pyrexia resulting from endometritis.

Like other prostaglandins, carboprost causes vasoconstriction as well as constriction of the bronchi. As a result, treatment carries a risk of hypertension and impaired respiration.

64.2.3.3 Precautions and Contraindications

Carboprost is contraindicated for women with acute pelvic inflammatory disease and active disease of the heart, lungs, kidneys, or liver. The drug should be used with caution in women with a history of asthma, hypertension, diabetes, or uterine scarring.

64.3 DRUGS USED TO PROMOTE CERVICAL RIPENING

The term *cervical ripening* refers to changes the cervix undergoes prior to normal delivery. During pregnancy, the cervix is elongated, rigid, and constricted. When ripening occurs, the cervix shortens, softens, and dilates, thereby permitting the fetus to pass through the birth canal. If induced delivery using oxytocin is attempted in the absence of ripening, maternal and fetal injury can result.

Accordingly, if oxytocin is to be used before natural ripening has occurred, a ripening agent should be used first. Two drugs are employed: dinoprostone and misoprostol. Both are prostaglandins. Of the two, only dinoprostone is FDA approved for cervical ripening. However, misoprostol is also effective, and much less expensive.

64.3.1 Dinoprostone

Dinoprostone [Prepidil, Cervidil] is the most widely used agent for promoting cervical ripening prior to induction of labor with oxytocin. The drug is a synthetic prostaglandin identical in structure to endogenous prostaglandin E₂ (PGE₂), a compound produced by fetal membranes and the placenta. Endogenous PGE₂ has two roles in the birthing process: It promotes cervical ripening, and later it stimulates uterine contractions. Cervical ripening results from activation of collagenase, an enzyme that breaks down the collagen network that makes the cervix rigid. When used to promote ripening, dinoprostone shortens the duration of labor, allows a reduction in oxytocin dosage, and decreases the need for cesarean delivery. Because it can stimulate uterine contractions, dinoprostone is also used to induce abortion (see [Chapter 61](#)). For promotion of cervical ripening, dinoprostone is available in two formulations: a gel and a vaginal insert.

64.3.1.1 Dinoprostone Gel

Dinoprostone gel [Prepidil] is available in single-dose, pre-filled syringes that contain 0.5 mg dinoprostone/2.5 mL gel. Administration is intracervical, using the syringe and endocervical catheter (10- or 20-mm tip) supplied by the manufacturer. To prevent leakage, the patient should lie supine during administration and for at least 30 minutes after. If the desired response has not occurred within 6 hours, a second 0.5-mg dose can be given, followed 6 hours later by a third, if needed. (Most women need at least two doses, and 50% need a third.) Because dinoprostone can stimulate uterine contractions, and may thereby cause fetal distress, uterine activity and fetal heart rate should be monitored continuously. Monitoring should start before each dose and continue at least 2 hours after. Oxytocin is given 6 to 12 hours after the last dose of dinoprostone. The major adverse effect of dinoprostone is hyperstimulation of the uterus, which occurs in 1% of patients using the gel. Rarely, systemic absorption results in nausea, vomiting, diarrhea, and fever. Dinoprostone gel is unstable and must be stored refrigerated, between 2° C

and 8° C (36° F and 46° F). Treatment is moderately expensive: Each 0.5-mg dose costs about \$150, making the total cost \$450 for women who require three doses.

64.3.1.2 Dinoprostone Vaginal Inserts

Dinoprostone vaginal inserts [Cervidil] consist of a pouch (containing 10 mg of the drug) to which a long tape is attached. The purpose of the tape is to permit rapid removal of the pouch. Following insertion in the posterior fornix of the vagina, the pouch releases dinoprostone slowly (0.3 mg/hr) for 12 hours. The patient should remain supine for at least 2 hours after pouch insertion. The pouch is removed when active labor occurs or when 12 hours have elapsed, whichever comes first. If oxytocin is needed, administration can begin 30 minutes after removing the pouch. As with dinoprostone gel, the major adverse effect is uterine hyperstimulation, which develops in 5% of patients (compared with only 1% of those receiving the gel). To minimize harm, uterine activity and fetal heart rate should undergo continuous monitoring while the insert is in place and for at least 15 minutes after its removal. Compared with dinoprostone gel, the insert has two advantages. First, treatment is almost always cheaper. Second, because inserts can be easily removed, drug delivery can be stopped as soon as (1) labor starts (thereby avoiding unnecessary drug exposure) or (2) uterine hyperstimulation develops (thereby minimizing uterine contractions and related fetal distress). The vaginal inserts are unstable and must be stored frozen, between –10° C and –20° C (14° F and –4° F). The cost of one insert is about \$175, compared with \$150 for one dose of the gel. Nonetheless, treatment with the inserts is generally less expensive. Why? Because most women require two or three doses of the gel (total cost: \$300 to \$450), but only one insert (total cost: \$175).

766

767

64.3.2 Misoprostol

Misoprostol [Cytotec] is an attractive alternative to dinoprostone for promoting cervical ripening, although misoprostol is not approved for this use. Compared with dinoprostone, misoprostol is more effective, more convenient (stores at room temperature versus refrigerated), and *much* less expensive (treatment costs about \$1 versus \$175 to \$450). Unfortunately, misoprostol also causes a higher incidence of uterine hyperstimulation. To induce cervical ripening, a 25-mg dose (one-fourth of a 100-mg tablet) is inserted into the posterior fornix of the vagina. Dosing is repeated every 4 hours as needed. In women given misoprostol, delivery occurs faster than in those given dinoprostone, and there is less need for oxytocin. To minimize risk from uterine hyperstimulation, fetal heart rate and uterine activity should be monitored continuously. In addition to its use for cervical ripening, misoprostol is used to induce abortion (see [Chapter 61](#)) and, primarily, to protect against peptic ulcers (see [Chapter 77](#)).

64.3.2.1

KEY POINTS

- Tocolytic drugs suppress contraction of uterine smooth muscle.
- Tocolytic drugs have only one indication: delay of preterm labor.
- On average, tocolytic drugs delay labor for 48 hours.
- All tocolytics work to decrease the availability of phosphorylated light-chain myosin, the form of myosin needed for contractile interaction with actin.
- The major tocolytic drugs—beta-adrenergic agonists, calcium channel blockers, and COX inhibitors—appear equally good at suppressing preterm labor, and hence selection among them is based largely on side effects.
- Oxytocic agents stimulate contraction of uterine smooth muscle.
- Oxytocics have three major applications: induction or augmentation of labor, control of postpartum bleeding, and induction of abortion.
- The principal indication for oxytocin is induction of labor, which is appropriate when (1) pregnancy has continued beyond term or (2) early vaginal delivery is likely to decrease morbidity or mortality for the mother or infant.
- Used improperly (eg, in pregnancies with cephalopelvic disproportion), oxytocin can cause uterine rupture.
- Two oxytocic drugs—oxytocin and carboprost tromethamine—are preferred agents for controlling postpartum hemorrhage.
- Because they pose a risk of severe hypertension, ergonovine and methylergonovine are generally considered second-line drugs for controlling postpartum hemorrhage.
- Dinoprostone is a prostaglandin used to promote cervical ripening prior to inducing labor with oxytocin.

64.3.2.2

Summary of Major Nursing Implications

64.3.2.2.1

OXYTOCIN

The implications summarized here apply only to the use of oxytocin for induction of labor, the drug's principal use.

Preadministration Assessment

Therapeutic Goal

Oxytocin is given to initiate or improve uterine contractions. Treatment is reserved for pregnancies that have gone beyond term and for pregnancies in which early vaginal delivery is likely to decrease morbidity and mortality for the mother or infant.

Baseline Data

The history should determine parity, previous obstetric problems, stillbirths, and abortions. Full maternal and fetal status should be assessed, including the degree of cervical ripening and fetal lung maturity.

Identifying High-Risk Patients

Induction of labor is *contraindicated* in the presence of cephalopelvic disproportion, fetal malpresentation, placental abnormality, umbilical prolapse, previous major surgery to the uterus or cervix, fetal distress, and active genital herpes.

Use with *caution* in women of high parity (five or more pregnancies).

Induction should not be conducted in the absence of cervical ripening or fetal lung maturation. If indicated, promote cervical ripening mechanically or with drugs, and promote fetal lung maturation with glucocorticoids.

Implementation: Administration

Route

Intravenous.

Administration

Administer by carefully controlled infusion, using an infusion pump.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Uterine contractions of excessive intensity, frequency, and duration can cause maternal and fetal harm. Monitor uterine contractility (frequency, duration, and intensity),

	maternal blood pressure, and fetal and maternal heart rate. Interrupt the infusion if any of the following occur: (1) resting intrauterine pressure rises above 15 to 20 mm Hg, (2) individual contractions persist longer than 1 minute, (3) contractions occur more often than every 2 to 3 minutes, and (4) fetal heart rate or rhythm changes significantly.	767 768

64.3.2.2...	Administration	
	As a rule, administer after passage of the placenta. Perform IV injections slowly (over 60 seconds or more).	
64.3.2.2...	Ongoing Evaluation and Interventions	
64.3.2.2...	Evaluating Therapeutic Effects	
	Monitor blood pressure, pulse rate, and uterine activity. Report sudden increases in blood pressure, excessive uterine bleeding, and insufficient uterine tone. Cramping is normal but may also indicate overdose.	

64.3.2.2...

Minimizing Adverse Effects

Significant adverse effects—*hypertension, nausea, vomiting, headache, convulsions, and death*—usually occur only with IV administration. To minimize risk, infuse slowly (over 60 seconds or more) and reserve IV administration for emergencies.

64.3.2.2.3

DINOPROSTONE

64.3.2.2...

Preadministration Assessment

64.3.2.2...

Therapeutic Goal

Dinoprostone is used to promote cervical ripening.

64.3.2.2...

Identifying High-Risk Patients

Dinoprostone is *contraindicated* for women with acute pelvic inflammatory disease and active disease of the heart, lungs, kidneys, or liver.

Use with *caution* in women with a history of asthma, hypotension, hypertension, diabetes, or uterine scarring.

64.3.2.2...

Implementation: Administration

64.3.2.2...

Route

Vaginal insert and vaginal gel, both for intracervical instillation.

64.3.2.2...

Ongoing Evaluation and Interventions

64.3.2.2...

Evaluating Therapeutic Effects

Assess the cervix for elongation, softening, and dilation.

64.3.2.2...

Minimizing Adverse Effects

64.3.2.2...

GI Disturbances.

Nausea, vomiting, and diarrhea can be reduced by pretreatment with antiemetic and antidiarrheal drugs.

64.3.2.2...

Fever.

Fever may be induced by dinoprostone or it may indicate endometritis. If fever develops, a differential diagnosis is needed.

65 CHAPTER 64 Androgens

Androgen hormones are produced by the testes, ovaries, and adrenal cortex. The major endogenous androgen is testosterone. Androgens are noted most for their ability to promote expression of male sex characteristics. However, androgens also influence sexuality in females. In addition, androgens have significant physiologic and pharmacologic effects unrelated to sex. The primary clinical application of the androgens is management of androgen deficiency in males. Principal adverse effects are virilization and hepatotoxicity.

65.1 TESTOSTERONE

Testosterone is the prototype of the androgen hormones. This compound is the principal endogenous androgen in both males and females. In addition to its physiologic role, testosterone is representative of the androgens employed clinically. The structural formula of testosterone is shown in [Figure 64-1](#).

65.1.1 Biosynthesis and Secretion

65.1.1.1 Males.

Testosterone is made by Leydig cells of the testes. Daily production in men ranges from 2.5 to 10 mg. Synthesis is promoted by two hormones of the anterior pituitary: follicle-stimulating hormone (FSH) and luteinizing hormone (LH), also known as interstitial cell-stimulating hormone. Production of testosterone is regulated by negative feedback control: Rising plasma levels of testosterone act on the pituitary to suppress further release of FSH and LH, thereby decreasing the stimulus for further testosterone formation.

Some of the testosterone present in plasma is produced by the adrenals. However, androgenic activity of adrenal origin is much less than that of testicular origin. Hence, in males, adrenal androgens have minimal functional significance.

Figure 64-1 Structural formulas of representative androgens.

Testosterone production changes over time. Peak production occurs around age 17. Production then remains steady until age 30 or 40, after which it slowly declines. By the time a man reaches 80, testosterone production is only half what it was in his youth.

65.1.1.2 Females.

In women, preandrogens (precursors of testosterone) are secreted by the adrenal cortex and ovaries. Conversion into testosterone takes place in peripheral tissues. Synthesis of preandrogens by the adrenals is regulated by adrenocorticotrophic hormone (ACTH), whereas synthesis of preandrogens by the ovaries is regulated by LH. Daily testosterone production is about 300 mcg (150 mcg from the ovaries and 150 mcg from the adrenals). The total is 10 to 40 times less than the amount produced in men. In the event of ovarian or adrenocortical pathology (eg, adenoma, carcinoma, hyperplasia), secretion of androgens can increase greatly, and may be sufficient to produce virilization. At menopause, testosterone production decreases.

65.1.2 Mechanism of Action

Effects of testosterone on its target tissues are mediated by specific receptors located in the cell cytoplasm. Following binding of testosterone to its receptor, the hormone-receptor complex migrates to the cell nucleus, and then acts on DNA to promote synthesis of specific messenger RNA molecules. These, in turn, serve as templates for production of specific proteins, which then mediate testosterone effects. It should be noted that in some tissues—prostate, seminal vesicles, and hair follicles—androgen receptors do not interact with testosterone itself. Rather, they interact with dihydrotestosterone, a metabolite of testosterone.

65.1.3 Physiologic and Pharmacologic Effects

65.1.3.1 Effects on Sex Characteristics in Males

65.1.3.1.1 Pubertal Transformation.

Increased production of testosterone promotes the transformations that signal puberty in males. Under the influence of testosterone, the testes enlarge, after which the penis and scrotum enlarge. Pubic and axillary hair appear, and hair on the trunk, arms, and legs assumes adult male patterns. Testosterone stimulates growth of bone and skeletal muscle, causing height and weight to increase rapidly. Testosterone also accelerates epiphyseal closure, causing bone growth to cease within a few years. The larynx enlarges, thereby deepening the voice. Sebaceous glands increase in number, causing the skin to become oily; acne results if

the glands become clogged and infected. The final pubertal change is beard development. Several years are required for all of these changes to occur.

65.1.3.1.2 Spermatogenesis.

Androgens are necessary for production of sperm by the seminiferous tubules, and for maturation of sperm as they pass through the epididymis and vas deferens. Androgen deficiency causes sterility.

65.1.3.2 Effects on Sex Characteristics in Females

Under physiologic conditions, endogenous androgens have only moderate effects in females. Principal among these are promotion of clitoral growth and, perhaps, maintenance of normal libido. However, when production of androgens becomes excessive (eg, in girls with congenital adrenal hyperplasia), virilization can take place. Virilization can also occur in response to therapeutic use of androgens or to androgen abuse.

65.1.3.3 Anabolic Effects

Testosterone promotes growth of skeletal muscle. This anabolic effect results from binding of androgens to the same type of receptor that mediates androgen actions in other tissues. Effects in young males, and in females of any age, can be dramatic. In contrast, effects in healthy adult males are modest. Why? Because the testes of adult males already produce enough testosterone to cause near-maximal stimulation of the musculature. Hence, in adult males, the increment in muscle mass that can be achieved with exogenous androgens is relatively small.

65.1.3.4 Erythropoietic Effects

Testosterone promotes synthesis of erythropoietin, a hormone that acts on bone marrow to increase production of erythrocytes. This action of testosterone, together with the high levels of testosterone present in males, explains why men have a greater hematocrit than women. When women are given testosterone, the hematocrit rises and hemoglobin levels increase by an average of 4.3 gm/dL. In contrast, since men have high testosterone levels to begin with, the increase in plasma hemoglobin that can be elicited with exogenous androgens is smaller—only 1 gm/dL.

65.2 CLINICAL PHARMACOLOGY OF THE ANDROGENS

In addition to testosterone, several other androgens are employed clinically. All of these agents can bind to androgen receptors, and therefore all can elicit similar responses. Major differences among

individual androgens pertain to route of administration, pharmacokinetics, adverse effects, and specific applications.

65.2.1 Classification

The androgens used clinically fall into two basic groups: (1) testosterone and testosterone esters, and (2) 17-alphaalkylated compounds (noted for their hepatotoxicity). Androgens belonging to each group are listed in [Table 64-1](#).

When speaking of testosterone-like compounds, it is traditional to distinguish between “androgens” and “anabolic steroids.” However, we will not make this distinction. Why? Because it is now clear that the receptor type that mediates the androgenic actions of the androgens is the same receptor type that mediates the anabolic actions of these hormones. Consequently, it has not been possible to separate anabolic activity from androgenic activity: Virtually all anabolic hormones are also androgenic. Accordingly, rather than creating two categories—androgens versus anabolic steroids—and assigning some agents to one category and some to the other, we will simply refer to all of the testosterone-like drugs as androgens.

65.2.2 Therapeutic Uses

Individual androgens differ in their applications. No single androgen is employed for all of the uses discussed below. Specific applications of individual androgens are summarized in [Table 64-1](#).

770

TABLE 64-1 Approved Uses of Individual Androgens

Androgen	Indications				
	Hypogonadism (Male)	Replacement Therapy (Male)	Delayed Puberty (Male)	Breast Cancer (Female)	Catabolic States
Testosterone and Testosterone Esters					
Testosterone	✓	✓	✓		
Testosterone cypionate	✓	✓			
Testosterone enanthate	✓	✓	✓	✓	
17-Alpha-Alkylated Androgens					
Fluoxymesterone	✓	✓	✓	✓	
Methyltestosterone	✓	✓	✓	✓	
Oxandrolone					✓

TABLE 64-2 Products for Androgen Replacement Therapy in Hypogonadal Males

Formulation	Drug	Trade Name	Dosage	Comments
Oral	Fluoxymesterone	Generic only	5–20 mg/day	These 17-alpha-alkylated androgens are hepa-totoxic and androgenic effects are erratic. Oral therapy is not generally recommended.
	Methyltestosterone	Android, Methitest, Testred, Virilon	10–50 mg/day	
Intramuscular	Testosterone cypionate	Depo-Testosterone	50–400 mg every 2–4 wk	Safe, but require an office visit every 2–4 wk. Blood levels fluctuate widely (high after dosing and low before the next dose) and thereby cause variations in libido, energy, and mood.
	Testosterone enanthate	Delatestryl	50–400 mg every 2–4 wk	
Transdermal Patch	Testosterone	Androderm	One 12- or 24-mg patch/day (delivers 2.5 or 5 mg/24 hr)	Applied to the arm, back, abdomen, or thigh, but <i>not</i> the scrotum. Causes local irritation.
Transdermal Gel	Testosterone	AndroGel, Testim	5–10 gm of 1% gel/day (delivers 50–100 mg/day)	Apply AndroGel to upper arm, shoulder, or abdomen, but <i>not</i> the scrotum. Apply Testim only to upper arm or shoulder. Easier to use and better tolerated than testosterone patches. Can transfer to others via intimate contact.
Implantable Pellets	Testosterone	Testopel	150–450 mg (2–6 pellets) subQ every 3–4 mo	Implanted subQ. Long lasting. Produce steady blood levels.
Buccal System	Testosterone	Striant	One buccal system (30 mg) twice daily	Provides fairly steady testosterone levels, but may cause mouth or gum irritation.

65.2.2.1 Male Hypogonadism.

Hypogonadism in males is the principal indication for androgens. In this condition, the testes fail to produce adequate amounts of testosterone, and hence replacement therapy is required.

Male hypogonadism may be hereditary or it may result from other causes, including pituitary failure, hypothalamic failure, and primary dysfunction of the testes.

When complete hypogonadism occurs in boys, puberty cannot take place, unless exogenous androgens are supplied. To induce puberty, a long-acting parenteral preparation (usually *testosterone enanthate* or *testosterone cypionate*) is chosen; injections are given IM every 2 to 4 weeks for 3 to 4 years. Under the influence of these androgens, the normal sequence of pubertal changes occurs: growth is accelerated, the penis enlarges, the voice deepens, and other secondary sex characteristics become expressed. As in normal males, these changes take place over several years.

65.2.2.2 Replacement Therapy.

Androgen replacement therapy is beneficial when testicular failure occurs in adult males. Treatment restores libido, increases ejaculate volume, and supports expression of secondary sex characteristics. However, treatment will not restore fertility. The principal drugs employed for testosterone replacement are testosterone itself and two testosterone esters: testosterone enanthate and testosterone cypionate. Preparations and dosages for replacement therapy are summarized in [Table 64-2](#) and discussed below under *Androgen Preparations for Male Hypogonadism*. Replacement therapy in older males is discussed further in [Box 64-1](#).

BOX 64-1 Special Interest Topic

TESTOSTERONE REPLACEMENT: CAN IT ENHANCE SEXUALITY IN MEN? OR WOMEN?

In Men

More and more elderly men are taking testosterone, despite limited information on efficacy and safety. Why? Because they want to alleviate aging-related symptoms—specifically, erectile dysfunction, loss of libido, hot flushes, fatigue, muscle atrophy, and depression and other mood disturbances. Unfortunately, there's no proof that testosterone replacement can help. In fact, there's not even proof that low testosterone is the cause: Although these symptoms can occur in men with low testosterone levels, they can also occur in older men with normal levels.

In an effort to document the benefits and risks of testosterone replacement, a committee of the Institute of Medicine (IOM) conducted a systematic review of the medical literature. Unfortunately, the committee was unable to reach any firm conclusions. Why? Because even the best relevant studies were of short duration (most covered less

than 12 months) and had few subjects (typically less than 50), and most were not placebo controlled. Hence, the committee couldn't say with certainty that testosterone replacement is either safe or effective. To generate more reliable information, the committee recommended performing (1) short-term, randomized, placebo-controlled trials to evaluate the potential benefits of testosterone, followed by (2) long-term trials to evaluate potential risks.

Although the existing data on testosterone replacement are generally weak, do they tell us anything useful at all? According to the IOM committee, available data suggest—but don't prove—that testosterone may enhance both libido and sexual function. There's also pretty good evidence that testosterone can reduce body fat and increase muscle mass, although it may not increase muscle strength. Testosterone may also improve mood, increase energy, and promote a sense of well-being, but does not seem to improve cognition or memory. The IOM committee also identified potential risks. Testosterone stimulates production of red blood cells, and may thereby cause polycythemia. The hormone can also increase LDL cholesterol (bad cholesterol) and reduce HDL cholesterol (good cholesterol), and may thereby promote cardiovascular disease. Perhaps the greatest concern is prostate cancer. Although testosterone doesn't *cause* cancer, it can promote growth of prostate cancer cells.

Given our limited understanding of testosterone therapy, how should replacement be conducted? As with all other treatments, we want to balance benefits and risks. However, since we don't know what the benefits and risks really are, a cautious approach would seem prudent. According to an article by Dr. Peter Snyder, published in the January 29, 2004, issue of the *New England Journal of Medicine*, the following principles should be observed:

- Elderly candidates for replacement therapy should have testosterone levels that are clearly low, defined as less than 200 ng/dL.
- To ensure that the replacement doses are sufficient, serum testosterone levels should be monitored. A reasonable target is 300 to 450 ng/dL (the mid-normal range for elderly men).
- Avoid androgens in men with diagnosed prostate cancer; for all other men, monitor for exacerbation of covert prostate cancer and other testosterone-dependent diseases.

65.2.2.2.1....

These principles represent an interim approach. Once long-term studies on safety and efficacy have been conducted, development of more detailed guidelines should be possible.

In Women

Can testosterone replacement enhance the sex lives of postmenopausal women? Yes. But the benefits are modest, and only some women respond. Furthermore, the long-term risks are unknown.

When menopause occurs—either naturally or following oophorectomy (surgical removal of the ovaries)—many women experience a decline in libido. Reduced testosterone is believed to be the cause. Prior to menopause, women produce about 300 mcg of testosterone daily—half of it is made by the adrenals and half by the ovaries. After menopause, ovarian production stops, and hence testosterone levels drop about 50%. As a result, women may experience a decline in sexual desire, genital sensitivity, and sense of well-being, even with estrogen therapy.

What's the effect of testosterone therapy? To answer this question, the manufacturer of *Intrisa* (an investigational testosterone patch for women) conducted clinical trials in women with low testosterone owing to bilateral oophorectomy. All of the women were receiving estrogen replacement and all were in monogamous sexual relationships. And they all suffered from documented hypoactive sexual desire disorder (HSDD), which began after surgically induced menopause. (HSDD is characterized by a persistent reduction in sexual desire that causes significant personal distress.) The testosterone trial was double-blinded, and the women were randomly assigned to receive either a placebo patch or Intrisa, which delivers 300 mcg of testosterone a day. The result? Women using Intrisa had more sex and were happier about it. Testosterone increased the frequency of sexually satisfying encounters (from a baseline of three encounters per month up to five per month, versus four per month with placebo). In addition, testosterone increased sexual arousal, pleasure, responsiveness, and orgasms; decreased distress regarding sexual encounters; and improved self-image. Benefits began after 4 weeks of treatment, and reached a maximum by 12 weeks. In 2005, after considering this study and many others, the North American Menopause Society (NAMS) issued a position statement on the role of testosterone therapy in women following spontaneous or surgically induced menopause. The statement notes that testosterone can have a positive effect on sexual function—primarily desire, arousal, and orgasmic response—

and that a woman with no other identifiable cause of decreased desire may be a candidate for testosterone therapy, provided that estrogen is taken as well.*

Did Intrisa cause *short-term* adverse effects? Yes—but they were generally mild. About 30% of the women had application-site reactions. Less common effects were hirsutism (7.3% with Intrisa vs. 5.9% with placebo), acne (6.7% vs. 5.1%), alopecia (4.2% vs. 2.9%), voice deepening (2.7% vs. 2.2%), migraine (2.7% vs. 1.5%), and weight gain (2% vs. 1.5%). There were no clinically significant effects on cardiovascular parameters, including serum lipid levels, coagulation, blood pressure, and hematology.

What about *long-term* safety? No one knows. Testing to date has not ruled out the possibility that testosterone therapy could increase the risk of stroke, heart disease, breast cancer, or other disorders. The absence of information on long-term safety is of special concern in light of data from the Women's Health Initiative, which revealed that long-term estrogen therapy is less beneficial than previously believed—and more dangerous.

What's the current status of Intrisa? In December 2004, members of the Reproductive Health Drugs Advisory Committee of the Food and Drug Administration (FDA) voted 14 to 0 against approving the patch at this time. They noted that the benefits of Intrisa were only modest, and expressed concern over possible long-term risks. They did, however, acknowledge that safe and effective treatments for HSDD would be welcome. Of note, Intrisa was approved in the United Kingdom in 2007.

If a woman, after consultation with her prescriber, wants to try testosterone therapy, what options are available? At this time, there are no FDA-approved products for women. And all of the products for men deliver much more testosterone than women need. (Remember the goal is to mimic premenopausal testosterone production—about 300 mcg/day.) Accordingly, formulations for women have to be custom compounded by the pharmacist. Formulations for *topical* therapy include *testosterone propionate* (1% to 2%) in *petrolatum* and *2% micronized testosterone gel*. The testosterone propionate formulation is applied to the genital mucosa. The micronized formulation is applied to the skin of the arm, thigh, or abdomen. For both formulations, the initial daily dosage is one-quarter teaspoon or less. Over time, the frequency of topical administration (genital or dermal) can be reduced to 3 or 4 times per week.

* In 2006, The Endocrine Society released another publication—*Androgen Therapy in Women: An Endocrine Society Clinical Practice Guideline*—in which they caution against *generalized* use of testosterone in women, even

though the hormone *can* be appropriate for *specific* women, namely those with HSDD resulting from spontaneous or surgically induced menopause.

772

773

65.2.2.3 Delayed Puberty.

In some boys, puberty fails to occur at the usual age (ie, prior to 15 years). Most often, this failure reflects a familial pattern of delayed puberty and does not indicate pathology. Puberty can be expected to occur spontaneously, but later than usual. Hence, although androgen therapy can be employed, treatment is not an absolute necessity. However, although therapy is not required, the psychologic pressures of delayed sexual maturation are sometimes greater than a boy (or his parents) can tolerate. In these cases, a limited course of androgen therapy is indicated. If delayed puberty is the result of true hypogonadism, long-term replacement therapy is indicated.

65.2.2.4 Breast Cancer.

Testosterone and other androgens have been used for palliation in women with advanced and metastatic breast carcinoma. The mechanism of palliation is unknown. For palliative care, high doses are required. As a result, some virilization is inevitable. In contrast to their beneficial effects in women, androgens *exacerbate* breast cancer in males, and hence are contraindicated.

65.2.2.5 Replacement Therapy in Menopausal Women.

Testosterone replacement therapy can alleviate some menopausal symptoms, especially fatigue, reduced libido, and reduced genital sensitivity. In the United States, testosterone is not approved for replacement in women, although it is approved in the United Kingdom. Testosterone replacement in women is discussed in [Box 64-1](#).

65.2.2.6 Wasting in Patients with AIDS.

Testosterone levels often decline in patients with AIDS, putting them at risk of wasting and loss of muscle mass. Testosterone therapy decreases this risk.

65.2.2.7 Anemias.

Androgens may be used in men and women to treat anemias that have been refractory to other therapy. Anemias that may respond include aplastic anemia, anemia associated with renal failure, Fanconi's anemia, and anemia caused by cancer chemotherapy. Androgens help relieve anemia by promoting synthesis of erythropoietin, the renal hormone that stimulates production of red blood cells. Androgens may also stimulate production of white blood cells and platelets.

65.2.3 Adverse Effects

65.2.3.1 Virilization.

Virilization is the most common complication of androgen therapy. When taken in high doses by women, androgens can cause acne, deepening of the voice, proliferation of facial and body hair, male-pattern baldness, increased libido, clitoral enlargement, and menstrual irregularities. Clitoral growth, hair loss, and lowering of the voice may be irreversible. Masculinization can also occur in children. Boys may experience growth of pubic hair, penile enlargement, increased frequency of erections, and even priapism (persistent erection). In girls, growth of pubic hair and clitoral enlargement may occur. To prevent irreversible masculinization, androgens must be discontinued when virilizing effects first appear. In the treatment of breast carcinoma, some virilization should be tolerated.

65.2.3.2 Premature Epiphyseal Closure.

When given to children, androgens can accelerate epiphyseal closure, thereby decreasing adult height. To evaluate androgen effects on the epiphyses, radiographic examination of the hand and wrist should be performed every 6 months.

65.2.3.3 Hepatotoxicity.

Androgens can cause *cholestatic hepatitis* and other disorders of the liver. Clinical *jaundice* may occur, but this is rare. Patients receiving androgens should undergo periodic tests of liver function. If jaundice develops, it will reverse following discontinuation of androgen use. Androgens may also be carcinogenic: *Hepatocellular carcinoma* has developed in some patients following prolonged use of these drugs.

It must be emphasized that not all androgens are hepatotoxic: Liver damage is associated primarily with the *17-alpha-alkylated androgens*. As indicated in [Figure 64-1](#) (see methyltestosterone), these androgens all share a structural feature in common: an alkyl group substituted on carbon 17 of the steroid nucleus. Because of their capacity to cause liver damage, *the 17-alpha-alkylated compounds* should not be used long term. In contrast to the 17-alpha-alkylated androgens, the testosterone esters (testosterone propionate, testosterone cypionate, testosterone enanthate) are not associated with liver disease.

773

774

65.2.3.4 Effects on Cholesterol Levels.

Androgens can lower plasma levels of high-density lipoprotein (HDL) cholesterol (“good cholesterol”) and elevate plasma levels of low-density lipoprotein (LDL) cholesterol (“bad cholesterol”). These actions may increase the risk of atherosclerosis.

65.2.3.5 Use in Pregnancy.

Because of their ability to induce masculinization of the female fetus, androgens are contraindicated during pregnancy. Potential fetal changes include vaginal malformation, clitoral enlargement, and formation of a structure resembling the male scrotum. Virilization is most likely when androgens are taken during the first trimester. Women who become pregnant while using androgens should be informed about the possible impact on the fetus. Androgens are classified in Food and Drug Administration Pregnancy Risk Category X: The ability to cause fetal harm outweighs any possible therapeutic benefit.

65.2.3.6 Prostate Cancer.

Androgens do not cause prostate cancer, but they can promote the growth of this cancer once it occurs. Accordingly, androgens are contraindicated for men with diagnosed prostate cancer. Men without diagnosed prostate cancer should be monitored for emergence of covert cancer.

65.2.3.7 Edema.

Edema can result from androgen-induced retention of salt and water. This complication is a concern for patients with heart failure and for those with a predisposition to developing edema from other causes. Treatment consists of discontinuing the androgen, and giving a diuretic, if needed.

65.2.3.8 Gynecomastia.

Breast enlargement may occur in males receiving androgen replacement therapy. This effect results from converting certain androgens into estrogen.

65.2.3.9 Abuse Potential.

As discussed below, androgens are frequently misused (abused) to enhance athletic performance. Because of their abuse potential, most androgens are now regulated as controlled substances. All of the androgens listed in [Table 64-1](#) are classified as Schedule III drugs.

65.2.4 Androgen Preparations for Male Hypogonadism

Treatment options for androgen replacement therapy have expanded in recent years. In the past, IM therapy with a long-acting testosterone ester was the major treatment mode. Today, we have four attractive alternatives: transdermal patches, transdermal gels, buccal tablets, and implantable subcutaneous pellets. [Table 64-2](#) presents a summary of these and other androgen preparations used for replacement therapy in hypogonadal males.

65.2.4.1 Oral Androgens.

Only two androgens are approved for oral therapy of male hypogonadism. Both drugs—*fluoxymesterone* and *methyltestosterone*—are *17-alpha-alkylated androgens*, and hence pose a risk of hepatotoxicity. Accordingly, they should not be used long term, and hence are not first-line agents. Oral androgens are used only rarely.

65.2.4.2 Intramuscular Testosterone Esters.

Two IM testosterone esters are available: *testosterone cypionate* [Depo-Testosterone] and *testosterone enanthate* [Delatestryl]. Both drugs are formulated in oil, and both are long acting. Following IM injection, these drugs are slowly absorbed and then hydrolyzed to release free testosterone. For replacement therapy in hypogonadal males, the usual dosage for both is 50 to 400 mg IM every 2 to 4 weeks. Unfortunately, these preparations produce testosterone blood levels that vary widely: Testosterone levels are higher than normal immediately after dosing, and decline to lower than normal before the next dose. As a result, patients may experience significant variations in libido, energy, and mood.

65.2.4.3 Transdermal Testosterone Patches.

Testosterone patches are indicated for male hypogonadism. Currently, only one patch is available. This product, known as *Androderm*, is applied to the upper arm, thigh, back, or abdomen. Two other products—*Testoderm* and *Testoderm TTS*—have been withdrawn. (They were applied to the scrotum, which had to be shaved once a week—making these patches less appealing than Androderm.) Androderm patches are available in two strengths: 12 mg (which delivers 2.5 mg of testosterone in 24 hours) and 24 mg (which delivers 5 mg in 24 hours). The dosage is 12 or 24 mg once daily. The principal adverse effect is rash at the site of application.

65.2.4.4 Transdermal Testosterone Gels.

Testosterone is available in two 1% gel formulations: *AndroGel* and *Testim*. Both are applied once daily to treat male hypogonadism. After the gel is applied, testosterone is absorbed rapidly

into the skin, and then slowly into the blood over the next 24 hours. Compared with transdermal patches, the gels have three advantages: they (1) cause less local irritation, (2) can't fall off, and (3) produce more consistent testosterone levels.

The principal disadvantage of the gels is that testosterone can be transferred to others by skin-to-skin contact. This is possible because only 10% of an applied dose is absorbed; the other 90% remains on the skin after the gel dries. In one study, blood levels of testosterone were doubled in female partners of gel users following 15 minutes of intimate contact 2 to 12 hours after gel application. Testosterone transfer is a concern because the drug can cause virilization of female partners and fetal harm. In children, contact exposure can cause genital enlargement (penis or clitoris), premature development of pubic hair, advanced bone age, increased libido, and aggressive behavior. In most cases, these effects regress after testosterone exposure stops.

AndroGel is supplied in unit-dose foil packets (2.5 and 5 gm). The 2.5-gm packet contains 25 mg of testosterone (of which 2.5 mg becomes absorbed) and the 5-mg packet contains 50 mg of testosterone (of which 5 mg becomes absorbed). The gel is applied once daily (preferably in the morning) to clean, dry skin of the shoulders, upper arms, or abdomen—but *not* the genitalia. Instruct patients to squeeze the entire contents of the packet into the palms, and then immediately apply the gel to the skin and rub it in. To prevent the transfer of testosterone to others, patients should wash their hands and, once the gel has dried, keep the treated area covered with clothing. Because testosterone can be washed off, patients should wait 5 to 6 hours before showering or swimming. To ensure safe and effective dosing, blood levels of testosterone should be measured 14 days after initiating therapy and periodically thereafter.

Testim is available in 5-gm tubes that contain 50 mg of testosterone, of which 10% (5 mg) gets absorbed. The usual dosage is 1 or 2 tubes (50 or 100 mg) applied once daily to skin of the shoulders or upper arms, but not to the abdomen or scrotum. As with *AndroGel*, patients should wash their hands immediately and keep the treated area covered. They should also avoid showering for at least 2 hours. Testosterone levels should be checked after 14 days and periodically thereafter.

65.2.4.5 Implantable Testosterone Pellets.

Testosterone pellets [*Testopel*] are long-acting formulations indicated for male hypogonadism and delayed puberty. The pellets are implanted subdermally in the abdominal wall lateral to the umbilicus. Each pellet contains 75 mg of testosterone. The usual dosage is 150 to 450 mg (2 to 6 pellets) every 3 to 4 months. About one-third of the dose is absorbed the first month, one-quarter the second month, and one-sixth the third month. For patients switching from IM testosterone propionate or testosterone enanthate, the recommended dosage is 2 pellets for each

25 mg of IM testosterone used weekly. For example, a patient receiving 75 mg of IM testosterone enanthate each week would switch to 6 pellets every 3 to 4 months.

65.2.4.6 Testosterone Buccal Tablets.

Testosterone buccal tablets [Striant], approved for male hypogonadism, produce steady blood levels of testosterone. Tablets are applied to the gum area just above the incisor tooth, and are designed to stay in place until removed. To ensure good adhesion, tablets should be held in place (with a finger over the lip) for 30 seconds. The recommended dosage is 1 tablet every 12 hours, alternating sides of the mouth with each dose. If a tablet falls out before 8 hours, it should be replaced with a new one for the remainder of the dosing interval. If a tablet falls out after 8 hours, it should be replaced with a new one, which can remain in place until the next scheduled dose (ie, up to 16 hours or so). The tablets are not affected by eating, drinking, chewing gum, or toothbrushing. Adverse effects, which are usually transient, include local irritation, bitter taste, and taste distortion. Treatment for up to 1 year has not caused serious gum changes.

65.3 ANDROGEN (ANABOLIC STEROID) ABUSE BY ATHLETES

Many athletes take androgens (anabolic steroids) and androgen precursors to enhance athletic performance. The potential benefits of this practice, although substantial, are accompanied by significant risks. Drugs commonly used by athletes include nandrolone, stanozolol, and methenolone. All of these drugs are regulated as controlled substances, making their use by athletes illegal.

774
775

TABLE 64-3 Impact of Testosterone on Muscle Mass and Strength in Normal Men

	Increase in Muscle Mass (pounds)	Increase in Bench Press (pounds)
Regimen		
Testosterone* alone	7	20
Exercise alone	4	20
Testosterone* + exercise	13	48
Data from Bhasin S, Storer TW, Berman N: The effects of supraphysiologic doses of testosterone on muscle size and strength in normal men. N Engl J Med 335:1, 1996.		

* Testosterone dosage = 600 mg testosterone enanthate, IM, daily for 10 weeks.

Who takes steroids? Steroid use is especially prevalent among baseball and football players, weight lifters, discus throwers, shot-putters, and bodybuilders. The drugs are also used by sprinters and athletes in endurance sports (eg, cycling, Nordic skiing). Steroids are used by athletes of all ages. This includes professionals as well as athletes in college, high school, and junior high. Use is not limited to males: Some females also take them, despite masculinizing effects.

What can anabolic steroids do for the athlete? The answer depends partly on the age and gender of the athlete, and partly on whether an athlete or a scientist is answering the question. Scientists and athletes have agreed for years that steroids can increase muscle mass in *young males* and in *females of all ages*. However, it was not until 1996 that scientists finally demonstrated what athletes have claimed for years: Exogenous androgens can significantly increase muscle mass and strength in *sexually mature males*. In order to demonstrate these effects, scientists gave normal men *large* daily injections of testosterone enanthate for 10 weeks. Some subjects did regular strength training while receiving the drug, and some did not. As indicated in [Table 64-3](#), testosterone treatment produced a 7-pound increase in muscle mass in the subjects who did not exercise, and a 13-pound increase in the subjects who exercised along with taking the drug. In contrast, exercise in the absence of exogenous testosterone produced only a 4-pound increase in muscle mass. Similar increases were shown in the subjects' ability to bench-press weights (see [Table 64-3](#)). Why did it take so long for scientists to agree with the athletes? The principal reason is that, in studies performed prior to 1996, the doses of androgens employed were too small to elicit a clear response. When sufficiently large doses were finally given, the results were unequivocal. (In the 1996 study, the testosterone dosage was equivalent to 6 to 8 times the amount produced by the testes.)

The potential for adverse effects of androgens is substantial. Salt and water retention can lead to hypertension. When administered in the high doses used by athletes, androgens suppress release of LH and FSH, resulting in testicular shrinkage, sterility, and gynecomastia (breast development). Acne is common. Reduction of HDL cholesterol and elevation of LDL cholesterol may accelerate development of atherosclerosis (although no effect was seen on lipids in the study just noted). Because most of the androgens that athletes take are 17-alpha-alkylated compounds, hepatotoxicity (cholestatic hepatitis, jaundice, hepatocellular carcinoma) is an ever-present risk. In females, androgens can cause menstrual irregularities and virilization (growth of facial hair, deepening of the voice, decreased breast size, uterine atrophy, clitoral enlargement, and male-pattern baldness); hair loss, growth of facial hair, and voice change may be irreversible. In boys and girls, androgens promote premature epiphyseal closure, thereby reducing attainable adult height. In boys, androgens can induce premature puberty.

What about psychologic effects? Interestingly, although androgens are reputed to cause depression, manic episodes, and aggressiveness ('roid rage), none of these effects was observed in the 1996

study. The authors suggested that, if an athlete is mentally healthy, testosterone will not make him into a beast. On the other hand, if an athlete is already psychologically unbalanced, it is possible that steroids could intensify aggressive behavior.

Long-term androgen use can lead to an “abuse” or “addiction” syndrome. Characteristics include preoccupation with androgen use and difficulty in stopping use. When androgens finally are discontinued, an abstinence syndrome can develop similar to that produced by withdrawal of alcohol, opioids, and cocaine.

Because of their abuse potential, nearly all androgen preparations are regulated under an amendment to the Controlled Substances Act, known as the *Anabolic Steroid Control Act of 2004*, which updates the *Anabolic Steroid Control Act of 1990*. Under the 2004 legislation, most androgens are classified as Schedule III substances. The new act covers anabolic steroids as well as their precursors, and lists a large number of currently available drugs, including tetrahydrogestrinone (THG), 1-testosterone, and 4-hydroxytestosterone. In addition, it has a provision for regulating new anabolic steroids as they become available, hence new agents can be subject to regulation even though they are not specifically identified in the 2004 Act.

For more information on drug abuse in sports, a good place to start is www.wada-ama.org, the web site of the World Anti-Doping Agency. This organization, created in 1999, is dedicated to promoting, coordinating, and monitoring the fight against use of anabolic steroids and other banned substances in sports of all forms. Other good resources include the United States Anti-Doping Agency (www.usantidoping.org) and the National Center for Drug-Free Sport (www.drugfreesport.com).

775

776

65.3.1

KEY POINTS

- Testosterone is the principal endogenous androgen.
- Important physiologic effects of androgens are pubertal transformation in males, maintenance of adult male sexual characteristics, promotion of muscle growth, and stimulation of erythropoiesis.
- The major indication for androgens is male hypogonadism.
- The major side effects of androgens are edema, virilization in females, premature epiphyseal closure in children, and liver toxicity (in people taking 17-alpha-alkylated androgens).
- Androgens are contraindicated during pregnancy.

- Large doses of androgens can increase muscle mass and strength in athletes. However, athletic use of androgens is illegal and carries significant risks.

65.3.2 Summary of Major Nursing Implications*

65.3.... ANDROGENS

Fluoxymesterone

Methyltestosterone

Oxandrolone

Testosterone

Testosterone cypionate

Testosterone enanthate

65.3.... Preadministration Assessment

65.3.... Therapeutic Goals

65.3.... Males.

Treatment of hypogonadism and delayed puberty.

65.3.... Females.

Treatment of breast cancer and breast engorgement.

65.3.... Males and Females.

Treatment of anemias and catabolic states.

65.3.... Identifying High-Risk Patients

Androgens are *contraindicated* for pregnant women, for males who have prostate cancer or breast cancer, and for enhancing athletic performance.

Implementation: Administration

Routes

PO, IM, transdermal, buccal, and subQ (implantable pellets).

Administration

Oral.

Advise patients to take oral androgens with food if GI upset occurs.

Transdermal.

Advise patients using a testosterone gel to wash their hands after applying the gel and to cover the site of application (to reduce the risk of transferring testosterone to others). Advise patients not to shower or swim for several hours (to avoid washing the drug off).

Buccal.

Instruct patients to apply buccal tablets to the gum just above the upper incisor tooth, and to apply pressure (using a finger on the lip) to ensure good adhesion.

Implantable Pellets.

Pellets are implanted subdermally (under local anesthesia) in the abdominal wall lateral to the umbilicus.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Virilization.

Virilization may occur in women, girls, and boys. **Inform female patients about signs of virilization (deepening of the voice, acne, changes in body and facial hair, menstrual irregularities), and instruct them to notify the prescriber if these occur.** Irreversible changes may be avoided if androgens are withdrawn early. In the treatment of breast carcinoma, some virilization should be tolerated.

65.3....

Premature Epiphyseal Closure.

Accelerated bone maturation can decrease attainable adult height. Monitor effects on epiphyses with radiographs of the hand and wrist twice yearly.

65.3....

Hepatotoxicity.

The *17-alpha-alkylated androgens* can cause cholestatic hepatitis, jaundice, and other liver disorders. Rarely, liver cancer develops. Obtain periodic tests of liver function.

Inform patients about signs of liver dysfunction (jaundice, malaise, anorexia, fatigue, nausea), and instruct them to notify the prescriber if these occur. Liver function normalizes following cessation of drug use. Avoid long-term use of 17-alpha-alkylated preparations.

65.3....

Edema.

Salt and water retention may result in edema. **Inform patients about signs of salt and water retention (swelling of the extremities, unusual weight gain), and instruct them to notify the prescriber if these occur.** Treatment consists of androgen withdrawal and, if necessary, use of a diuretic.

65.3....

Teratogenesis.

Androgens can cause masculinization of the female fetus. Rule out pregnancy prior to androgen use. **Warn women against becoming pregnant while taking androgens.**

65.3....

Prostate Cancer.

Avoid androgens in men with diagnosed prostate cancer. In men without diagnosed prostate cancer, monitor for exacerbation of pre-existing but covert prostate cancer.

* Patient education information is highlighted as **blue text**.

⁶⁶CHAPTER 65 Drugs for Erectile Dysfunction and Benign Prostatic Hyperplasia

^{66.1}ERECTILE DYSFUNCTION

Erectile dysfunction (ED), also known as impotence, is defined as a persistent inability to achieve or sustain an erection suitable for satisfactory sexual performance. In the United States, ED affects up to 30 million men, and accounts for 525,000 physician visits each year. ED is commonly associated with chronic illnesses, especially diabetes, hypertension, and depression. The cause may be the disease or the drugs used for treatment. Among men with diabetes, the incidence of ED is between 35% and 75%. The risk of ED increases with advancing age. According to the Massachusetts Male Aging Study, among men ages 40 to 70, 52% have some degree of ED, and among men over 70, 67% suffer from ED. Of the men in the 40- to 70-year-old group, 17% report minimal ED, 25% report moderate ED, and 10% report complete ED (ie, no erection at all). Only 48% report their erections are OK.

Before discussing drugs for ED, we need to review the physiology of erection. As indicated in [Figure 65-1](#), the process begins with sexual arousal, which increases parasympathetic nerve traffic to the penis, causing local release of nitric oxide. Nitric oxide then activates guanylyl cyclase, an enzyme that makes cyclic guanosine monophosphate (cGMP). Through a series of steps, cGMP promotes relaxation of arterial and trabecular smooth muscle. The resultant arterial dilation increases local blood flow and blood pressure, which, in combination with relaxation of trabecular smooth muscle, causes expansion and engorgement of sinusoidal spaces in the corpus cavernosum. This, in turn, causes venous occlusion and thereby reduces venous outflow. The combination of increased arterial pressure and inflow plus reduced venous outflow causes sufficient engorgement to produce erection. Erection subsides when cGMP is removed by phosphodiesterase type 5 (PDE5), an enzyme that converts cGMP into guanosine monophosphate.

We can treat ED with drugs, psychotherapy, and surgical implantation of a penile prosthesis. Discussion here is limited to drugs that fall into two basic groups: oral agents and nonoral agents. The oral drugs—PDE5 inhibitors—are by far the most common treatments for ED, and hence constitute our primary focus. The nonoral drugs—papaverine plus phentolamine, alprostadil—are considered briefly.

^{66.1.1} PDE5 Inhibitors: Sildenafil

Sildenafil [Viagra] was introduced in 1998 as the first oral treatment for ED. The drug is reliable and easy to use. Benefits derive from enhancing the natural response to sexual stimuli. Sildenafil

does not cause erection directly. Although sildenafil is generally well tolerated, it can be dangerous for men taking certain vasodilators, specifically alpha-adrenergic blockers, and nitroglycerin and other nitrates used for angina pectoris. In addition to ED, sildenafil was approved for treating pulmonary arterial hypertension (PAH) (see [Chapter 106](#)).

Sildenafil has been wildly popular. First-year sales were the hottest in pharmaceutical history. By now, tens of millions of men in over 100 countries have used the drug.

The erection-enhancing effects of sildenafil were discovered by accident. The drug was developed as a cardiac medicine, but benefits were minimal. However, in the course of testing, some men noticed a surprising side effect: Their impotence had been cured. The rest, as they say, is history.

66.1.1.1 Mechanism of Action

Sildenafil causes selective inhibition of PDE5. By doing so, it increases and preserves cGMP levels in the penis, thereby making the erection harder and more long lasting. Please note that the drug only enhances the normal erectile response to sexual stimuli (eg, erotic imagery, fantasies, physical contact). In the absence of sexual stimuli, nothing happens.

66.1.1.2 Pharmacokinetics

Sildenafil is well absorbed following oral administration. Bioavailability is about 40%. In fasting subjects, plasma levels peak about 1 hour after dosing. A high-fat meal slows absorption. As a result, plasma levels peak in 2 hours (rather than 1), and the peak concentration is reduced. Sildenafil is metabolized in the liver, primarily by the 3A4 isozyme of cytochrome P450 (CYP3A4). Both the parent drug and its major metabolite (*N*-desmethyl sildenafil) are biologically active. Both compounds are eliminated primarily in the feces (80%) and partly in the urine (13%). For both compounds, the half-life is 4 hours. Clearance of both is delayed in men older than 65 and in men with hepatic impairment or severe renal insufficiency, causing drug levels to rise higher and persist longer.

777

Figure 65-1 Physiology of penile erection. In the flaccid state, there is free outflow of venous blood and restricted inflow of arterial blood. During sexual arousal, cGMP relaxes arterial and trabecular smooth muscle, thereby permitting free inflow of arterial blood and subsequent engorgement of sinusoidal spaces, whose expansion compresses penile veins, thereby restricting blood outflow. The resultant accumulation of blood at elevated pressure increases penile size and rigidity. Removal of cGMP by PDE5 restores penile smooth muscle to the nonaroused state, and hence detumescence ensues. (cGMP = cyclic guanosine monophosphate, GMP = guanosine monophosphate, GTP = guanosine triphosphate, PDE5 = phosphodiesterase type 5.)

66.1.1.3 Sexual Benefits**66.1.1.3.1 In Men with ED.**

Sildenafil has been evaluated in several thousand men (ages 19 to 87) with ED of organic, psychogenic, or mixed-cause origin. At least some improvement in erection hardness and duration was seen in 70% of men taking the drug, compared with 20% taking placebo.

Benefits were dose related and persisted up to 4 hours, although they began to fade after 2 hours. Sildenafil was able to help a wide range of patients, including those with ED resulting from diabetes, spinal cord injury, and transurethral prostate resection, as well as ED of no known physical cause.

66.1.1.3.2 In Men Without ED.

Despite anecdotal reports to the contrary, sildenafil has little or no effect on erection quality or duration in men who do not have ED. After all, there's a limit to how good an erection can get. Sildenafil cannot improve on that limit. Any apparent benefits in healthy men are likely the result of a placebo response.

66.1.1.3.3 In Women.

Sildenafil is not approved for use in women and probably won't be. Although several large-scale studies have shown the drug is safe in women, they have failed to show much enhancement of sexual arousal. Hence, the manufacturer has decided not to seek Food and Drug Administration (FDA) approval for treating female sexual arousal disorder or any other condition in women.

66.1.1.4 Adverse Effects**66.1.1.4.1 Hypotension.**

At recommended doses, sildenafil produces a small (8.4/5.5 mm Hg) reduction in blood pressure. However, in men taking nitrates or alpha blockers (see below), severe hypotension can develop.

66.1.1.4.2 Priapism.

A few cases of priapism (painful erection lasting more than 6 hours) have been reported. If an erection persists more than 4 hours, immediate medical intervention is required. Left

untreated, priapism can damage penile tissue, thereby causing permanent loss of potency. Persistent erection can be relieved by aspirating blood from the corpus cavernosum followed by irrigation with a solution containing a vasoconstrictor (eg, epinephrine, phenylephrine, metaraminol).

66.1.1.4.3 Nonarteritic Ischemic Optic Neuropathy (NAION).

Very rarely, men taking sildenafil have developed NAION, resulting in irreversible blurring or loss of vision. The cause is blockage of blood flow to the optic nerve. In most cases, men had underlying anatomic or vascular risk factors for NAION. Also, although NAION developed during sildenafil use, a direct causal relationship has not been established. Nonetheless, patients with NAION in one eye should not use sildenafil, owing to a potential risk of developing NAION in the other eye.

66.1.1.4.4 Sudden Hearing Loss.

Very rarely, men taking sildenafil have experienced sudden hearing loss, usually in one ear, sometimes in association with dizziness, vertigo, and tinnitus (ringing in the ears). Hearing loss may be partial or complete. Hearing returned by the time the loss was reported in one-third of cases, but had not returned in the remaining two-thirds. At this time, a direct causal relationship between sildenafil and hearing loss has not been established. Nonetheless, the drug is suspected because (1) sudden hearing loss is unusual and (2) it developed when sildenafil was taken. Men who experience sudden hearing loss should discontinue the drug—but only if they are taking it for ED; men taking the drug for PAH should continue treatment.

66.1.1.4.5 Other Adverse Effects.

The most common adverse effects are headache (16%), flushing (10%), and dyspepsia (7%). Sildenafil may also cause nasal congestion (4%), diarrhea (3%), rash (2%), and dizziness (2%). About 3% of patients experience mild transient visual disturbances (blue color tinge to vision, increased sensitivity to light, blurring). In addition, sildenafil may intensify symptoms of obstructive sleep apnea (perhaps by relaxing pharyngeal muscles and/or dilating pulmonary blood vessels).

66.1.1.5 Drug Interactions

66.1.1.5.1 Nitrates.

Both sildenafil and nitrates (eg, nitroglycerin, isosorbide dinitrate) promote hypotension, and they both do so by increasing cGMP (nitrates increase cGMP formation and sildenafil slows cGMP breakdown). If these drugs are combined, life-threatening hypotension could result. Therefore, *sildenafil is absolutely contraindicated for patients taking nitrates*. At least 24 hours should elapse between the last dose of sildenafil and giving a nitrate. If elimination of sildenafil is slowed (owing to a CYP3A4 inhibitor or hepatic or renal impairment), an even longer time should elapse before nitrate use.

66.1.1.5.2 Alpha Blockers.

Alpha-adrenergic antagonists—including doxazosin [Cardura] and other alpha blockers used for prostatic hypertrophy (see below)—dilate arterioles, and can thereby lower blood pressure. Combined use with sildenafil has caused symptomatic postural hypotension. Accordingly, these combinations should be used with caution.

66.1.1.5.3 Inhibitors of CYP3A4.

Inhibitors of CYP3A4 (eg, ketoconazole, itraconazole, erythromycin, cimetidine, saquinavir, ritonavir, grapefruit juice) can suppress metabolism of sildenafil, thereby increasing its levels. Accordingly, these combinations should be used with caution.

66.1.1.6 Is Sildenafil Safe for Men with CHD?

Reports of adverse cardiovascular events, including at least 130 cardiac deaths, raised concern about the safety of sildenafil in men with coronary heart disease (CHD). However, there was a question as to what caused the adverse events: sildenafil or the sexual activity that sildenafil permitted. When attempting to answer this question, researchers made two important observations: First, giving sildenafil to resting men with severe CHD produced no harmful effects on coronary blood flow or any other hemodynamic parameter. Second, in men with stable CHD who were performing exercise, sildenafil had no effect on either CHD symptoms, exercise tolerance, or exercise-induced ischemia. Taken together, these results suggest that, in men with CHD, sexual activity—and not sildenafil—is the likely cause of ischemic events. However, even though sildenafil itself appears safe for men with CHD, sexual activity may not be. Accordingly, the drug should be used with caution by men with the following conditions:

- Myocardial infarction, stroke, or life-threatening dysrhythmia within the last 6 months
- Resting hypotension (blood pressure below 90/50 mm Hg)
- Resting hypertension (blood pressure above 170/110 mm Hg)
- Heart failure
- Unstable angina

In addition, *sildenafil should not be used at all by men taking nitroglycerin or any other drug in the nitrate family.*

To reduce the risk of adverse events, candidates for sildenafil therapy should undergo a careful evaluation of cardiovascular function. Those with impaired function should be counseled about the risks posed by sexual activity, and all other moderate to intense physical activity.

779

780

66.1.1.7 Preparations, Dosage, and Administration

Sildenafil [Viagra] is available in 25-, 50-, and 100-mg tablets. The usual dose is 50 mg taken 1 hour before sexual activity. The dosage range is 25 to 100 mg taken 30 minutes to 4 hours before sexual activity. A low dose (25 mg) should be considered for men older than 65, men with hepatic dysfunction or severe renal dysfunction, and men taking alpha blockers or drugs that inhibit CYP3A4. Dosing should be done no more than once a day.

66.1.2 PDE5 Inhibitors: Vardenafil and Tadalafil

Vardenafil and tadalafil are very similar to sildenafil. All three drugs inhibit PDE5, and all three are approved for oral therapy of ED. Vardenafil is unique in that it prolongs the QT interval, and tadalafil is unique in that its effects last 36 hours. Otherwise, the clinical effects of all three drugs appear about equal, although some patients may respond better to one than to the others. Properties of all three are summarized in [Table 65-1](#).

66.1.2.1 Vardenafil

66.1.2.1.1 Actions and Use.

Vardenafil [Levitra], approved in August 2003, was the second selective PDE5 inhibitor released for ED. As with sildenafil, benefits derive from relaxing arterial and trabecular

smooth muscle in the penis. Effects begin about 60 minutes after dosing, and persist about 4 hours. There is no evidence that vardenafil works faster, longer, or better than sildenafil.

66.1.2.1.2 Pharmacokinetics.

Oral bioavailability is low (15%), and is decreased further by a high-fat meal. Plasma levels peak about 1 hour after dosing, or after 2 hours if dosing is done with a high-fat meal. Vardenafil undergoes extensive metabolism by hepatic CYP3A4, followed by excretion mainly in the feces. The drug's half-life is 4 to 5 hours.

66.1.2.1.3 Adverse Effects.

The most common adverse effects are headache (15%), flushing (11%), rhinitis (9%), and dyspepsia (4%). Like other PDE5 inhibitors, vardenafil can lower blood pressure. Like sildenafil, vardenafil can cause visual changes, and has been associated with sudden hearing loss and vision loss from NAION.

Vardenafil can prolong the cardiac QT interval, and may thereby pose a risk of serious dysrhythmias. However, dysrhythmias have not been reported. To reduce risk, vardenafil should be used with caution in patients taking other drugs that cause QT prolongation—specifically, class I antidysrhythmics (eg, procainamide, quinidine) and class III antidysrhythmics (eg, amiodarone, sotalol).

66.1.2.1.4 Drug Interactions.

Vardenafil is contraindicated for use with alpha-adrenergic blockers, and with nitroglycerin and other nitrates. Plasma levels can be increased by inhibitors of CYP3A4 (eg, ketoconazole, ritonavir), and hence such combinations must be used with caution. As noted, caution is needed in patients taking drugs that prolong the QT interval.

66.1.2.1.5 Preparations, Dosage, and Administration.

Vardenafil [Levitra] is available in tablets (2.5, 5, 10, and 20 mg) for oral use. The usual dose is 10 mg taken 60 minutes before intercourse. The maximum dose is 20 mg. Doses should be reduced in men older than 65, men with hepatic impairment, and men taking inhibitors of CYP3A4. Dosing should be done no more than once a day.

66.1.2.2 Tadalafil

66.1.2.2.1 Actions and Use.

Tadalafil [Cialis], approved in November 2003, is the third PDE5 inhibitor to hit the market. Like sildenafil and vardenafil, the drug is indicated for oral therapy of ED. As with other PDE5 inhibitors, benefits derive from relaxation of penile arterial and trabecular smooth muscle brought on by accumulation of cGMP. On average, therapeutic levels of the drug are reached by 2 hours after dosing and persist about 36 hours—much longer than with other inhibitors of PDE5. As a result, timing of drug administration and sexual activity needn't be tightly coupled. Furthermore, in addition to being approved for PRN dosing (like sildenafil and vardenafil), tadalafil is now approved for *daily* dosing (but only for men who anticipate sexual activity at least twice a week).

66.1.2.2.2 Pharmacokinetics.

Administration is oral, and absorption is not affected by food. Plasma levels peak 0.5 to 6 hours after dosing, and then slowly decline. Tadalafil undergoes metabolism by hepatic CYP3A4, followed by excretion primarily in the feces. The drug's half-life is 17.5 hours.

TABLE 65-1 Comparison of PDE5 Inhibitors

Parameter	Drug		
	Sildenafil [Viagra]	Tadalafil [Cialis]	Vardenafil [Levitra]
Date approved	3/27/98	11/21/03	8/19/03
Dosing schedule	PRN only	PRN or once daily	PRN only
Dosing with food	May be taken without regard to meals— but high-fat meals delay absorption and reduce peak levels	May be taken without regard to meals	May be taken without regard to meals—but high-fat meals delay absorption and reduce peak levels
Median time to peak level	1 hr	2 hr	1 hr
Half-life	4 hr	17.5 hr	4–5 hr
Duration of action	4 hr	36 hr	4 hr
Major mode of metabolism	CYP3A4	CYP3A4	CYP3A4
Drug interactions Nitrates	Contraindicated: Wait 24 hr before giving a nitrate	Contraindicated: Wait 48 hr before giving a nitrate	Contraindicated: Wait 24 hr before giving a nitrate
Alpha blockers	Use with caution	Contraindicated (except for tamsulosin, 0.4 mg once daily)	Contraindicated
CYP3A4 inhibitors	Reduce sildenafil dosage	Reduce tadalafil dosage to no more than 10 mg every 72 hr	Reduce vardenafil dosage
Class I and class III anti-dysrhythmic drugs	No interaction	No interaction	Vardenafil prolongs the QT interval—avoid class I and class III antidysrhythmics

780

66.1.2.2.3 Adverse Effects.

The most common adverse effects are headache (11%), dyspepsia (8%), back pain (5%), myalgia (4%), limb pain (3%), flushing (3%), and nasal congestion (3%). Like other PDE5 inhibitors, tadalafil can lower blood pressure. Very rarely (0.1%), the drug alters color vision. A few cases of NAION and sudden hearing loss have been reported, but a causal relationship has not been established. Because tadalafil has a long duration of action, any adverse effects that occur may persist for many hours.

66.1.2.2.4 Drug Interactions.

Tadalafil is contraindicated for use with nitrates or alpha blockers (except tamsulosin [Flomax], 0.4 mg once daily). As with sildenafil and vardenafil, CYP3A4 inhibitors can cause levels of tadalafil to rise. To avoid toxicity, men taking CYP3A4 inhibitors should limit tadalafil dosage to 10 mg every 72 hours.

66.1.2.2.5 Preparations, Dosage, and Administration.

Tadalafil [Cialis] is available in tablets (2.5, 5, 10, and 20 mg). Dosing may be done with or without food. Two dosing schedules are approved: PRN and daily.

66.1.2.2.5.1 PRN Dosing.

The usual initial dose is 10 mg. The dosage range is 5 to 20 mg, taken no more than once a day. The manufacturer does not identify a minimum time between dosing and sexual activity. However, since blood levels peak more slowly than with sildenafil or vardenafil, allowing at least 1 hour for absorption would seem reasonable. Dosage should be reduced in men with moderate renal or hepatic insufficiency. Men with severe hepatic insufficiency should not use the drug. For men taking CYP3A4 inhibitors, the maximum dosage is 10 mg every 72 hours.

66.1.2.2.5.2 Daily Dosing.

The approved dosage is 2.5 or 5 mg once a day. Daily dosing is recommended only for men who anticipate sexual activity at least twice a week.

66.1.3 Papaverine Plus Phentolamine

66.1.3.1 Therapeutic Use.

The combination of papaverine (a smooth muscle relaxant) plus phentolamine (an alpha-adrenergic blocking agent) can counteract impotence when *injected directly into the corpus cavernosum*. Erection develops within 10 minutes and lasts 2 to 4 hours. In clinical trials, erection suitable for intercourse was produced in 65% to 100% of males with impotence of neurologic or vascular origin. For men who do not respond to papaverine plus phentolamine, addition of alprostadil may help (see below).

66.1.3.2 Mechanism of Action.

Papaverine and phentolamine produce erection by increasing arterial inflow to the penis and decreasing venous outflow. Arterial inflow is augmented by alpha-adrenergic blockade (causing arterial dilation) and by the direct relaxant action of papaverine on arterial smooth muscle. Venous outflow is reduced, probably because relaxation of trabecular smooth muscle results in occlusion of the venules that drain the corporal spaces.

66.1.3.3 Adverse Effects.

Priapism (persistent erection lasting more than 6 hours) occurs in about 10% of patients. Development of painless *fibrotic nodules* in the corpus is common. Other adverse effects include orthostatic hypotension with dizziness, transient paresthesias, ecchymosis (extravasation of blood into subcutaneous tissue), and difficulty in achieving orgasm or ejaculation. The injections are nearly painless.

66.1.3.4 Dosage and Administration.

For men with psychogenic or neurogenic impotence, erection can be achieved by injecting as little as 0.1 mL of a solution containing 30 mg of papaverine/mL and 1 mg of phentolamine/mL. A 1-mL syringe with a 27- or 28-gauge, 3/8-inch needle is used. Injections are made directly into the corpus cavernosum through the lateral aspect of the shaft of the penis. These injections are nearly painless and can be administered by the patient.

66.1.4 Alprostadil (Prostaglandin E₁)

66.1.4.1 Intracavernous.

Like the combination of phentolamine plus papaverine, alprostadil [Caverject, Caverject Impulse, Edex] can produce erection when *injected directly into the corpus cavernosum*. The response is rapid and the injections are relatively painless. As with papaverine, erection results from relaxation of smooth muscle (arterial, venous, and trabecular), causing arterial inflow to increase and venous outflow to decrease. Dosages range from 5 to 40 mcg and should be determined in the prescriber's office. The dosing endpoint is an erection that is sufficient for intercourse, but that does not last for more than 1 hour. Alprostadil should be used no more than 3 times a week and not more than once in 24 hours. Acute adverse effects are burning sensations (37%), prolonged erection (4%), and priapism (erection lasting more than 6 hours; 0.4%). Penile fibrosis may develop with continued use.

66.1.4.2 Transurethral.

Alprostadil pellets [Muse], inserted into the urethra, are an alternative to intracavernous injections. Administration is accomplished by loading a pellet into a small plastic applicator, which is then inserted an inch and a half into the urethra. The procedure is painless. Erection develops 5 to 10 minutes after drug insertion and lasts 30 to 60 minutes. Alprostadil pellets are available in four strengths: 125, 250, 500, and 1000 mcg. Dosage should be determined in the prescriber's office; the objective is to employ the smallest dose required to produce an erection sufficient for intercourse. Alprostadil pellets should be used no more than twice every 24 hours. The most common adverse effect, dull ache in the penis, occurs in 11% of users. Priapism and penile fibrosis, which have developed with alprostadil injections, have not been reported with the pellets.

66.2 BENIGN PROSTATIC HYPERPLASIA

66.2.1 Pathophysiology and Overview of Treatment

Benign prostatic hyperplasia (BPH) is a common condition that develops in more than 50% of men by age 60 and 90% by age 85. The disorder accounts for 1.7 million physician visits each year and leads to 300,000 prostatectomies. The total annual cost exceeds \$2 billion. Although BPH and prostate cancer can coexist, there is no evidence that one predisposes to the other.

66.2.1.1 Pathophysiology

The prostate is a heart-shaped gland that surrounds the urethra. Its major function is to produce fluids that contribute to ejaculate volume. In healthy men, the prostate is walnut sized and weighs between 4 and 20 gm. In men with BPH, prostate mass may reach 50 to 80 gm.

BPH is a nonmalignant prostate enlargement caused by excessive growth of epithelial (glandular) cells and smooth muscle cells. Overgrowth of epithelial cells causes *mechanical obstruction* of the urethra, whereas overgrowth of smooth muscle causes *dynamic obstruction* of the urethra. In men with BPH, the ratio of epithelium to smooth muscle varies from 1:3 to 4:1—in general, the larger the prostate, the higher the percentage of epithelium.

Signs and symptoms of BPH include urinary hesitancy, urinary urgency, increased frequency of urination, dysuria, nocturia, straining to void, postvoid dribbling, decreased force and caliber of the urinary stream, and a sensation of incomplete bladder emptying. There is no direct correlation between symptoms and prostate size. Hence, some men with only moderate enlargement may be highly symptomatic, whereas others with substantial enlargement may have no symptoms. Long-term complications of BPH include obstructive nephropathy, bladder stones, and recurrent urinary tract infections.

66.2.1.2 Treatment Modalities

BPH can be managed in three ways: invasive treatments, drug therapy, and “watchful waiting.” Invasive options include transurethral resection of the prostate, laser prostatectomy, transurethral electrovaporization of the prostate, and transurethral microwave therapy. These procedures are most appropriate for men with severe symptoms or the complications noted above. Drugs are indicated for men with moderate symptoms. Watchful waiting, which consists of reassurance and annual re-evaluation, is appropriate for men with minimal symptoms.

66.2.2 Drug Therapy

BPH can be treated with two major classes of drugs: *5-alpha-reductase inhibitors* and *alpha₁-adrenergic antagonists*. With both, the goal is to relieve bothersome urinary symptoms and delay disease progression. As discussed below, 5-alpha-reductase inhibitors are most appropriate for men with very large prostates (mechanical obstruction), whereas alpha blockers are preferred for men with relatively small prostates (dynamic obstruction).

781

782

66.2.2.1 5-Alpha-Reductase Inhibitors

Two 5-alpha-reductase inhibitors are available: finasteride and dutasteride. Both can reduce prostate size—but several months are required for a noticeable effect. There is no proof that one drug works any better than the other.

66.2.2.1.1 Finasteride.

Finasteride [Proscar] acts in reproductive tissue to inhibit 5-alpha-reductase, an enzyme that converts testosterone to dihydrotestosterone (DHT), the active form of testosterone in the prostate. Treatment reduces levels of DHT in blood by 70% (but does not decrease testosterone levels). By decreasing DHT availability, finasteride promotes regression of prostate epithelial tissue, and thereby decreases *mechanical obstruction* of the urethra. Since the percentage of epithelial tissue is highest in very large prostates, finasteride is most effective in men whose prostates are highly enlarged. Conversely, the drug has little or no effect if the degree of enlargement is small. It should be noted that benefits develop slowly—over a period of 6 to 12 months. In addition to reducing symptoms of BPH, long-term dosing with finasteride can reduce the risk of prostate cancer.

Finasteride is generally well tolerated. However, it does decrease ejaculate volume and libido in 5% to 10% of patients. In addition, gynecomastia (breast enlargement) develops in some men.

Finasteride decreases serum levels of prostate-specific antigen (PSA), a marker for prostate cancer. The expected decline is 30% to 50%. PSA levels should be determined prior to treatment and 6 months later. If PSA levels do not fall as expected, the patient should be evaluated for cancer of the prostate.

For treatment of BPH, finasteride is available in 5-mg tablets sold as *Proscar*. (As discussed in [Chapter 104](#), the drug is also available in 1-mg tablets, sold as *Propecia*, for treatment of male-pattern baldness.) For men with BPH, the usual dosage is 5 mg once a day, taken with or without food. Treatment continues for life.

66.2.2.1.2 Dutasteride.

Dutasteride [Avodart] is similar to finasteride in most respects. However, there are three significant differences. First, with dutasteride, the reduction in circulating DHT is more complete. Second, dutasteride is harmful to the developing male fetus. Third, dutasteride has

an extremely long half-life (about 5 weeks), and hence it takes months to clear the drug after dosing has stopped.

Like finasteride, dutasteride inhibits 5-alpha-reductase, and thereby suppresses production of DHT. However, whereas finasteride inhibits only the form of 5-alpha-reductase found in reproductive tissues, dutasteride also inhibits the form found in the skin and liver. As a result, dutasteride produces a greater reduction in circulating DHT (93% vs. 70%). Whether this translates to a greater clinical response has not been established (dutasteride and finasteride have not been directly compared).

Like finasteride, dutasteride reduces ejaculate volume and libido in some men, and causes a decline in PSA in all.

Animal studies indicate that dutasteride can inhibit development of the external genitalia in the male fetus. Accordingly, the drug is classified in FDA Pregnancy Risk Category X. Dutasteride can be absorbed through the skin, and hence pregnant women should not handle it. Men should not donate blood while using dutasteride or for at least 6 months after stopping it (to avoid transmission to women via an infusion).

Dutasteride is available in 0.5-mg capsules. The dosage is 0.5 mg once a day, taken with or without food. As with finasteride, treatment continues indefinitely.

66.2.2.2 Alpha₁-Adrenergic Antagonists

Five alpha₁ blockers are approved for BPH: *alfuzosin* [Uroxatral], *terazosin* [Hytrin], *doxazosin* [Cardura], *silodosin* [Rapaflo], and *tamsulosin* [Flomax]. These drugs have never been directly compared in clinical trials, and hence we can't say if one is more effective than the others. However, two newer ones—silodosin and tamsulosin—may be better tolerated. The basic pharmacology of these drugs is presented in [Chapter 18](#). Discussion here is limited to their use in BPH.

66.2.2.2.1 Mechanism of Action.

Blockade of alpha₁ receptors relaxes smooth muscle in the bladder neck (trigone and sphincter), prostate capsule, and prostatic urethra, thereby decreasing *dynamic obstruction* of the urethra. Symptomatic improvement and increased urinary flow develop rapidly. Because dynamic obstruction is the major contributor to symptoms in patients with relatively mild prostatic enlargement, alpha blockers are preferred to 5-alpha-reductase inhibitors for these men. To maintain benefits, alpha blockers must be taken lifelong.

66.2.2.2.2 Receptor Specificity and Impact on Blood Pressure.

The alpha blockers differ regarding specificity of receptor blockade and resultant impact on blood pressure. Specifically, whereas silodosin and tamsulosin are selective for alpha₁ receptors in the prostate, alfuzosin, terazosin, and doxazosin block alpha₁ receptors in blood vessels too. By blocking alpha₁ receptors in blood vessels, the three nonselective agents promote vasodilation, and can thereby lower blood pressure. In fact, two of these drugs—doxazosin and terazosin—were developed as antihypertensive agents; their use in BPH came later. Because of their impact on blood pressure, the nonselective alpha₁ blockers are especially useful for patients who have hypertension in addition to BPH—but may be dangerous for men with low blood pressure. Conversely, because silodosin and tamsulosin have little or no effect on blood pressure, they are of no benefit to men with hypertension—but are preferred if reducing blood pressure would be a problem.

66.2.2.2.3 Adverse Effects.

The alpha₁ blockers are generally well tolerated. For the nonselective agents (alfuzosin, doxazosin, and terazosin), principal adverse effects are hypotension, fainting, dizziness, somnolence, and nasal congestion. Because *silodosin* and *tamsulosin* have minimal effects on vascular smooth muscle, these drugs are less likely to cause hypotension, fainting, dizziness, or nasal congestion. However, silodosin and tamsulosin *can* cause abnormal ejaculation (ejaculation failure, reduced volume, retrograde ejaculation), whereas the nonselective agents do not. In contrast to dutasteride and finasteride, the alpha blockers do not reduce levels of PSA.

66.2.2.2.4 Drug Interactions.

Exercise caution when combining nonselective alpha blockers with other drugs that lower blood pressure; excessive hypotension could result. Drugs of concern include organic nitrates (eg, nitroglycerin), antihypertensive drugs, and PDE5 inhibitors used for ED (eg, sildenafil [Viagra]).

Strong inhibitors of CYP3A4 (an isozyme of cytochrome P450) can dramatically increase levels of alfuzosin and silodosin. Accordingly, alfuzosin and silodosin must not be combined with these drugs. Among them are erythromycin, itraconazole, nefazodone, and HIV protease inhibitors (eg, ritonavir).

66.2.2.2.5 Dosage and Administration.

All of the alpha blockers are taken orally. Dosages for BPH are as follows:

- *Doxazosin* [Cardura]—Start with 1 mg once daily and gradually increase to a maximum of 8 mg once daily.
 - *Terazosin* [Hytrin]—Start with 1 mg once daily at bedtime and gradually increase to a maximum of 10 mg once daily.
 - *Alfuzosin* [Uroxatral]—Treat with 10 mg once daily, taken immediately after the same meal each day.
-
- *Silodosin* [Rapaflo]—For men with normal renal function, dosage is 8 mg once daily, taken with the same meal each day. For men with moderate renal impairment, dosage is reduced to 4 mg once daily. And for men with severe renal impairment, silodosin should be avoided.
 - *Tamsulosin* [Flomax]—Treat with 0.4 mg once daily, taken about 30 minutes after the same meal (eg, breakfast) each day.

782

783

Note that dosages of terazosin and doxazosin must be titrated, whereas dosages for alfuzosin, silodosin, and tamsulosin are fixed. Titration is done to minimize hypotension.

66.2.2.3 Combination Therapy

Studies have shown that *combining* a 5-alpha-reductase inhibitor with an alpha blocker is superior to treatment with either agent alone. For example, in a study known as MTOPS, men with moderate BPH were given either (1) finasteride (a 5-alpha-reductase inhibitor), (2) doxazosin (an alpha blocker), (3) both drugs, or (4) placebo. The result? After 4 years, the incidence of disease progression was 17% among men taking the placebo, 10% among men taking one drug, and only 5% among men taking both drugs. In another study, involving men with more advanced BPH, the combination of two newer drugs—dutasteride and tamsulosin—was again superior to either agent alone. Although use of a 5-alpha-reductase inhibitor with an alpha blocker has been common practice for years, it was not until 2008 that a specific combination—dutasteride plus tamsulosin—was given FDA approval for use in BPH. Presumably, other combinations of a 5-alpha-reductase inhibitor and an alpha blocker would be equally effective.

66.2.2.4 Other Drugs for BPH

66.2.2.4.1 Saw Palmetto.

Saw palmetto is an herbal preparation used widely to treat BPH. The product, available as a dietary supplement, is an extract prepared from the dried ripe berries of the American dwarf saw palmetto (*Serenoa repens*; *Sabal serrulata*), a small palm tree native to the southeastern United States. The active ingredient, if any, has not been identified, and commercial products are not standardized. How effective is saw palmetto? Not very. In fact, according to a 2006 report in the *New England Journal of Medicine*, saw palmetto is not effective at all: The herb had no effect on maximal urinary flow rate, prostate size, residual volume after voiding, or quality of life. Since this study was randomized, double-blinded, and placebo-controlled, the results are hard to ignore—even though they conflict with the results of earlier, less rigorous trials. Saw palmetto is discussed further in [Chapter 107](#) (Dietary Supplements).

66.2.2.4.2 Newer Drug Therapies.

Recent studies have shown relief of urinary symptoms using tolterodine, PDE5 inhibitors, and botulinum toxin. *Tolterodine* [Detrol] is a muscarinic antagonist developed for urge incontinence (see [Chapter 14](#)). When used alone or combined with tamsulosin (an alpha blocker), tolterodine can improve urinary symptoms associated with BPH. Improvement has also been shown with two *PDE5 inhibitors*: sildenafil [Viagra] and vardenafil [Levitra]. *Botulinum toxin* [Botox], a well-known remedy for facial wrinkles (see [Box 104-1](#) in [Chapter 104](#)), can also help men with BPH. A single injection into the prostate can relieve urinary symptoms for up to 1 year. Benefits derive in part from blocking release of acetylcholine from neurons that innervate urinary tract smooth muscle. However, since the drug also reduces both prostate size and blood levels of PSA, other mechanisms must also be involved.

66.2.2.4.2.1

KEY POINTS

- Erectile dysfunction (ED) is defined as a persistent inability to achieve or sustain an erection suitable for satisfactory sexual performance.
- Sildenafil [Viagra] is the prototype of the PDE5 inhibitors, the only oral drugs for ED.
- By inhibiting PDE5, sildenafil prevents conversion of cGMP to GMP, and thereby preserves erection.

- Sildenafil is contraindicated for men taking organic nitrates, because the combination poses a risk of life-threatening hypotension.
- Sildenafil does not increase the risk of cardiovascular events in patients with coronary heart disease—although the sexual activity that sildenafil permits may.
- Sildenafil and other PDE5 inhibitors have been associated with rare cases of sudden hearing loss and vision loss from NAION.
- Symptoms of benign prostatic hyperplasia (BPH) result from (1) mechanical obstruction of the urethra (secondary to overgrowth of epithelial cells), and (2) dynamic obstruction of the urethra (secondary to overgrowth of smooth muscle).
- Finasteride [Proscar] promotes regression of prostate epithelial tissue, and thereby decreases mechanical obstruction of the urethra. Since the percentage of epithelial tissue is highest in very large prostates, finasteride is most effective in men whose prostates are highly enlarged.
- Tamsulosin [Flomax] and other α_1 blockers relax smooth muscle in the prostate capsule, prostatic urethra, and bladder neck (trigone and sphincter), and thereby decrease dynamic obstruction of the urethra.

66.2.2.4.2.2

Summary of Major Nursing Implications*

66.2.2.4.2.2.1

PDE5 INHIBITORS

Sildenafil

Tadalafil

Vardenafil

The nursing implication summarized below pertain only to the use of PDE5 inhibitors for ED, not for their use in pulmonary arterial hypertension (PAH).

66.2.2.4.2.2.1.1	Preadministration Assessment	
66.2.2.4.2.2.1...	Therapeutic Goal PDE5 inhibitors are used to enhance both the hardness and duration of erection in men with ED.	783
66.2.2.4.2.2.1...	Baseline Data Evaluate patients for cardiovascular disorders, including stroke, hypotension, hypertension, heart failure, unstable angina, myocardial infarction, and recent history of a severe dysrhythmia.	784
66.2.2.4.2.2.1...	Identifying High-Risk Patients PDE5 inhibitors are <i>contraindicated</i> for men taking nitrates (eg, nitroglycerin), and should generally be avoided by men taking alpha blockers. Avoid <i>varденаfil</i> —but not sildenafil or tadalafil—in men taking class I or class III antidysrhythmic drugs. Use PDE5 inhibitors with <i>caution</i> in men taking CYP3A4 inhibitors and in those with nonarteritic ischemic optic neuropathy (NAION), coronary heart disease, and other cardiovascular disorders.	
66.2.2.4.2.2.1.2	Implementation: Administration	
66.2.2.4.2.2.1...	Route Oral.	
66.2.2.4.2.2.1...	Administration	
66.2.2.4.2.2.1...	Dosing with Food. Inform patients that dosing may be done with or without food, although a high-fat meal will delay absorption of sildenafil or vardenafil (but not tadalafil).	

66.2.2.4.2.2.1...

PRN Dosing.

All PDE5 inhibitors may be used PRN. **Advise patients to take these drugs about 1 hour before sexual activity.**

66.2.2.4.2.2.1...

Daily Dosing.

Only tadalafil is approved for daily dosing. **Warn men that the maximum dosage is 5 mg once a day.**

66.2.2.4.2.2.1.3

Ongoing Evaluation and Interventions

66.2.2.4.2.2.1...

Minimizing Adverse Effects

66.2.2.4.2.2.1...

Cardiac Risk.

Inform men with pre-existing cardiovascular disease about the cardiac risk of sexual activity (not the PDE5 inhibitor). Advise men who experience symptoms (eg, anginal pain, dizziness) during sex to refrain from further sexual activity and discuss the event with their prescriber.

66.2.2.4.2.2.1...

Priapism.

PDE5 inhibitors can cause priapism (persistent erection), which can result in permanent impotence owing to local tissue damage. **Advise patients to seek immediate medical attention if an erection lasts more than 4 hours.**

Treatment involves aspiration of blood from the corpus cavernosum followed by irrigation with a vasoconstrictor.

66.2.2.4.2.2.1...

Nonarteritic Ischemic Optic Neuropathy.

Very rarely, men taking PDE5 inhibitors have developed NAION with resultant irreversible blurring of vision or blindness. **Advise patients to stop their PDE5 inhibitor and seek immediate medical attention if they experience sudden loss of vision in one or both eyes.**

66.2.2.4.2.2.1...

Sudden Hearing Loss.

Very rarely, men taking PDE5 inhibitors have developed sudden loss of hearing, sometimes associated with dizziness, vertigo, and tinnitus. **Advise men with ED**

to discontinue the drug if hearing loss develops. (Men taking sildenafil for PAH should not interrupt treatment.)

Minimizing Adverse Interactions

Nitrates.

Combining a PDE5 inhibitor with a nitrate (eg, nitroglycerin) can cause a severe drop in blood pressure, and hence concurrent use of these drugs is contraindicated. **Instruct patients to avoid nitrates for at least 24 hours after taking sildenafil or vardenafil, and for at least 48 hours after taking tadalafil.**

Alpha-Adrenergic Blockers.

Combining a PDE5 inhibitor with an alpha blocker (eg, doxazosin) can cause a serious drop in blood pressure. To avoid harm, use caution when combining *sildenafil* with an alpha blocker; do not combine *tadalafil* with any alpha blockers except tamsulosin (0.4 mg once daily); and do not combine *vardenafil* with any alpha blockers at all.

Inhibitors of CYP3A4.

Agents that inhibit CYP3A4 (eg, ketoconazole, ritonavir, grapefruit juice) can raise PDE5 inhibitor levels. To avoid harm, dosage of the PDE5 inhibitor should be reduced.

Antidysrhythmic Drugs.

Avoid *vardenafil* in men taking class I or class III antidysrhythmic drugs. Vardenafil prolongs the QT interval, and can thereby cause a severe dysrhythmia when combined with these agents.

* Patient education information is highlighted as **blue text**.

⁶⁷CHAPTER 66 Review of the Immune System

Life is a constant battle—and the immune system is the army that helps us prevail. This system protects us from invading organisms (viruses, bacteria, fungi, and parasites) and can destroy cancer cells before they destroy us. Unfortunately, the army does not always act in our best interest: It can attack transplanted organs and tissues and, when it runs amok, can turn on the very cells it was intended to protect.

To study the immune system, we begin with an overview. After that, we discuss the two major types of specific immune responses: antibody-mediated immunity (humoral immunity) and cell-mediated immunity.

^{67.1}INTRODUCTION TO THE IMMUNE SYSTEM

Our objective in this section is to establish an overview of immune system components and how they function. Much of the information introduced here is amplified later.

^{67.1.1} Natural Immunity Versus Specific Acquired Immunity

Our bodies can mount two types of immune responses, referred to as *natural immunity* (innate or native immunity) and *specific acquired immunity*. Factors that confer natural immunity include physical barriers (eg, skin), phagocytic cells, and natural killer cells. All of these factors are present prior to exposure to a particular infectious agent and all respond nonspecifically. In contrast, specific acquired immune responses occur only after exposure to a foreign substance. The foreign substances that induce specific responses are called *antigens*, and the objective of the immune response is to destroy them. With each succeeding re-exposure to a particular antigen, the specific immune response to that antigen becomes faster and more intense. Specific immune responses are possible because certain cells of the immune system (T lymphocytes and B lymphocytes) possess receptors that can recognize individual antigens. In this chapter, our focus is on specific acquired immunity and not on natural immunity.

^{67.1.2} Cell-Mediated Immunity Versus Antibody-Mediated (Humoral) Immunity

Specific acquired immune responses can be classified as either cell mediated or humoral. *Cell-mediated immunity* refers to immune responses in which targets are attacked directly by immune system cells—specifically, cytolytic T cells and macrophages. *Humoral immunity* refers to immune responses that are mediated by *antibodies*. (The term *humoral*—defined as “pertaining to elements dissolved in blood or body fluids”—simply connotes that antibodies are present dissolved in the blood.)

67.1.3 Introduction to Cells of the Immune System

Immune responses are mediated by several types of cells, some of which play a bigger role than others. The major actors are the *lymphocytes* (B cells, cytolytic T cells, helper T cells), *macrophages*, and *dendritic cells*. Accessory cells include neutrophils and basophils. With the exception of some dendritic cells, all of the cells involved in the immune response arise from pluripotent stem cells in the bone marrow ([Fig. 66-1](#)) and, for at least part of their life cycle, circulate in the blood. Defining characteristics of individual immune system cells are summarized in [Table 66-1](#).

67.1.3.1 B Lymphocytes (B Cells).

B lymphocytes have the job of making *antibodies*. Hence, B cells mediate humoral immunity. As discussed below, antibody specificity is determined by the structure of highly specific receptors found on the surface of B cells. Like all other lymphocytes, B cells circulate in the blood and lymph. B cells are so named because in chickens, where B cells were discovered, these cells are produced in the *bursa of Fabricius*, a structure not found in mammals. In humans and other mammals, B cells are produced in the bone marrow.

67.1.3.2 Cytolytic T Lymphocytes (Cytolytic T Cells, CD8 Cells).

Cytolytic T cells are key players in cellular immunity. These cells do not produce antibodies. Rather, they

785

Figure 66-1 **Maturation of blood cells.** With the exception of platelets and erythrocytes, all of the mature blood cells shown participate in immune responses. However, only cells of lymphoid origin (cytolytic T cells, helper T cells, B cells) possess receptors that can recognize specific antigens. (CFU = colony-forming unit.)¹ Monocytes that have moved into tissues are called macrophages.² Basophils that have moved into tissues are called mast cells.

attack and kill target cells directly. Specificity of attack is determined by the presence of antigen molecules on the surface of the target cell and specific receptors for that antigen on the surface of the T cell. Cytolytic T cells are also known as *CD8 cells* and *cytotoxic T cells*. The designation “CD8” refers to the presence of cell-surface marker molecules known as *cell differentiation complex 8*. The “T” in T cell stands for thymus, the organ in which cytolytic T cells and helper T cells mature. Like B cells, cytolytic T cells circulate in the blood and lymph.

67.1.3.3 Helper T Lymphocytes (Helper T Cells, CD4 Cells).

Helper T cells contribute to the immune response in three ways: (1) they have an essential role in antibody production by B cells, (2) they release factors that promote delayed-type hypersensitivity (DTH), and (3) they participate in the activation of cytolytic T cells. Specificity of helper T cells is achieved through highly specific cell-surface receptors that recognize individual antigens. Like other lymphocytes, helper T cells circulate in the blood and lymph. Helper T cells carry CD4 (cell differentiation complex 4) marker molecules on their surface, and hence are referred to as *CD4 cells*.

The term *helper* is somewhat misleading, in that it connotes a useful but dispensable role. Nothing could be further from reality. Helper T cells are not simply nice to have around, they are absolutely required for an effective immune response. The critical nature of their contribution—and the grim consequences of their absence—are manifested in people with HIV/AIDS: Helper T cells are the immune cells that HIV attacks; because of helper T-cell loss, AIDS patients are at high risk of death from opportunistic infection.

67.1.3.4 Macrophages.

Macrophages begin their existence in the bone marrow, enter the blood as monocytes, and then infiltrate tissues, where they evolve into macrophages. Macrophages are present in all organs and tissues.

The primary function of macrophages is *phagocytosis* (ie, ingestion of microbes, other foreign material, and cellular debris). In their role as phagocytes, macrophages are the principal scavengers of the body. Although their major job is phagocytosis, macrophages also have an important role in specific acquired immunity, natural immunity, and inflammation.

In specific acquired immunity, macrophages have three functions: (1) they are required for activation of T cells (both helper T cells and cytolytic T cells), (2) they are the final mediators of DTH, and (3) they phagocytize cells that have been tagged with antibodies. Of these three immune-related roles, activation of T cells is arguably the most critical. When performing this function, macrophages are referred to as *antigen-presenting cells* (APCs). Because antigen presentation is an absolute requirement for a specific immune response to occur (see below), we can appreciate how important macrophages are.

786

787

TABLE 66-1 Cells of the Immune System

Cell Type	Synonyms	Primary Immune-Related Actions
Major Cell Types		
B lymphocytes	B cells	• Produce antibodies
Cytolytic T lymphocytes (CTLs)	Cytolytic T cells, cytotoxic T cells, CD8 cells	• Lyse target cells
Helper T lymphocytes	Helper T cells, CD4 cells	• Promote proliferation and differentiation of B cells and CTLs • Initiate delayed-type hypersensitivity
Macrophages		• Promote proliferation and differentiation of helper T cells and CTLs by serving as antigen-presenting cells • Participate in delayed-type hypersensitivity • Phagocytize cells tagged with antibodies • Phagocytize cells in the effector stage of delayed-type hypersensitivity
Dendritic cells		• Promote proliferation of cytolytic T cells and helper T cells by serving as antigen-presenting cells
Accessory Cells		
Mast cells		• Mediate immediate hypersensitivity reactions
Basophils		• Mediate immediate hypersensitivity reactions
Neutrophils	Polymorphonuclear leukocytes	• Phagocytize foreign particles (eg, bacteria), especially those tagged with IgG • Mediate inflammation
Eosinophils		• Attack helminths and foreign particles that have been coated with IgE • Contribute to immediate hypersensitivity reactions
IgE = immunoglobulin E, IgG = immunoglobulin G.		

67.1.3.5 Dendritic Cells.

Dendritic cells perform the same antigen-presenting task as do macrophages. However, unlike macrophages, dendritic cells do not also serve as scavengers. Dendritic cells are found in lymph nodes and other lymphoid tissues.

67.1.3.6 Mast Cells and Basophils.

These cells mediate immediate hypersensitivity reactions. Mast cells, which are derived from basophils, are concentrated in the skin and other soft tissues; basophils circulate in the blood. Both cell types release histamine, heparin, and other compounds that cause the symptoms of immediate hypersensitivity. Release of these mediators is triggered when an antigen binds to antibodies on the cell surface. The role of mast cells and basophils in allergic reactions is discussed further in [Chapter 69](#) (Antihistamines).

67.1.3.7 Neutrophils.

Neutrophils, also known as *polymorphonuclear leukocytes*, phagocytize bacteria and other foreign particles. As discussed below, neutrophils avidly devour cells that have been tagged with antibodies of the immunoglobulin G (IgG) class. Accordingly, neutrophils can be viewed as important effectors in humoral immunity. Neutrophils are also major contributors to inflammation.

67.1.3.8 Eosinophils.

Eosinophils attack and destroy foreign particles that have been coated with antibodies of the immunoglobulin E (IgE) class. Their usual target is helminths (parasitic worms). Eosinophils also contribute to tissue injury and inflammation associated with immediate hypersensitivity reactions.

67.1.4 Antibodies

Antibodies are a family of structurally related glycoproteins that mediate humoral immunity. The most characteristic feature of antibodies is their ability to recognize and bind with specific antigens. Alternative names for antibodies are *immunoglobulins* and *gamma globulins*.

All antibodies are produced by B lymphocytes. Some of the antibodies that B cells produce are retained on the surface of the B cell, where they serve as the receptors whereby B cells recognize specific antigens. However, most of the antibodies that B cells produce are secreted from the cell,

after which they bind to their specific antigen, thereby initiating the effector phase of humoral immunity. The process of antibody production is discussed in detail below.

All antibodies are composed of units that have the same basic structure. As shown in [Figure 66-2](#), antibodies have four chains: two heavy chains and two light chains. Disulfide bridges connect the four chains to form a unit. Each heavy chain and each light chain has two regions, one in which the sequence of amino acids is *constant* and one in which the sequence is highly *variable*. The variable regions form the antigen-binding site.

There are five classes of antibodies (immunoglobulins), known as IgA, IgD, IgE, IgG, and IgM. All are constructed from the same basic parts just described. However, the heavy chains differ for each class. Primary functions of the five classes are summarized in [Table 66-2](#).

When antibodies are subjected to digestion by papain in the laboratory, they break down into three pieces (see [Fig. 66-2](#)). Two of the pieces retain the ability to bind antigen, and hence are called *Fab fragments* (fragment, antigen binding).

787

788

Figure 66-2 Antibody structure. The basic antibody structure depicting heavy and light chains is shown on the left. Variable regions of the heavy and light chains, which form the antigen-binding site, appear in green. As shown on the right, papain digestion of antibodies produces two types of fragments: Fab fragments, which retain the ability to bind antigen, and Fc fragments, which do not bind antigen and tend to crystallize in the test tube.

Pharmacology for Nursing Care, 7th Edition

The third piece does not bind antigen and tends to form crystals in the test tube, and hence is called the *Fc fragment* (fragment, crystalline).

TABLE 66-2 Functions of Antibody Classes

Class	Function
IgA	• Located in mucous membranes of the GI tract and lungs and in many secretions, where it serves as the first line of defense against microbes entering the body via these routes • Transferred to infants via breast milk; is not absorbed from the GI tract but does protect the infant against microbes <i>in</i> the GI tract
IgD	• Found only on the surface of mature B cells, where it serves as a receptor for antigen recognition (along with IgM)
IgE	• Binds to the surface of mast cells; subsequent binding of antigen to IgE stimulates release of histamine, heparin, and other mediators from the mast cells, thereby causing symptoms of allergy (eg, hives, hay fever) • Binds to parasitic worms, after which eosinophils bind to IgE and release compounds that lyse the worms
IgG	• Produced in copious amounts in response to antigenic stimulation, and hence is the major antibody in blood • Fixes complement and thereby promotes target-cell lysis • Binds target cells and thereby enhances phagocytosis • Transferred across the placenta to the fetal circulation, thereby providing neonatal immunity
IgM	• First class of antibody produced in response to an antigen • Fixes complement and thereby promotes target-cell lysis • Present on the surface of mature B cells, where it serves as a receptor for antigen recognition (along with IgD)

67.1.5 Antigens

Antigens are molecules that induce specific immune responses and, as a result, become the targets of those responses. By way of analogy, an antigen is like the child who pokes a stick in a hornet's nest, at once triggering a response and becoming its target. An antigen may trigger production of antibodies, cytotoxic T cells, or both—all of which can then attack the antigen.

Most antigens are large molecules. Because antigens are big, the antigen-binding region of the resultant antibodies cannot recognize and bind the entire antigen molecule. Rather, the antibodies recognize and bind selected small portions of the antigen, referred to as *epitopes* or *antigenic*

determinants. All antigens have multiple epitopes. As a result, more than one antibody can bind the antigen.

In research and in clinical practice, we may want to generate antibodies to molecules that are too small to induce an immune response. To overcome this obstacle, we can link the small molecule to a larger molecule, usually a protein. When this is done, the small molecule is referred to as a *hapten*, and the large molecule is referred to as a *carrier*. At least some of the resultant antibodies will be selective for the hapten.

67.1.6 Characteristic Features of Immune Responses

Cell-mediated immunity and humoral immunity share five characteristic features: specificity, diversity, memory, time limitation, and selectivity for antigens of nonself origin (ie, the ability to discriminate between self and nonself).

67.1.6.1 Specificity.

Cell-mediated and humoral immune responses are triggered by specific antigens, and their purpose is to destroy the antigen that triggered the response. The ability to respond to a specific antigen (ie, the ability to make subtle distinctions among related molecules) is conferred by highly specific receptors on B cells and T cells.

67.1.6.2 Diversity.

Our immune systems can respond to millions of different antigenic determinants. This is possible because our immune systems have millions of clones of B and T lymphocytes—each of which is preprogrammed to recognize a different antigenic determinant. As noted, this ability to discriminate between antigens is the result of having unique cell-surface receptors.

67.1.6.3 Memory.

Exposure to an antigen affects the immune system such that re-exposure produces a faster, larger, and more prolonged response than did the initial exposure ([Fig. 66-3](#)). Why does this happen? Because during the initial response,

788

Figure 66-3 Memory and time limitation of immune responses.

After the initial exposure to antigen X, antibody levels rise slowly, peak at a low level, and then decline rapidly. After the second exposure to antigen X, antibody levels rise more rapidly, reach a higher peak, persist longer, and then slowly decline.

B and T lymphocytes that recognize the antigen undergo proliferation. Most of the new cells participate in the attack against the antigen. However, some of the new cells become *memory cells*, thereby increasing the pool of antigen-specific cells available to respond in the future. Hence, when the antigen is encountered again, the memory cells mobilize, and thereby accelerate and intensify the response.

67.1.6.4 Time Limitation.

As indicated in [Figure 66-3](#), immune responses don't last indefinitely. Rather, they are time limited. The reasons are twofold. First, as the immune response proceeds, it greatly decreases the level of antigen that initiated the response, thereby attenuating the stimulus for continuing. Second, activated B cells and T cells only function for a short time, after which they become

quiescent or die. Hence, in the absence of a continuing stimulus to generate more active B cells and T cells, the immune response fades.

67.1.6.5 Selectivity for Antigens of Nonself Origin.

Under normal conditions, our immune systems target only foreign antigens, leaving potentially antigenic molecules on our own cells untouched. Sparing of self is possible because, as T cells develop in the thymus, cells that are able to react with antigens of self origin are eliminated. As discussed below, this discrimination between self and nonself is made possible by *major histocompatibility complex* (MHC) molecules.

When the ability to discriminate between self and nonself fails, our immune systems can attack our own cells. The result is an *autoimmune disease*. There are many diseases of autoimmune origin, including psoriasis, multiple sclerosis, rheumatoid arthritis, myasthenia gravis, type 1 diabetes, systemic lupus erythematosus, two inflammatory bowel diseases (ulcerative colitis and Crohn's disease), and two thyroid diseases (Graves' disease and Hashimoto's thyroiditis).

67.1.7 Phases of the Immune Response

Specific immune responses can be viewed as having three main phases: recognition, activation, and effector.

67.1.7.1 Recognition Phase.

The recognition phase occurs when a mature lymphocyte encounters its matching antigen. All specific immune responses begin with antigen recognition by B cells and T cells. Antigen recognition is possible because of antigen-specific receptors on the lymphocyte surface.

67.1.7.2 Activation Phase.

Antigen recognition causes the lymphocyte involved to become activated. The activated lymphocyte then undergoes proliferation and differentiation. Some of the daughter cells differentiate into cells that actively participate in the immune response, attacking the source of the antigen. Other daughter cells differentiate into memory cells, thereby preparing the host for a more intense, rapid, and prolonged response in the event of antigen re-exposure.

67.1.7.3 Effector Phase.

In this stage, the immune system attempts to eliminate the specific antigen that initiated the response. With cell-mediated or antibody-mediated immunity, several effector mechanisms can be involved. In cell-mediated immunity, antigen-bearing cells can be lysed by cytolytic T cells,

or they can be ingested by macrophages. In antibody-mediated immunity, target cells may be primed for attack by phagocytes or by the complement system.

67.1.8 Major Histocompatibility Complex Molecules

The *major histocompatibility complex* is a group of *genes* that codes for *MHC molecules*, which become expressed on the surface of all cells. MHC molecules are critical to immune system function. They play a key role in the activation of helper and cytotoxic T lymphocytes; they guide cytotoxic T lymphocytes toward target cells; and they provide the basis for distinguishing between self and nonself.

There are two classes of MHC gene products, referred to as *class I MHC molecules* and *class II MHC molecules*. Class I MHC molecules are found on virtually all cells except erythrocytes; class II MHC molecules are found primarily on B cells and antigen-presenting cells (macrophages and dendritic cells). As discussed below, *class I MHC molecules* on the surface of antigen-presenting cells (APCs) help initiate immune responses by “presenting” antigen to *cytotoxic T cells*. In contrast, *class II MHC molecules* on the surface of APCs help initiate immune responses by presenting antigen to *helper T cells*.

As a rule, the sequence of amino acids in MHC molecules produced by one individual differs from the sequence of amino acids in MHC molecules produced by everyone else. That is, it is rare for two individuals to have MHC molecules that are identical. As a result, MHC molecules from one individual are recognized as foreign (nonself) by the immune systems of nearly everyone else. Hence, when we attempt to transplant organs between individuals who are not identical twins, immune rejection of the transplant is likely. To reduce the risk of rejection, we can treat patients with immunosuppressants (see [Chapter 68](#)).

67.1.9 Cytokines, Lymphokines, and Monokines

The terms *cytokine*, *lymphokine*, and *monokine* are encountered frequently when discussing the immune system and can be a source of confusion. Accordingly, clarification is in order. The term *cytokine* refers to any mediator molecule (other than an antibody) released by *any* immune-system cell. A *lymphokine* is simply a cytokine released by a *lymphocyte*, and a *monokine* is simply a cytokine released by a *mononuclear phagocyte* (monocyte or macrophage). Put another way, *cytokine* is a generic term for the whole class of nonantibody mediators released by immune cells, whereas the terms *lymphokine* and *monokine* are more restrictive, referring only to nonantibody mediators released by lymphocytes and mononuclear phagocytes, respectively. Examples of cytokines and their functions are listed in [Table 66-3](#).

789

790

TABLE 66-3 Functions of Selected Cytokines

Cytokine	Function
Interleukin-1	Stimulates lymphocyte progenitor cells
Interleukin-2	Stimulates proliferation and differentiation of helper T cells and cytolytic T cells
Interleukin-3	Stimulates proliferation of bone marrow lineage cells, B cells, and T cells
Interleukin-4	Activates B cells, T cells, and macrophages
Interleukin-5	Stimulates generation of eosinophils
Interleukin-6	Stimulates proliferation of bone marrow cells and plasma cells
Interleukin-7	Stimulates B cells and T cells
Interleukin-8	Attracts neutrophils, B cells, and T cells
Interleukin-9	Stimulates proliferation of mast cells
Interleukin-10	Inhibits some T cells
Interleukin-11	Enhances actions of interleukin-3
Interleukin-12	Enhances actions of interleukin-2
Interferon alpha	Activates macrophages, cytolytic T cells, and natural killer cells
Interferon gamma	Activates macrophages and T cells and enhances expression of MHC molecules
Tumor necrosis factor	Kills tumor cells; promotes inflammation
Granulocyte-macrophage colony-stimulating factor	Stimulates proliferation of monocytes, macrophages, and granulocytes (neutrophils, eosinophils, basophils)
MHC = major histocompatibility complex.	

^{67.2} ANTIBODY-MEDIATED (HUMORAL) IMMUNITY

As noted, there are two types of immune responses: humoral immunity and cell-mediated immunity. In this section, we review humoral immunity, focusing on (1) how antibodies are produced and (2) the mechanisms by which antibodies protect us. Cell-mediated immunity is discussed in the section that follows.

^{67.2.1} Production of Antibodies

Antibody production requires the cooperative interaction of three types of cells: *B cells*, which actually make the antibodies; *helper T cells* (CD4 cells), which stimulate the B cells; and an *antigen-presenting cell* (either a macrophage or a dendritic cell), which activates the CD4 cells so that they can then help the B cells. The major steps in the process are depicted in [Figure 66-4](#).

67.2.1.1 Overview of Antibody Production

As indicated in [Figure 66-4](#), production of antibodies begins with binding of a specific antigen (Ag) to two types of cells: a virgin B cell and an APC. The APC may be either a macrophage or a dendritic cell. After processing the Ag, the APC is able to bind with a specific CD4 cell, thereby causing the CD4 cell to proliferate and differentiate into active CD4 cells and memory CD4 cells. The active CD4 cells then bind with processed Ag on B cells, thereby causing the B cells to proliferate and differentiate into (1) plasma cells, which manufacture the antibodies; and (2) memory B cells, which await the next Ag exposure.

67.2.1.2 Specific Cellular Events in Antibody Production

67.2.1.2.1 B Cells.

Participation of B cells in the immune response begins with recognition and binding of a *specific antigen*. The receptor that B cells employ for antigen recognition is actually an antibody (IgD or IgM). For any given B cell, this antibody (receptor) is highly specific for just one antigenic determinant. After the antigen binds the B-cell receptor, the receptor-antigen complex is internalized and the antigen is broken down into small peptide fragments. Each fragment is then complexed with a *class II MHC molecule*, after which the *MHC II–antigen complexes* are transported to the cell surface. (In [Figure 66-4](#), only one such complex is shown. However, in a real cell, many such complexes, each with a different piece of the antigen, would appear on the cell surface.) The final step of B-cell activation occurs when a CD4 helper T cell recognizes and binds with an MHC II–antigen complex on the B cell. This binding causes the CD4 cell to secrete cytokines, which then stimulate the B cell to proliferate and differentiate into two types of cells: plasma cells and memory B cells. The plasma cells are the cells that make antibodies; the memory cells serve to hasten, intensify, and prolong the immune response if antigen exposure should recur.

67.2.1.2.2 Antigen-Presenting Cells.

APCs are essential for activation of CD4 helper T cells. Why? Because CD4 cells cannot recognize antigen that is free in solution. Rather, they can only recognize antigen that has been complexed with an MHC II molecule.

Participation of APCs in the immune response begins with nonspecific binding of antigen to the APC (see [Fig. 66-4](#)). Next, as in B cells, the antigen is internalized and broken into fragments, which are then complexed with MHC II molecules and transported to the cell surface, where they are available for interaction with CD4 cells.

67.2.1.2.3 Helper T Cells (CD4 Cells).

The job of CD4 cells in humoral immunity is to activate B cells. In the absence of activation by CD4 cells, B cells are unable to proliferate and produce antibodies.

Participation of CD4 cells in the immune response begins when these cells bind with an MHC II–antigen complex on the surface of an APC. Binding is mediated by a receptor on the CD4 cell that is specific for the particular antigen in the MHC II–antigen complex. (As noted, in order for the CD4 cell to recognize the antigen, the antigen must be complexed with an MHC II molecule, which is why the APC is essential for CD4 cell activation.) Upon binding with the MHC II–antigen complex, the CD4 cell releases cytokines, which then cause the CD4 cell itself to proliferate and differentiate into memory CD4 cells and activated CD4 cells. The activated CD4 cells then bind with their corresponding MHC II–antigen complexes on B cells, release cytokines, and thereby cause proliferation and differentiation of the B cells.

790

791

Figure 66-4 Major events in antibody-mediated (humoral) immunity. Humoral immunity requires three types of cells: B cells, APCs, and helper T cells (CD4 cells). Binding of a CD4 cell with an APC activates the CD4 cell, which then binds with a B cell and releases cytokines, which then stimulate the B cell. (Ag = antigen, APC = antigen-presenting cell [macrophage or dendritic cell], Ig = immunoglobulin [antibody], MHC II = class II MHC molecule.)

67.2.2 Antibody Effector Mechanisms

Antibodies are simply molecules with the ability to bind to other molecules. Antibodies have no special destructive powers. Hence, in order to rid the body of antigens, which is what antibodies are for, antibodies usually work in conjunction with other factors, namely, *phagocytic cells* and the *complement system*. The only antigens that antibodies can neutralize without help are bacterial toxins and viruses.

67.2.2.1 Opsonization of Bacteria

One mechanism for ridding the body of pathogenic bacteria is phagocytosis by macrophages and neutrophils. However, because of their structures, some bacteria are difficult for phagocytes to grab hold of, and hence are resistant to ingestion. Antibodies help promote phagocytosis of these bacteria by acting as *opsonins*. (An opsonin is a molecule that binds to a bacterium or other target particle and thereby promotes phagocytosis by providing a handle for phagocytes to grab.)

Bacterial opsonization by antibodies occurs in two steps. First, the antigen-binding region of the antibody binds with antigen on the bacterial surface, which leaves the Fc portion of the antibody projecting away from the surface. Second, phagocytes link up with the Fc portion of the antibody, which brings them in close contact with the bacterium, and hence enables them to commence phagocytosis. Phagocytes are able to bind the Fc fragment because they have high-affinity receptors for Fc on their surface. Most of the antibodies that act as opsonins belong to the IgG class.

67.2.2.2 Activation of the Complement System

The complement cascade is a complex system consisting of at least 20 serum proteins that, when activated, can cause multiple effects, including cell lysis, opsonization, degranulation of mast cells, and infiltration of phagocytes. The system can be activated in two ways, known as the *classical pathway* and the *alternative pathway*. The classical pathway is activated by *antibodies*; the alternative pathway is not. However, with both pathways, the end results are essentially the same. Consideration here is limited to the classical pathway.

The classical pathway is turned on when C1 (the first component of the complement system) encounters an antigen-antibody complex and then binds with the Fc region of the antibody. C1 will not bind with antibody that is free in solution; as a result, free antibodies cannot activate the system. Activation of the complement system triggers a cascade of reactions that amplify the response at each stage. The result is production of compounds that can injure target cells.

791

792

Lysis of target cells that have been tagged with antibodies is the most dramatic effect of the complement system. Lysis is caused by cylindrical *membrane attack complexes*, which are formed by the complement cascade. Following their insertion into the target cell membrane, the attack complexes act as pores through which fluid can enter the cell. Fluid influx causes the cell to swell and then burst.

67.2.2.3 Neutralization of Viruses and Bacterial Toxins

Neutralization of toxins and viruses is the only protective action that antibodies can perform unassisted. In order to hurt us, bacterial toxins must first bind with receptors on our cells. Likewise, in order to infect us, viruses must first bind with cell-surface receptors. By binding with antigenic determinants on toxins and viruses, antibodies make it impossible for toxins and viruses to bind with cellular receptors. As a result, these agents can no longer hurt us.

67.3 CELL-MEDIATED IMMUNITY

Cell-mediated immunity has two branches, one mediated by *helper T lymphocytes* (CD4 cells) plus *macrophages*, and one mediated primarily by *cytolytic T lymphocytes* (CD8 cells). In the branch mediated by CD4 cells and macrophages, the result is called *delayed-type hypersensitivity*. In the branch mediated by CD8 cells, the result is *target-cell lysis*.

67.3.1 Delayed-Type Hypersensitivity

The object of delayed-type hypersensitivity (DTH) is to rid the body of bacteria that replicate primarily within macrophages (eg, *Listeria monocytogenes*, *Mycobacterium tuberculosis*). For DTH to occur, two cells are needed: an *infected macrophage* and a *CD4 helper T cell*. The macrophage serves to activate the CD4 cell, which in turn activates the macrophage, thereby enabling the macrophage to kill the bacteria residing within. Hence, the same cell (ie, the macrophage) is both the activator of the CD4 cell and the recipient of the activated CD4 cell's help.

67.3.1.1 Activation of Helper T Cells.

Activation of CD4 cells in DTH is essentially identical to the activation of CD4 cells in humoral immunity. As shown in [Figure 66-5](#), the process begins when a macrophage becomes infected with intracellular bacteria. As in humoral immunity, the macrophage breaks down the antigen to small peptides, combines each peptide with a class II MHC molecule, and then presents the antigen–MHC II complexes on its surface. In the next step, a CD4

Figure 66-5 **Cell-mediated immunity: delayed-type hypersensitivity.** DTH requires two cells: an infected macrophage and a CD4 cell. Binding of the CD4 cell to the macrophage activates the CD4 cell, which then releases interferon gamma and several cytokines. Interferon gamma activates the macrophage. The cytokines cause the CD4 cell to proliferate and differentiate into memory cells. (Ag = antigen, MHC II = class II MHC molecule.)

cell binds with an antigen–MHC II complex on the macrophage. As discussed above, selectivity of binding is determined by receptors on the CD4 cell that recognize a specific antigen fragment—but only when the fragment is bound to a class II MHC molecule. Binding of the CD4 cell with the APC causes the CD4 cell to release (1) cytokines that cause the CD4 cell itself to proliferate and differentiate into memory cells and (2) mediators of DTH, including interferon gamma and tumor necrosis factor.

67.3.1.2 Activation of Macrophages.

Interferon gamma, released from the activated CD4 cell, is the major stimulus for macrophage activation. In response to interferon gamma, macrophages increase production of lysosomes and reactive oxygen. The reactive oxygen is ultimately responsible for killing bacteria inside the macrophage. In addition to ridding macrophages of bacteria, DTH produces local inflammation.

67.3.2 Cytolytic T Lymphocytes

Cytolytic lymphocytes (CTLs, CD8 cells) kill other cells. Their principal job is to kill self cells that are infected with viruses, thereby halting viral replication. In addition, CTLs participate in rejection of transplants. In this chapter, discussion is limited to killing virally infected cells.

The process by which CTLs kill other cells has two stages: activation of CTLs, followed by recognition and killing of the target cell. The overall process is depicted in [Figure 66-6](#).

67.3.2.1 Activation of Cytolytic T Cells.

Activation of CTLs requires the participation of an *antigen-presenting cell* and a *helper T cell* (CD4 cell). The process is very similar to the activation of CD4 cells discussed above. However, there is one important difference: Whereas CD4 cells specifically recognize antigen that is bound to a *class II* MHC molecule on an APC, CTLs specifically recognize antigen that is bound to a *class I* MHC molecule on an APC.

Figure 66-6 Cell-mediated immunity: cytolytic T cells. This branch of cell-mediated immunity requires three types of cells: CTLs, APCs, and CD4 cells. Binding of the CTL with the APC begins the activation of the CTL. Stimulation of the CTL by cytokines from the CD4 cell completes the activation of the CTL, which then binds with and kills its target. Activation of the CD4 cells, which is not shown, takes place essentially as depicted in [Figures 66-4](#) and [66-5](#). (Ag = antigen, APC = antigen-presenting cell, CTL = cytolytic T lymphocyte, MHC I = class I MHC molecule.)

793

794

In viral infections, activation of CTLs begins with processing of viral antigens by an APC. As shown in [Figure 66-6](#), the APC combines the antigen with a class I MHC molecule and then presents the antigen–MHC I complex on its surface. Next, a pre-CTL binds to the antigen–MHC

I complex. (Like CD4 cells, each pre-CTL has receptors that are specific for a particular antigen–MHC I complex.) Linking of the pre-CTL with the APC primes the pre-CTL for the next stage of activation: stimulation by cytokines (interleukin-2, interferon gamma, and probably others) provided by an activated CD4 cell. (Activation of the CD4 cell, which is not shown in [Figure 66-6](#), occurs when the CD4 cell encounters an APC that has a viral antigen–MHC II complex.) In response to the cytokines released by the CD4 cell, the pre-CTL undergoes proliferation and differentiation into memory CTLs and activated CTLs.

67.3.2.2 Recognition of Virally Infected Target Cells.

CTLs recognize their targets by the presence of an antigen–MHC I complex. This is the same process by which CTLs recognize APCs. As noted earlier, virtually all cells in the body carry class I MHC molecules. (Class II molecules are limited to APCs and B cells.) Hence, when a cell is infected with a virus, viral antigens form intracellular complexes with MHC I molecules, after which the antigen–MHC I complexes are presented on the cell surface. As shown in [Figure 66-6](#), activated CTLs recognize the antigen–MHC I complex, and hence bind with the target cell. Since only cells that are infected with the virus will bear viral antigens on their class I MHC molecules, attack by CTLs is limited to infected cells; all others are spared.

67.3.2.3 Mechanisms of Cell Kill.

Binding of a CTL to its target cell causes the CTL to release mediators that kill the target. Two mechanisms of cell kill are involved: *lysis* and *apoptosis* (programmed cell death). The mediator of lysis is called *perforin*, a molecule that forms pores in the target-cell membrane; the resultant influx of fluid causes the cell to swell and then burst. (This mechanism is very similar to one by which the complement system causes cell lysis.) The mediators of apoptosis have not been identified with certainty. However, their effects are very clear. The initial effect is activation of intracellular enzymes that digest the cell's own DNA. This is followed by fragmentation of the nucleus and cell death. Only the target cell is harmed; bystander cells and the CTL itself are not touched. In fact, after releasing its mediators, the CTL disconnects from the doomed target and goes on to seek another victim.

67.3.2.3.1

KEY POINTS

- The immune system helps us by attacking invading organisms (viruses, bacteria, fungi, and parasites) and cancer cells. The immune system can hurt us by attacking transplants and our own healthy cells.
- There are two basic types of immune responses: natural immunity (native or innate immunity) and specific acquired immunity.

- There are two types of specific acquired immunity: cell-mediated immunity and antibody-mediated (humoral) immunity.
- The immune system has five major types of cells: B lymphocytes (B cells), helper T lymphocytes (CD4 cells), cytolytic T lymphocytes (CD8 cells, CTLs), macrophages, and dendritic cells.
- Only lymphocytes have receptors that can recognize specific antigens.
- B cells make antibodies.
- CTLs kill target cells directly.
- Helper T cells are essential for the activation of B cells, CTLs, and the macrophages involved in delayed-type hypersensitivity (DTH).
- Macrophages have three functions in specific immunity: (1) they serve as antigen-presenting cells (APCs) in the activation of helper T cells and CTLs, (2) they are involved in DTH, and (3) they phagocytize opsonized cells in humoral immunity.
- Like macrophages, dendritic cells serve as APCs.
- An antigen is a molecule that triggers a specific immune response, and then becomes the target of that response.
- Most antigens are large molecules.
- Antibodies bind to specific, small regions of an antigen, referred to as epitopes or antigenic determinants.
- The major histocompatibility complex (MHC) is a group of genes that codes for MHC molecules, which are found on the surface of cells.
- MHC molecules have three major functions: (1) they play a key role in the activation of helper T cells and CTLs, (2) they guide CTLs toward target cells, and (3) they provide the basis for distinguishing between self and nonself.
- Class II MHC molecules are found only on B cells and APCs, whereas class I MHC molecules are found on virtually all cells (including B cells and APCs).
- It is rare for two individuals to have MHC molecules that are precisely the same. As a result, MHC molecules from one individual are usually recognized as foreign (nonself) by the immune systems of everyone else.

- A cytokine is defined as any mediator molecule (other than an antibody) released by any immune-system cell.
- The most characteristic feature of antibodies is their ability to recognize specific antigens.
- Antibody production requires the cooperative interaction of three types of cells: B cells, which make the antibodies; helper T cells (CD4 cells), which stimulate the B cells; and APCs, which activate the CD4 cells so that they can then activate B cells.
- B cells have antibodies on their surface that serve as receptors for recognizing specific antigens. Binding of the antigen to the receptor is the first step in B-cell activation.
- Activation of B cells is completed when a CD4 cell binds with an MHC II–antigen complex on the B cell and then releases cytokines, which then stimulate the B cell.
- In order to activate a B cell, a CD4 cell must first become activated itself. CD4 activation is initiated by binding of the CD4 cell with an MHC II–antigen complex on an APC.
- Antibodies eliminate antigens by three mechanisms: (1) direct neutralization of toxins and viruses, (2) opsonization of bacteria, and (3) activation of the complement system.

794

795

- Opsonization (coating bacteria with antibodies) helps macrophages and neutrophils grab onto bacteria, and thereby facilitates phagocytosis.
- The complement system forms pores in the bacterial cell membrane, thereby promoting death by lysis.
- Cell-mediated immunity can result in delayed-type hypersensitivity (DTH) and lysis of target cells by CTLs.
- DTH involves two types of cells: an infected macrophage and a CD4 cell. The macrophage activates the CD4 cell, which then releases interferon gamma, which in turn stimulates the macrophage, thereby enabling the macrophage to kill the bacteria inside it.
- The major role of CTLs is to kill self cells that have become infected with viruses.

- Activation of CTLs proceeds in two steps: first, the CTL binds to an APC; second, the CTL is stimulated by cytokines provided by a CD4 cell.
- Binding of CTLs with APCs differs from binding of CD4 cells with APCs in that CTLs specifically recognize antigen that is bound to a class I MHC molecule on the APC, whereas CD4 cells specifically recognize antigen that is bound to a class II MHC molecule.
- CTLs kill target cells in two ways: (1) they release perforin, which creates pores in the cell, thereby causing death by lysis; and (2) they release compounds that cause apoptosis (programmed cell death).
- Activated CTLs attack only self cells that have MHC I–antigen complexes; all other self cells, including the CTLs, are spared.
- Specific immune responses result in production of memory T cells and memory B cells. As a result, the next time an antigen is encountered, the immune response occurs faster and with greater intensity.

⁶⁸CHAPTER 67 Childhood Immunization

The purpose of immunization is to protect against infectious diseases. As a result of widespread immunization, the incidence of several infectious diseases has been dramatically reduced, and one disease—smallpox—has been eliminated from the planet.

Experience has shown that the most effective way to reduce vaccine-preventable diseases (VPDs) is to create a highly immune population. Accordingly, universal vaccination is a national goal. Although immunization carries some risk, the risks from failing to vaccinate are much greater.

In this chapter, discussion is limited to childhood immunization. [Appendix A](#) addresses vaccines for adult immunization. [Chapter 109](#) (Potential Weapons of Biologic, Radiologic, and Chemical Terrorism) addresses vaccines for anthrax and smallpox. And [Chapter 92](#) (Antiviral Agents I: Drugs for Non-HIV Viral Infections) addresses a vaccine for avian flu.

^{68.1}GENERAL CONSIDERATIONS

^{68.1.1}Definitions

In order to discuss immunization, we need to use special terminology. Accordingly, we begin the chapter by defining some terms.

^{68.1.1.1}Vaccine.

A vaccine is a preparation containing whole or fractionated microorganisms. Administration causes the recipient's immune system to manufacture antibodies directed against the microbe from which the vaccine was made. Most of the preparations discussed in this chapter are vaccines.

^{68.1.1.2}Killed Vaccines Versus Live Vaccines.

There are two major classes of vaccines: killed and live (albeit attenuated). Killed vaccines are composed of whole, killed microbes or isolated microbial components (eg, the polysaccharide of *Haemophilus influenzae* type b or the surface antigen of hepatitis B). In contrast, live, attenuated vaccines are composed of live microbes that have been weakened or rendered completely avirulent. Live vaccines can be dangerous in recipients who are immunocompromised. Why? Because these people are unable to mount an effective immune response, even against an avirulent organism.

68.1.1.3 Toxoid.

A toxoid is a bacterial toxin that has been changed to a nontoxic form. Administration causes the recipient's immune system to manufacture antitoxins (ie, antibodies directed against the natural bacterial toxin). Antitoxins protect against injury from toxins, but do not kill the bacteria that produce them. In this chapter, only two toxoids are considered: tetanus toxoid and diphtheria toxoid.

68.1.1.4 Vaccination.

The terms *vaccination* and *vaccine* derive from *vaccinia*, a virus whose name in turn derives from *vacca* (Latin for cow). At one time, vaccinia virus was used as a vaccine against smallpox. (Vaccinia itself causes cowpox—a mild sickness—and in the process induces synthesis of smallpox antibodies.) Hence, when the term *vaccination* was originally coined, it had the limited meaning of giving vaccinia to generate immunity against smallpox. Today, vaccination refers broadly to administration of any vaccine or toxoid.

68.1.1.5 Immunization: Active Versus Passive.

Immunization is a more inclusive term than *vaccination*, in that immunization refers to production of both active immunity and passive immunity, whereas vaccination refers only to production of active immunity.

796

TABLE 67-1 Impact of Vaccination on the Incidence of Some Vaccine-Preventable Diseases in the United States

	Prevaccine Era: Peak Number of Cases (Year the Peak Occurred)	Vaccine Era: Number of Cases Reported in 2006	Percentage Decrease in Cases Vaccine Introduced Before 1980
Vaccine Introduced Before 1980			
Diphtheria	30,508 (1938)	0	100
Smallpox	110,672 (1920)	0	100
Poliomyelitis (wild)	21,269 (1952)	0	100
Rubella	488,796 (1964)	11	99.99
Measles	763,094 (1958)	55	99.99
Mumps	212,932 (1964)	6584	96.91
Pertussis	265,269 (1934)	15,632	94.11
Tetanus	601 (1948)	41	93.18
Vaccine Introduced Between 1980 and 2005			
Varicella (chickenpox)	5,358,595* (1988)	48,445	99.10
Hepatitis A	254,518* (1971)	3579	98.59
Acute hepatitis B	74,361* (1985)	4713	93.66
Invasive <i>Haemophilus influenzae</i> type B	20,000* (1984)	208	98.96
Invasive pneumococcal disease	64,400* (1999)	5169	91.97
Data from Roush SW, Murphy TV, and the Vaccine-Preventable Disease Table Working Group: Historical comparisons of morbidity and mortality for vaccine-preventable diseases in the United States. JAMA 298:2155–2163, 2007.			

* Estimated peak number.

Active immunity develops in response to infection or to administration of a vaccine or toxoid. In either case, the result is endogenous production of antibodies. Active immunity takes weeks or months to develop, but is long lasting. Discussion in this chapter is limited almost exclusively to active immunization.

Passive immunity is conferred by giving a patient *preformed* antibodies (immune globulins). Unlike active immunity, passive immunity protects immediately, but persists only as long as the antibodies remain in the body.

68.1.1.6 Specific Immune Globulins.

These preparations contain a high concentration of antibodies directed against a specific antigen (eg, hepatitis B virus). Administration provides immediate passive immunity. These preparations are made from donated blood and do not transmit infectious diseases.

68.1.2 Public Health Impact of Immunization

Widespread vaccination has had a profound impact on public health. In the United States, vaccination has greatly reduced the incidence of some infectious diseases (eg, pertussis, mumps, tetanus) and virtually eliminated five others: diphtheria, smallpox, poliomyelitis, rubella, and measles ([Table 67-1](#)). With two diseases, results have been even more dramatic: wild-type polio is gone from the Western hemisphere, and smallpox is gone from the planet.

Despite these successes, we still have a long way to go: Although our national vaccination rate is at an all-time high, every year 2.1 million children ages 1 to 3 years receive few or no vaccinations. In some parts of the country, more than 50% of the children are not current. The consequences of failing to vaccinate can be enormous. For example, between 1989 and 1991, a measles epidemic occurred; 55,000 cases were reported, 11,000 people were hospitalized, and more than 130 people died, half of them young children.

The Childhood Immunization Initiative, begun in 1993, is directed at preventing such epidemics in the future. The goal is to eliminate all indigenous cases of diphtheria, measles, rubella, tetanus, and *H. influenzae* type b infection from the United States. The program aims to achieve these goals by improving vaccine delivery systems, increasing community participation, reducing vaccine costs to parents, developing safer and simpler vaccines, and involving more federal agencies in providing vaccines to populations who otherwise might not have access to them. Thanks to these strategies, three of these diseases—diphtheria, rubella, and measles—are virtually gone from this country.

From a strictly economic viewpoint, vaccination is a sound investment. On average, we save \$14 in future healthcare costs for each dollar we spend on vaccination.

68.1.3 Reporting Vaccine-Preventable Diseases

Public health officials rely on healthcare providers to report cases of VPDs. Nearly all VPDs that occur in the United States are notifiable. Healthcare providers should report individual cases to their local or state health department. Each week, the state health departments make a report to the Centers for Disease Control and Prevention (CDC). The information gathered is used to (1) determine if an outbreak is occurring, (2) evaluate prevention and control strategies, and (3) evaluate the impact of national immunization policies and practices.

797

TABLE 67-2 Contraindications That Apply to All Vaccines and Conditions Often Incorrectly Regarded as Contraindications

798

True Contraindications (Vaccine Should Not Be Administered)	Not Contraindications (Vaccine May Be Administered)
Anaphylactic reaction to a specific vaccine:	Mild to moderate local reaction (soreness, erythema, swelling) following a dose of an injectable vaccine
Contraindicates further doses of that vaccine	Mild acute illness with or without low-grade fever
	Diarrhea
Anaphylactic reaction to a vaccine component:	Current antimicrobial therapy
Contraindicates use of all vaccines that contain that substance	Convalescent phase of illnesses
Moderate or severe illnesses with or without a fever	Prematurity (same dosage and indications as for normal, full-term infants)
	Recent exposure to an infectious disease
	Personal or family history of either penicillin allergy or nonspecific allergies

68.1.4 Immunization Records

The National Childhood Vaccine Act of 1986 requires a permanent record of each mandated vaccination a child receives. The information should be recorded in either (1) the permanent medical record of the recipient or (2) a permanent office log or file. The following data are required:

- Date of vaccination
- Route and site of vaccination
- Vaccine type, manufacturer, lot number, and expiration date

- Name, address, and title of the person administering the vaccine

The purpose of these records is twofold. First, they help ensure that children receive appropriate vaccinations. Second, they help avoid overvaccination, and thereby reduce the risk of possible hypersensitivity reactions. To promote uniformity in record keeping, an official immunization card has been adopted by every state and the District of Columbia.

68.1.5 Adverse Effects of Immunization

Vaccines are generally very safe. Mild reactions are common, but serious events are rare. Many children experience local reactions (discomfort, swelling, and erythema at the injection site). Fever is also common. Potential severe effects include anaphylaxis (eg, in response to measles, mumps, and rubella virus vaccine [MMR]); acute encephalopathy (caused by diphtheria and tetanus toxoids and pertussis vaccine [DTP]); and vaccine-associated paralytic poliomyelitis (VAPP) (caused by oral poliovirus vaccine [OPV]).

Immunocompromised children are at special risk from live vaccines. The reason is that, in the absence of an adequate immune response, the viruses or bacteria in these normally safe vaccines are able to multiply in profusion, thereby causing serious infection. Accordingly, live vaccines should generally be avoided in children who are severely immunosuppressed. Causes of immunosuppression include congenital immuno–deficiency, HIV infection, leukemia, lymphoma, generalized malignancy, and therapy with radiation, cytotoxic anticancer drugs, and high-dose glucocorticoids.

Some parents are concerned that *thimerosal*, a mercury-based preservative found in some vaccines, might cause *autism*. For two reasons, this concern is unfounded. First, several large, high-quality studies conducted in Denmark, Britain, and the United States have failed to show a causal link between childhood immunization using thimerosal-containing vaccines and development of autism. Second, thimerosal is being phased out of vaccines made here (owing to concerns about mercury exposure, not concerns about autism). At this time, the amount of thimerosal in most routinely used childhood vaccines is either zero or extremely low (less than 0.5 mcg per 0.5-mL dose). The only exceptions are certain flu vaccines, which still contain thimerosal as a preservative. However, even if these flu vaccines are used, total mercury exposure from childhood vaccination will still be well below the limit considered safe by the Food and Drug Administration (FDA) and the Environmental Protection Agency.

The risk of serious adverse reactions can be minimized by observing appropriate *precautions* and *contraindications*. [Table 67-2](#) lists contraindications that apply to all vaccines. Precautions and contraindications that apply to specific vaccines are discussed in the context of those preparations.

Certain conditions, such as diarrhea and mild illness, may be inappropriately regarded as contraindications by some practitioners. As a result, vaccination may be needlessly postponed. Conditions that are often considered contraindications, although they are not, are also listed in [Table 67-2](#).

Practitioners are required to report certain adverse events to the *Vaccine Adverse Event Reporting System* (VAERS). The information is used to help determine whether (1) a particular event that occurs after vaccination is actually caused by the vaccine, and (2) what the risk factors might be. In addition to reporting events that they are required to report, practitioners should report all other serious or unusual adverse events, regardless of whether they believe the event was caused by the vaccine. Forms for reporting adverse events can be obtained from the VAERS web site (www.vaers.hhs.gov) or by calling 1-800-822-7967.

798

799

The *National Vaccine Injury Compensation Program* (NVICP), established by the *National Childhood Vaccine Injury Act of 1986*, was created to provide compensation for injury or death resulting from vaccination. The program is intended as an alternative to civil litigation in that negligence need not be proved. As a provision of the law, a table was created listing the vaccines covered by the program and the injuries, disabilities, illness, and conditions—including death—for which compensation may be paid. Compensation may also be paid for injuries not listed in the table, provided that (1) a listed vaccine is involved and (2) causality can be demonstrated. Injuries related to vaccines not listed in the table are not covered under the program. Additional information can be obtained by calling the NVICP automated recording at 1-800-338-2382.

68.1.6 Vaccine Information Statements

The National Childhood Vaccine Injury Act requires that Vaccine Information Statements (VISs) be given to all vaccinees (or their parents or legal representatives) before certain vaccines are administered. The VISs, produced by the CDC, are one-page, two-sided documents that describe the benefits and risks of specific vaccines. For vaccines that require a series of shots, a VIS must be given *before each dose*, not just the first dose. The VISs are available in over 30 languages, and can be obtained online at www.cdc.gov/vaccines/pubs/vis/default.htm.

68.1.7 Childhood Immunization Schedule

Each year, the CDC's Advisory Committee on Immunization Practices (ACIP), in cooperation with the American Academy of Family Physicians and the American Academy of Pediatrics, issues revised recommendations for childhood immunization in the United States. [Figures 67-1](#) and [67-2](#) (see pp. 804–805, 806–807) show the recommended schedule for 2009. You can find the catch-up immunization schedule for persons ages 4 months through 18 years and the most recent updates online at www.cdc.gov/vaccines/.

68.2 TARGET DISEASES

Routine childhood vaccination is currently recommended for protection against 16 infectious diseases: diphtheria, tetanus (lockjaw), pertussis (whooping cough), measles, mumps, rubella, invasive *H. influenzae* type b, hepatitis A, hepatitis B, polio, varicella (chickenpox), influenza, invasive pneumococcal disease, meningococcal disease (meningitis), rotavirus gastroenteritis, and genital human papillomavirus infection. In the discussion below, certain VPDs are considered in a group (eg, measles, mumps, rubella). Why? Because vaccination against these VPDs is traditionally done simultaneously using a combination vaccine.

68.2.1 Measles, Mumps, and Rubella

68.2.1.1 Measles.

Measles is a highly contagious viral disease characterized by rash and high fever (103°F to 105°F). Infection is spread by inhalation of aerosolized sputum or by direct contact with nasal or throat secretions. Initial symptoms include fever, cough, headache, sore throat, and conjunctivitis. Three days later, rash develops. Rash begins at the hairline, spreads to the rest of the body in 36 hours, and then fades in a few days. Secondary infections can result in pneumonia and otitis media (inner ear infection). However, of the potential complications of measles, encephalitis is by far the most serious. Sequelae of encephalitis include blindness, deafness, and convulsions. Although encephalitis is rare (0.1% incidence), it carries a 10% risk of death. Thanks to widespread vaccination, measles is rarely seen in the Western hemisphere.

68.2.1.2 Mumps.

Mumps is a viral disease that primarily affects the parotid glands (the largest of the three pairs of salivary glands). Although mumps can occur in adults, it usually occurs in children ages 5 to 15. As a rule, the first symptom is swelling in one of the parotid glands, often accompanied by local pain and tenderness. The patient may also experience fever (100°F to 104°F). Swelling increases for 2 to 3 days and then fades entirely by day 6 or 7. Swelling in the second parotid gland often develops after swelling in the first, but may also occur simultaneously or not at all. Painful *orchitis* (inflammation of the testes) develops in about one-third of adult and adolescent males. Acute *aseptic meningitis* develops in about 10% of all patients; symptoms, which resolve completely, include dizziness, headache, and vomiting. In the United States, the incidence of reported mumps cases has declined from a high of 212,932 in 1984 to only 6584 in 2006.

68.2.1.3 Rubella.

Rubella, also known as German measles, is a generally mild viral infection. However, if it occurs during pregnancy, the consequences can be severe. Initial symptoms include sore throat, mild fever, and swelling in lymph nodes located behind the ears and in the back of the neck. Shortly after, a rash develops on the face and scalp, spreads rapidly to the torso and arms, and then fades in 2 or 3 days. Arthritis may also develop, mainly in women. In pregnant women, rubella can cause miscarriage, stillbirth, and congenital defects, especially if the disease occurs during the first trimester. Possible birth defects include cataracts, heart disease, mental retardation, and hearing loss. In the United States, rubella has been eliminated: Since 2002, all cases reported here have been traceable to foreigners who brought the disease from abroad.

68.2.2 Diphtheria, Tetanus, and Pertussis

68.2.2.1 Diphtheria.

Diphtheria is a potentially fatal infection caused by *Corynebacterium diphtheriae*, a gram-positive bacillus. The bacterium colonizes the throat and nasal passages, and produces a toxin that spreads throughout the body. Initial symptoms include sore throat, fever, headache, and nausea. Colonization of the airway begins as patches of gray or dirty-yellow membrane that eventually grow together, forming a thick coating. This coating, combined with swelling, can impede swallowing and breathing; in severe cases, a tracheostomy is needed. The toxin produced by *C. diphtheriae* can damage the heart and nerves, resulting in heart failure and paralysis. Diphtheria treatment includes giving diphtheria antitoxin and antibiotics (eg, erythromycin, penicillin G). In the United States, only 37 cases were reported between 1980 and 1992. However, of those infected, about 10% died, mainly children and the elderly. In 2006, no cases were reported.

799

68.2.2.2 Tetanus (Lockjaw).

Tetanus, also known as lockjaw, is a frequently fatal disease characterized by painful spasm of all skeletal muscles. The cause is a potent endotoxin elaborated by *Clostridium tetani*, a gram-positive bacillus. Infection with *C. tetani* typically results from puncturing the skin with a nail, splinter, or other object that is contaminated with soil, street dust, or animal or human feces. The first symptom is often stiffness of the jaw, hence the name *lockjaw*. As infection progresses, the patient may experience stiff neck, difficulty swallowing, restlessness, irritability, headache, chills, fever, and convulsions. Eventually, spasm develops in muscles of the abdomen, back, neck, and face. The case fatality rate is 21%. The yearly incidence of tetanus peaked at 601

800

cases in 1948, but was only 41 cases in 2006. Treatment options include tetanus antitoxin, a booster dose of tetanus toxoid, and antibiotics (eg, penicillin G, doxycycline).

68.2.2.3 Pertussis (Whooping Cough).

Pertussis, also known as *whooping cough* or the *100-day cough*, occurs primarily in infants and young children. The cause is *Bordetella pertussis*, a gram-negative bacillus. Initial symptoms include rhinorrhea, mild fever, and persistent cough. As infection worsens, coughing becomes more intense. The acute phase of the disease can last 4 to 6 weeks. During this time, infants experience difficulty eating, drinking, and breathing. Deaths have occurred. Complications of pertussis include pneumonia, seizures, ear infections, and, rarely, permanent neurologic injury. In the United States, reported cases dropped from a high of 265,269 in 1934 to 8483 in 2003. However, the rate of infant pertussis is rising. Worldwide, the disease afflicts about 60 million people, and kills 335,000 each year, mainly infants and young children. Erythromycin is the treatment of choice.

68.2.3 Poliomyelitis

Poliomyelitis, also known as polio or infantile paralysis, is a serious disease in which the poliovirus attacks neurons of the central nervous system that control muscle movement. The result is skeletal muscle paralysis, usually in the legs. However, muscles of respiration and muscles of the arms may also be affected. In about 10% of cases, polio is fatal. The disease is caused by three different polioviruses. Paralytic polio is usually caused by type 1 poliovirus. Polio has no cure. However, proper symptomatic treatment can improve comfort and reduce or prevent some crippling effects. Vaccination against polio has eliminated the disease from the Western hemisphere, except for eight to nine cases annually caused by the vaccine itself. To prevent vaccine-induced polio, use of the live virus vaccine (oral polio vaccine) has been discontinued in the United States. The number of cases worldwide was 1315 in 2007—nearly double the 784 cases documented in 2003.

68.2.4 *Haemophilus influenzae* Type b

Haemophilus influenzae type b is a gram-negative bacterium that can cause meningitis, pneumonia, and serious throat and ear infections. The bacterium is the leading cause of serious illness in children under the age of 5 years, and the most common cause of bacterial meningitis, which has a mortality rate of 5%. Among children who survive meningitis, between 25% and 35% suffer lasting neurologic deficits. As a result of childhood vaccination, the annual incidence of infection dropped from an estimated 20,000 cases in 1984 to less than 208 in 2008. Of the cases

that occurred, almost all were in unvaccinated children. Infection with *H. influenzae* can be treated successfully with antibiotics.

68.2.5 Varicella (Chickenpox)

Varicella (chickenpox) is a common, highly contagious, and potentially serious disease of childhood. The causative organism is varicella-zoster virus, a member of the herpesvirus group. Patients typically develop 250 to 500 maculopapular or vesicular lesions, usually on the face, scalp, or trunk. Other symptoms include fever, malaise, and loss of appetite. Among children, the most common complications are bacterial suprainfection and acute cerebellar ataxia. Reye's syndrome and encephalitis develop rarely. Among adults, the most serious common complication is varicella pneumonia. As a rule, symptoms in adults are more severe than in children: hospitalization is 10 times more likely in adults, and death is 20 times more likely. Although adults account for only 2% of varicella cases, they account for 50% of varicella-related deaths. Before varicella vaccine became available, over 90% of children in the United States got chickenpox by age 11, which corresponds to 4 million cases a year. In addition, about 11,000 victims were hospitalized each year, and about 100 died.

Herpes zoster, also known as *shingles* or simply *zoster*, develops in 15% of patients years after childhood chickenpox has resolved. The cause is reactivation of varicella-zoster viruses that had been dormant within sensory nerve roots. Episodes of zoster begin with neurologic pain in the area of skin supplied by the affected nerve roots. Blister-like lesions develop within 3 to 4 days, and usually disappear 2 to 3 weeks later. However, in about 14% of patients, neurologic pain persists for a month or more—and in a few cases, pain lasts for years.

68.2.6 Hepatitis B

Hepatitis B is a serious liver infection caused by the hepatitis B virus. Acute infection can cause anorexia, malaise, diarrhea, vomiting, jaundice, pain (in muscles, joints, and stomach), and death. Chronic infection can result in cirrhosis, liver cancer, and death. Each year in the United States, hepatitis B infects 50,000 people, puts 11,000 in the hospital, and kills 3000 to 5000. Worldwide, 170 million people have chronic hepatitis B, and 250,000 die from it annually.

Although hepatitis B is found in virtually all body fluids, only blood, serum-derived fluids, saliva, semen, and vaginal fluids are infectious. The most common modes of transmission are needle-stick accidents, sexual contact with an infected partner, maternal-child transmission during birth, and use of contaminated IV equipment or solutions.

Hepatitis B is discussed further in [Chapter 92](#) (Antiviral Agents I: Drugs for Non-HIV Viral Infections).

68.2.7 Hepatitis A

Hepatitis A is a serious liver infection caused by the hepatitis A virus. In the United States, hepatitis A infects between 125,000 and 200,000 people annually, and causes about 100 deaths (from acute liver failure). Symptoms of hepatitis A include fever, malaise, nausea, jaundice, anorexia, diarrhea, and stomach pain. However, not all infected persons become symptomatic.

800

Among children less than 6 years old, only 30% develop symptoms. In contrast, symptoms are present in most older infected children and adults. When symptoms do occur, they develop rapidly and then usually fade in less than 2 months. However, between 10% and 15% of patients experience prolonged or relapsing disease that persists up to 6 months. During the course of the infection, the virus undergoes replication in the liver, passage into the bile, and then excretion in the feces. As a result, the usual mode of transmission is fecal-oral in the context of close personal contact with an infected person. In addition, hepatitis A can be contracted by ingesting contaminated food or water. Blood-borne transmission is rare. Individuals at risk include household and sexual contacts of infected individuals, international travelers, and people living in areas where hepatitis A is endemic (eg, American Indian reservations, Alaskan Native villages).

801

68.2.8 Pneumococcal Infection

In the United States, *Streptococcus pneumoniae* (pneumococcus) is the leading bacterial cause of childhood meningitis, sepsis, pneumonia, and otitis media. Among children with pneumococcal meningitis, up to 50% suffer permanent brain damage or hearing loss, and about 10% die. The risk of acquiring pneumococcal infection is highest for children under the age of 2. Factors that increase infection risk include sickle cell disease, immunodeficiency, asplenia, chronic diseases, attending a group day care center, and being a Native American, African American, Alaskan Native, or socially disadvantaged. Worldwide, pneumococcal infection ranks among the leading causes of death from infectious disease. Routine childhood immunization against pneumococcal disease began in 2000. Since then, the incidence of severe pediatric infection has dropped sharply.

68.2.9 Meningococcal Infection

Meningococcal infection is a serious disease caused by *Neisseria meningitidis*, also known as the meningococcus. Invasive meningococcal disease is a leading cause of meningitis in American children. Worldwide, the majority of infections are caused by five *N. meningitidis* serogroups—designated A, B, C, Y, and W-135—identified on the basis of antigenic differences in surface polysaccharides. In the United States, only three serogroups—B, C, and Y—cause most cases. Meningococcal infection is readily transmitted through direct contact with respiratory secretions from patients and from asymptomatic carriers. Injury results from a meningococcal endotoxin,

which is produced so quickly that death can result within hours of infection onset. Although only 1400 to 2800 cases occur here each year, the disease is clearly of great concern, with a fatality rate of 10% to 14% despite antibiotic therapy. Furthermore, of those who survive, 11% to 19% suffer severe and permanent sequelae, including neurologic disability, deafness, mental retardation, and limb amputations. Infection rate is highest during infancy, with a second peak during adolescence and early adulthood. Outbreaks can occur in day care centers, schools, and colleges. Risk factors for acquiring the disease include immunodeficiency, antecedent viral infection, household crowding, chronic underlying disease, active and passive smoking, and anatomic and functional asplenia. A meningococcal vaccine was approved in 1981, but it was not very effective in children. Hence, routine childhood immunization was not recommended until 2005, the year a more effective vaccine was introduced.

68.2.10 Influenza

Influenza is a serious infection of the respiratory tract and a major cause of morbidity and mortality worldwide. Characteristics of the influenza virus and of influenza itself (mode of transmission, symptoms, time course, methods of prevention and treatment) are discussed in [Chapter 92](#).

68.2.11 Rotavirus Gastroenteritis

Rotavirus, which infects the intestinal mucosa, is the most common diarrheal pathogen worldwide. Infection presents initially as upset stomach and vomiting, usually with fever, and then progresses to several days of diarrhea, which can be mild to severe. The combination of vomiting and severe diarrhea can result in life-threatening dehydration. Virtually all children become infected repeatedly within the first 5 years of life. However, the first episode is generally the worst. As a result, severe diarrhea and dehydration are most likely in the very young—children 3 to 35 months old. In the United States, rotavirus infects 2.7 million children under the age of 5 each year, resulting in more than 400,000 office visits, 55,000 to 70,000 hospitalizations, and 20 to 60 deaths. Worldwide, annual deaths are much higher, estimated in the hundreds of thousands. Infected children shed large amounts of rotavirus in their stool, and hence transmission is usually fecal-oral, resulting from touching the stool or a contaminated object. Rotavirus infection can be prevented with two vaccines: RotaTeq and Rotarix. An older vaccine—RotaShield—was withdrawn owing to a high rate of intussusception, a life-threatening blockage of the intestine.

68.2.12 Genital Human Papillomavirus Infection

Human papillomavirus (HPV) infection is the cause of virtually all anogenital warts and cervical cancers. Transmission occurs most often by direct genital contact during vaginal or anal

intercourse. The types of HPV that infect the anogenital region can also cause cancers of the vulva, vagina, urethra, tongue, tonsils, penis, and anus. Cancer of the penis is rare. By contrast, cancer of the anus in men and women who have anal intercourse is now as common as cervical cancer was before the Papanicolaou (Pap) test was introduced. Discussion below focuses on the role of HPV in cervical cancer and genital warts. Treatment of genital warts is discussed in [Chapter 104](#) (Drugs for the Skin).

Genital HPV is the most common sexually transmitted infection. In the United States, about 6.2 million people become infected each year. Among sexually active males and females, about 50% will be infected at some time during their life. Fortunately, although HPV infections are common, most are benign and clear spontaneously, usually within a few months to a year. As a result, most men and women never get genital warts, and most women never get precancerous cervical lesions or cervical cancer.

About 100 types of HPV are known to exist, about 40 of which infect the anogenital region. The types of HPV associated with malignancy are referred to as *oncogenic* or *high-risk*, whereas the types associated with genital warts are called *low-risk*. About 95% of genital warts are caused by just two HPV types, known as HPV-6 and HPV-11. About 70% of cervical cancers are caused by two other types, known as HPV-16 and HPV-18. Fortunately, only 2.2% of women carry high-risk strains.

Worldwide, cervical cancer is the second leading cause of cancer deaths among women. Each year, more than 490,000 cases are diagnosed, and about 274,000 prove fatal. In the United States, cervical cancer is less prevalent: total new cases for 2006 were estimated at 9700, with about 3700 being fatal. Why so few deaths in the United States? Because American women undergo regular Pap tests, which detect precancerous and cancerous changes, thereby allowing early intervention (excision or ablation of the affected tissue) before advanced cancer can develop.

68.3 SPECIFIC VACCINES AND TOXOIDS

The discussion below is limited to the vaccines and toxoids used for routine childhood immunization. The major preparations employed are listed in [Table 67-3](#). Their adverse effects are summarized in [Table 67-4](#). Childhood immunization schedules for the year 2009—as recommended by the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention, the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians (AAFP)—are summarized in [Figures 67-1](#) and [67-2](#). As noted earlier, catch-up schedules and recent changes are available online at www.cdc.gov/vaccines/.

TABLE 67-3 Some Vaccines and Toxoids Available in the United States

Preparation Name (Synonym)	Trade Name	Type of Preparation	Route and Site
Measles, mumps, and rubella virus vaccine (MMR)	M-M-R II	Live virus	subQ, in outer aspect of upper arm
Measles, mumps, and rubella, and varicella virus vaccine (MMRV)	ProQuad*	Live virus	subQ, in anterolateral thigh or outer aspect of upper arm
Diphtheria and tetanus toxoids and acellular pertussis vaccine	Tripedia, DAPTACEL, Infanrix, Boostrix,† Adacel†	Toxoids (diphtheria and tetanus) plus inactivated bacteria components (pertussis)	IM, in deltoid or mediolateral thigh
Diphtheria and tetanus toxoids and acellular pertussis adsorbed, hepatitis B (recombinant), and inactivated poliovirus vaccine	PEDIARIX	Toxoids (diphtheria and tetanus) plus inactivated bacteria components (pertussis) plus inactive viral antigen (hepatitis B) plus inactivated viruses (poliovirus)	IM, in deltoid or anterolateral thigh
Tetanus and diphtheria toxoids	Generic only	Toxoids	IM, in deltoid or mediolateral thigh
<i>Haemophilus influenzae</i> type b (Hib) conjugate vaccine	HibTITER, ActHIB, PedvaxHIB, Comvax‡	Bacterial polysaccharide conjugated to protein	IM, in mid thigh or outer aspect of upper arm
Poliovirus vaccine, inactivated (IPV, Salk vaccine)	IPOL	Inactivated viruses of all three polio serotypes	subQ, in anterolateral thigh
Varicella virus vaccine	Varivax	Live virus	subQ, in deltoid or anterolateral thigh
Hepatitis A vaccine	Havrix, VAQTA	Inactive viral antigen	IM, in deltoid
Hepatitis B vaccine	Recombivax HB, Engerix-B, Comvax‡	Inactive viral antigen	IM, in deltoid or anterolateral thigh

Pharmacology for Nursing Care, 7th Edition

Pneumococcal conjugate vaccine	Prevnar	Bacterial polysaccharide conjugated to protein	IM, in deltoid or anterolateral thigh
Pneumococcal polysaccharide vaccine	Pneumovax 23	Bacterial polysaccharide (unconjugated)	IM, in deltoid or anterolateral thigh
Influenza vaccine (inactivated)	Fluzone, Fluvirin	Inactive viral antigen	IM, in deltoid or anterolateral thigh
Influenza vaccine (live)	FluMist	Live virus	Intranasal
Meningococcal conjugate vaccine (MCV4)	Menactra	Bacterial polysaccharide conjugated to protein	IM, in deltoid
Meningococcal polysaccharide vaccine (MPSV4)	Menomune	Bacterial polysaccharide (unconjugated)	subQ
Rotavirus vaccine	Rotarix, RotaTeq	Live virus	Oral
Human papillomavirus vaccine	Cervarix, [§] Gardasil	DNA-free virus-like particles	IM, in deltoid or anterolateral thigh

* ProQuad, approved in 2005, combines two older vaccines: M-M-R II and Varivax.

† Boostrix and Adacel are indicated for *booster* immunization, *not* for the *initial* immunization series. Boostrix is for patients 11 to 18 years old. Adacel is for patients 11 to 64 years old.

‡ Comvax is a combination vaccine for immunization against *H. influenzae* type b and hepatitis B.

§ Available in many countries but not the United States, where approval is expected in 2009.

TABLE 67-4 Adverse Effects of Some Vaccines and Toxoids

Preparation	Mild Effects	Serious Effects
Measles, mumps, and rubella virus vaccine	Local reactions; rash; fever; swollen glands in cheeks and neck and under the jaw; pain, stiffness, and swelling in joints	Anaphylaxis, thrombocytopenia
Diphtheria and tetanus toxoids and acellular pertussis vaccine	Local reactions, fever, fretfulness, drowsiness, anorexia, persistent crying	Acute encephalopathy, convulsions, shock-like state
<i>Haemophilus influenzae</i> type b conjugate vaccine	Local reactions, fever, crying, diarrhea, vomiting	None
Poliovirus vaccine (IPV and OPV*)	Local reactions (only from IPV)	Vaccine-associated paralytic polio- myelitis (only from OPV*)
Varicella virus vaccine	Local reactions, fever, mild varicella-like rash (local or generalized)	None
Hepatitis A vaccine	Local soreness, headache, anorexia, fatigue	Anaphylaxis
Hepatitis B vaccine	Local discomfort, fever	Anaphylaxis
Pneumococcal conjugate vaccine	Local reactions, fever	None
Influenza vaccine (inactivated)	Local reactions, fever	Guillain-Barré syndrome (association not proved)
Influenza vaccine (live attenuated)	Runny nose, headache, cough, fever	Guillain-Barré syndrome (association not proved)
Meningococcal conjugate vaccine	Local reactions, headache, fatigue	Guillain-Barré syndrome (association not proved)
Rotavirus vaccine	Diarrhea, vomiting, ear infection, runny nose, sore throat	None
Human papillomavirus vaccine	Local reactions, fainting	Guillain-Barré syndrome (association not proved)

* OPV is no longer available in the United States.

68.3.1 Measles, Mumps, and Rubella Virus Vaccine (MMR)

68.3.1.1 Description.

Measles, mumps, and rubella vaccine (MMR), marketed under the trade name *M-M-R II*, is a combination product composed of three live virus vaccines. Administration induces synthesis of

antibodies directed against measles, mumps, and rubella viruses. Immunization with MMR is preferred to immunization with the three vaccines separately.

68.3.1.2 Efficacy.

Following a single dose of MMR, an effective response develops in 97% of vaccinees within 2 to 6 weeks. A second dose increases protection.

68.3.1.3 Adverse Effects.

68.3.1.3.1 Mild.

Local soreness, erythema, and swelling may develop soon after vaccination. Within 1 to 2 weeks, some children experience glandular swelling in the cheeks and neck and under the jaw. Transient rash develops in 5% to 15% of vaccinees. Fever (103°F or higher) that persists for several days occurs in 5% to 15% of vaccinees 5 to 12 days after vaccination. MMR-induced fever poses a small risk of febrile seizures, but these seizures do *not* increase the risk of developing epilepsy. Within 1 to 3 weeks of the first dose, about 1% of vaccinees experience pain, stiffness, and swelling in one or more joints; these symptoms usually subside in a few days, but occasionally persist for a month or more. Fever, soreness, and pain can be reduced with ace-taminophen or a nonaspirin, nonsteroidal anti-inflammatory drug, such as ibuprofen.

68.3.1.3.2 Severe

Transient thrombocytopenia occurs very rarely (0.0025% incidence). MMR-induced thrombocytopenia is generally benign, but hemorrhage has developed in a few vaccinees.

MMR can induce anaphylactic reactions. However, the incidence is extremely low: Only 11 certain cases have occurred in over 70 million vaccinations. In the past, MMR-induced anaphylaxis was thought to result from allergy to eggs (the measles component of the vaccine is produced in chick embryo fibroblasts). However, it now appears that egg allergy is not involved. Rather, the leading suspect is a hydrolysis product of gelatin. Until more is known, authorities recommend that MMR be used with extreme caution in children with a known allergy to gelatin. The ACIP is reconsidering whether caution is still required for children with an allergy to eggs.

There is no causal link between MMR and development of autism, Crohn's disease, or any other serious long-term illness.

68.3.1.4 Precautions and Contraindications.

MMR is *contraindicated* during pregnancy and should be used with *caution* in children with a history of (1) thrombocytopenia or thrombocytopenic purpura or (2) anaphylactic-like reactions to gelatin, eggs, or neomycin (MMR contains a small amount of this antibiotic).

MMR can be administered to children with *mild febrile illness* (eg, upper respiratory infection with or without low-grade fever). However, for children with *moderate or severe febrile illness*, vaccination should be postponed until the illness has resolved.

Products that contain *immune globulins* (eg, whole blood, serum, specific immune globulins) contain antibodies against

803

Figure 67-1 **Recommended Immunization Schedule for Children from Birth Through 6 Years—United States, 2009.**

This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 17, 2008, for children from birth through age 6 years. These recommendations are approved by the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention, the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians (AAFP). *Gold-colored bars* indicate recommended ages for each dose; a bar that spans more than one age bracket indicates an acceptable range of ages for that dose. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any components of the combination are both indicated and approved by the FDA for that dose of the series, provided other components of the combination are not contraindicated. *Purple bars* indicate certain high-risk groups.

1. Hepatitis B vaccine (HepB) At birth

- Administer monovalent HepB to all newborns before hospital discharge.
- If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine mother's HBsAg status

as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

After the birth dose

- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1 or 2 months. The final dose should be administered no earlier than age 24 weeks.
- Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg (anti-HBs) after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).

4-month dose

- Administration of 4 doses of HepB to infants is permissible when combination vaccines containing HepB are administered after the birth dose.

2. Rotavirus vaccine (RV)

- Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks or older (ie, 15 weeks 0 days or older).
- Administer the final dose in the series by age 8 months 0 days.
- If Rotarix is administered at ages 2 and 4 months, a dose at 6 months is not indicated.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP)

- The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
- Administer the final dose in the series at age 4 through 6 years.

4. Haemophilus influenzae type b conjugate vaccine (Hib)

- If PRP-OMP (PedvaxHIB or Comvax [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
- TriHiBit (DTaP/Hib) should not be used for doses at ages 2, 4, or 6 months but can be used as the final dose in children aged 12 months or older.

5. Pneumococcal vaccine (*Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV]*)

- PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- Administer PPSV to children aged 2 years or older with certain underlying medical conditions (see *MMWR* 2000;49[No. RR-9]), including a cochlear implant.

6. Influenza vaccine (*Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV]*)

- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons (ie, those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
- Children receiving TIV should get 0.25 mL if aged 6 through 35 months or 0.5 mL if aged 3 years or older.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.

7. Measles, mumps, and rubella vaccine (MMR)

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.

8. Varicella vaccine

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For children aged 12 months through 12 years the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.

9. Hepatitis A vaccine (HepA)

- Administer to all children 12 through 23 months old. Administer 2 doses at least 6 months apart.
- Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
- HepA also is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

10. Meningococcal vaccine (MCV)

- Administer MCV to children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other high-risk groups. See *MMWR* 54:(No. RR-7), 2005.
- Persons who received MPSV 3 or more years previously and who remain at increased risk for meningococcal disease should be revaccinated with MCV.

Range of recommended ages

Certain high-risk groups

the viruses in MMR, and therefore can inhibit the immune response to the vaccine. Accordingly, in children who have received immune globulins, vaccination with MMR should be postponed for at least 3 to 6 months.

In vaccinees who are *immunocompromised*, replication of the viruses in MMR may be much greater than normal. If the immunodeficiency is severe, death may occur. However, of the more than 200 million people who have received MMR in the United States, only 5 such deaths have been reported. Nonetheless, *children with severe immunodeficiency should NOT be given MMR*. Severe immunodeficiency may result from immunosuppressive drugs (eg, glucocorticoids, cytotoxic anticancer drugs), certain cancers (eg, leukemia, lymphoma, generalized malignancy), and advanced HIV infection. It is important to note, however, that if HIV infection is *asymptomatic*, MMR should be given. In this situation, there is no risk of serious adverse events from MMR, whereas there *is* a risk of severe complications from measles should the disease develop. Vaccination with MMR early in the course of HIV infection is preferred. Why? Because the immune response to vaccination diminishes as HIV infection progresses.

68.3.1.5 Route, Site, and Immunization Schedule.

MMR is administered subQ into the outer aspect of the upper arm. Each child should receive two vaccinations, the first between 12 and 15 months of age, and the second between 4 and 6 years. If the scheduled second dose is missed, it can be given between ages 7 and 18 years.

68.3.2 Diphtheria and Tetanus Toxoids and Acellular Pertussis Vaccine

68.3.2.1 Preparations.

Primary vaccination against diphtheria, tetanus, and pertussis is usually done simultaneously using a combination product, composed of diphtheria toxoid, tetanus toxoid, and *acellular* pertussis vaccine (DTaP). This vaccine, which is relatively new, has replaced an older product, composed of diphtheria toxoid, tetanus toxoid, and *whole-cell* pertussis vaccine (DTP). DTaP is more effective than DTP and causes fewer and milder side effects. Vaccination with DTaP produces antibodies against diphtheria toxin, tetanus toxin, and *B. pertussis*. DTaP is available under several trade names, including *Tripedia*, *DAPTACEL*, and *Infanrix*.

After children have received a full series of DTaP shots, they will need subsequent booster shots. Two booster products are available: *Tdap* and *Td*. *Tdap*—sold as *Boostrix* and *Adacel*—is composed of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine—and hence boosts protection against all three diseases. By contrast, *Td* boosts protection against only two diseases: tetanus and diphtheria. *Tdap* was approved in 2005, whereas *Td* has been used for years. Because the incidence of pertussis is on the rise, a booster shot with *Tdap*, rather than *Td*,

is now recommended for all children 11 to 18 years old. Boosters with Td are given every 10 years thereafter.

Products used for immunization against diphtheria, tetanus, and pertussis are summarized in [Table 67-5](#).

68.3.2.2 Efficacy.

Immunization with DTaP reduces the risk of disease by 80% to 90%. Protection begins after the third dose and persists 4 to 6 years (against pertussis) and 10 years (against diphtheria and tetanus).

68.3.2.3 Adverse Effects.

68.3.2.3.1 Mild.

Mild reactions are common. The reactions seen most often are low fever (50%), fretfulness (50%), drowsiness (30%), anorexia (20%), and local reactions (pain [50%], swelling [40%], and redness [30%]). Mild reactions usually develop a few hours to 48 hours after vaccination and then resolve in 1 to 2 days. Acetaminophen or ibuprofen can decrease fever and pain. Mild reactions were more likely with DTP than with DTaP.

68.3.2.3.2 Moderate

Moderate reactions occur less often than mild reactions. Persistent, inconsolable crying lasting 3 hours or longer, occurs in 1% of vaccinees. Crying is most likely with the first dose of DTaP and is not associated with long-term sequelae. Fever (105°F or higher) occurs in 0.3% of vaccinees; the pertussis component appears responsible. Approximately 0.06% of vaccinees develop convulsions (with or without fever). These seizures have no permanent sequelae and do not increase the risk of subsequent febrile or afebrile seizures. A shock-like state develops in 0.06% of vaccinees and has no lasting sequelae.

68.3.2.3.3 Severe: Encephalopathy

Very rarely, DTaP causes acute encephalopathy. The incidence is between zero and 10.5 episodes per million doses. Most cases occur within 3 days of vaccination. Some of the children who experience acute encephalopathy develop chronic neurologic dysfunction later in life. However, the contribution of acute encephalopathy to long-term neurologic deficits is unclear.

68.3.2.4 Precautions and Contraindications.

DTaP can be administered to children with *mild febrile illness* (eg, upper respiratory infection with or without low-grade fever). However, for children with *moderate or severe febrile illness*, administration should be postponed until the illness has resolved.

DTaP is *contraindicated* if a prior vaccination with DTaP produced (1) an immediate anaphylactic reaction or (2) encephalopathy within 7 days of vaccination.

DTaP should be administered with *caution* (if at all) if a prior vaccination with DTaP produced any of the following:

- A shock-like state
- Fever (105°F or higher) occurring within 48 hours of vaccination and not attributable to another identifiable cause
- Persistent, inconsolable crying, lasting 3 or more hours and occurring within 48 hours of vaccination
- Convulsions (with or without fever) occurring within 3 days of vaccination.

805

Figure 67-2 **Recommended Immunization Schedule for Children 7 Through 18 Years of Age—United States, 2009.**

This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 17, 2008, for children from 7 through 18 years of age. These recommendations are approved by the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention, the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians (AAFP). *Gold-colored bars* indicate recommended ages for each dose; a bar that spans more than one age bracket indicates an acceptable range of ages for that dose. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any components of the combination are both indicated and approved by the FDA for that dose of the series, provided other components of the combination are not contraindicated. *Purple bars* indicate certain high-risk groups. *Green bars* indicate times for catch-up immunization.

1. Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap) (*Minimum age: 10 years for Boostrix and 11 years for Adacel*)

- Administer at age 11 or 12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoid (Td) booster dose.

- Persons aged 13 through 18 years who have not received Tdap should receive a dose.
- A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose; however, a shorter interval may be used if pertussis immunity is needed.

2. Human papillomavirus vaccine (HPV)

- Administer the first dose to females at age 11 or 12 years.
- Administer the second dose 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).
- Administer the series to females at age 13 through 18 years if not previously vaccinated.

3. Meningococcal conjugate vaccine (MCV)

- Administer at age 11 or 12 years, or at age 13 through 18 years if not previously vaccinated.
- Administer to previously unvaccinated college freshmen living in a dormitory.
- MCV is recommended for children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other groups at high risk. See *MMWR* 2005;54(No. RR-7).
- Persons who received MPSV 5 or more years previously and remain at increased risk for meningococcal disease should be revaccinated with MCV.

4. Influenza vaccine

- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons (ie, those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.

5. Pneumococcal polysaccharide vaccine (PPSV)

- Administer to children with certain underlying medical conditions (see *MMWR* 1997;46[No. RR-8]), including a cochlear implant. A single revaccination should be administered to children with functional or anatomic asplenia or other immunocompromising condition after 5 years.

6. Hepatitis A vaccine (HepA)

- Administer 2 doses at least 6 months apart.
- HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

7. Hepatitis B vaccine (HepB)

- Administer the 3-dose series to those not previously vaccinated.

- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.

8. Inactivated poliovirus vaccine (IPV)

- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

9. Measles, mumps, and rubella vaccine (MMR)

- If not previously vaccinated, administer 2 doses or the second dose for those who have received only 1 dose, with at least 28 days between doses.

10. Varicella vaccine

- For persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007;56[No. RR-4]), administer 2 doses if not previously vaccinated or the second dose if they have received only 1 dose.
- For persons aged 7 through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

 Range of recommended ages
 Catch-up immunization
 Certain high-risk groups

806

807

68.3.2.5 Route, Site, and Immunization Schedule.

DTaP is injected IM into the deltoid muscle or thigh. Most children should receive five injections, the first at 2 months, the second at 4 months, the third at 6 months, the fourth between 15 and 18 months, and the fifth between 4 and 6 years. Children who began the series with DTP (no longer available) should complete it with DTaP. Children 11 to 12 years old who completed the series at least 5 years previously should receive a booster shot of Tdap. Subsequent boosters with Td are recommended every 10 years.

68.3.3 Poliovirus Vaccine

68.3.3.1 Preparations.

In the past, two polio vaccines were available: *oral poliovirus vaccine* (OPV, Sabin vaccine) and *inactivated poliovirus vaccine* (IPV, Salk vaccine). OPV is composed of *live*, attenuated viruses. In contrast, IPV is composed of *inactivated* polioviruses. As discussed below, OPV has *caused* polio in a few children, whereas IPV has not and cannot. Because the benefit/risk ratio of IPV is clearly superior, OPV has been withdrawn from the U.S. market. The trade name for IPV is *IPOL*.

68.3.3.2 Efficacy.

Between 97.5% and 100% of children receiving IPV or OPV develop antibodies to poliovirus types 1, 2, and 3. Antibodies develop after two or more doses and persist for many years.

68.3.3.3 Adverse Effects of IPV.

IPV is devoid of serious adverse effects. As with other injected drugs, local soreness may occur. IPV contains trace amounts of streptomycin, neomycin, and bacitracin. Children with an allergy to these drugs should be monitored.

68.3.3.4 Adverse Effects of OPV.

Very rarely, OPV has caused *vaccine-associated paralytic poliomyelitis* (VAPP). The severity of VAPP is similar to that of paralytic poliomyelitis caused by the wild-type virus. In immunocompromised children, VAPP can prove fatal. The incidence of VAPP is 1 case for each 2.4 million doses of OPV administered, which corresponds to 1 case for each 750,000 children starting the vaccination series. In the United States, eight to nine cases of VAPP have occurred each year. Because wild-type poliovirus has been eliminated from the Western hemisphere, the risk for Americans of acquiring polio from OPV now greatly exceeds the risk of acquiring the disease from the environment. In response to this change in risk/benefit ratio, the ACIP changed its recommendations: Whereas OPV had been the preferred vaccine for many years, the ACIP now recommends exclusive use of IPV.

68.3.3.5 Route, Site, and Immunization Schedule.

IPV is administered subQ in the anterolateral thigh. All children should receive four doses, the first at 2 months of age, the second at 4 months, the third between 6 and 18 months, and the fourth between 4 and 6 years.

68.3.4 *Haemophilus influenzae* Type b Conjugate Vaccine

68.3.4.1 Preparations.

Vaccines directed against *H. influenzae* type b (Hib) are prepared by conjugating (covalently binding) a purified capsular polysaccharide (PRP) from *H. influenzae* to either (1) diphtheria toxoid, (2) tetanus toxoid, or (3) an outer membrane protein (OMP) isolated from *Neisseria meningitidis*. The reason for conjugating PRP to these other compounds is to enhance antigenicity. The vaccines made with OMP—marketed as *PedvaxHIB* and *Comvax**—and abbreviated PRP-OMP—elicit a stronger immune response than the vaccines made with diphtheria toxoid [HibTITER] or tetanus toxoid [ActHIB].

807

808

TABLE 67-5 Products for Immunization Against Diphtheria, Tetanus, and Pertussis

Symbol	Description	Trade Names	Comments
Vaccines for Children Younger Than 10 Years			
DTaP	Diphtheria toxoid, tetanus toxoid, and acellular pertussis vaccine	Tripedia, DAPTACEL, Infanrix	Used for routine vaccination against diphtheria, tetanus, and pertussis
DTP	Diphtheria toxoid, tetanus toxoid, and whole-cell pertussis vaccine	Tri-Immunol	Withdrawn because DTaP is safer and more effective
DT	Diphtheria toxoid and tetanus toxoid	Generic only	Used for children under 7 years who should not get pertussis vaccine
Vaccines for Adolescents and Adults			
Tdap	Tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, adolescent preparation	Boostrix, Adacel	Used as a <i>booster</i> in adolescents and adults to protect against all three diseases
Td	Tetanus toxoid and diphtheria toxoid	Generic only	Used as a <i>booster</i> for adolescents and adults to protect against tetanus and diphtheria, but not pertussis
* Comvax is a combination vaccine used for immunization against H. influenzae and hepatitis B.			

68.3.4.2 Efficacy.

Immunization with Hib vaccine decreases the risk of disease by 88% to 98%. When PedvaxHIB is used, protection begins 1 week after the first dose. However, when HibTITER or ActHIB is used, protection is delayed, beginning 1 to 2 weeks after the fourth dose. With all three vaccines, protection persists for several years.

68.3.4.3 Adverse Effects.

Hib vaccine is among the safest of all vaccines. Serious adverse effects have not been reported. The few adverse effects that do occur are generally transient and mild. Between 2% and 5% of vaccinees develop local reactions (swelling, erythema, warmth, and tenderness). About 1% experience fever (above 101°F), crying, diarrhea, or vomiting.

68.3.4.4 Route, Site, and Immunization Schedule.

Hib vaccines are administered IM into the midthigh or the outer aspect of the upper arm. Most children should receive four doses, the first at 2 months of age, the second at 4 months, the third at 6 months, and the fourth between 12 and 15 months. If PedvaxHIB or Comvax is used for the first two doses, the third dose (6-month dose) can be omitted.

68.3.5 Varicella Virus Vaccine

68.3.5.1 Description.

Varicella virus vaccine is composed of live, attenuated varicella viruses. Two subQ products are available: varicella vaccine by itself, sold as *Varivax*, and varicella vaccine combined with MMR [MMRV], sold as *ProQuad*. Varicella vaccine was developed in Japan in 1973, but was not available in the United States until 1995.

68.3.5.2 Efficacy.

Varicella vaccine, given as a two-dose series, confers full protection in about 99% of recipients. Furthermore, among those who get chickenpox despite vaccination, symptoms are always mild: These children develop fewer lesions (less than 50, compared with 250 to 500 for unvaccinated children), experience less fever, and recover more quickly. In Japan, herpes zoster (shingles) has not been observed in any adult who received varicella vaccine as a child, even if breakthrough chickenpox had occurred.

68.3.5.3 Adverse Effects.

Varicella vaccine is very safe; no serious adverse events have been reported. About 25% of vaccinees experience erythema, soreness, and swelling at the injection site; 15% develop fever (above 102°F); and 3% develop a mild, local varicella-like rash, consisting of just a few lesions. About 5% of healthy children develop a sparse, generalized varicella-like rash within a month of the injection. In children with leukemia, the incidence of generalized rash is much higher—about 50%. For all vaccinees, rates of fever and rash are higher when MMRV is used than when MMR and varicella vaccine are given separately.

In theory, children receiving the vaccine can transmit vaccine viruses to others. However, among otherwise healthy vaccinees, such transmission has not been reported. In contrast, among leukemic children who developed a rash after vaccination, a few cases of viral transmission have occurred. To reduce the risk of transmission, vaccinees should temporarily avoid close

contact with susceptible, high-risk individuals (eg, neonates, pregnant women, immunocompromised people).

68.3.5.4 Precautions and Contraindications.

Varicella vaccine is *contraindicated* during pregnancy, for individuals with certain cancers (eg, leukemia, lymphomas), and for those with hypersensitivity to neomycin or gelatin, both of which are in the vaccine. In addition, the vaccine should generally be avoided by individuals who are immunocompromised, including those with HIV infection or congenital immunodeficiency and those taking immunosuppressive drugs.

Children receiving the vaccine should avoid aspirin and other salicylates for 6 weeks. This precaution is based on the theoretical risk of developing Reye's syndrome: If the child develops chickenpox (albeit a mild case) in response to the vaccine, the very small risk of developing Reye's syndrome is somewhat increased by concurrent use of salicylates.

68.3.5.5 Route, Site, and Immunization Schedule.

Varicella vaccine is administered subQ into the outer aspect of the upper arm or into the anterolateral thigh. All recipients should get *two* doses. Because the vaccine wasn't available in the United States before 1995, many children missed their first shot at the preferred age: 12 to 15 months. Accordingly, the vaccination schedule for older children necessarily differs from that for younger children. Current recommendations are as follows:

- *Children who have never had chickenpox*—Give the first dose between 12 and 15 months of age, and the second dose between 4 and 6 years of age. If needed, the second dose can be given sooner—but no sooner than 3 months after the first dose.
- *Children 13 or more years old who have not been vaccinated yet and have not had chickenpox*—Give two doses at least 28 days apart.
- *Catch-up vaccination*—Anyone who is not fully vaccinated and has never had chickenpox should receive one or two doses. Dosage timing depends on the person's age (see the catch-up immunization schedule at www.cdc.gov/vaccines/).

68.3.5.6 We Need to Vaccinate More Children.

Although rates of varicella vaccination have increased, many eligible children still do not get vaccinated. Several misconceptions are responsible: Some parents believe chickenpox is a mild disease (it's actually the leading cause of vaccine-preventable child death in the United States); some think vaccine is not effective (vaccination prevents severe chickenpox in 100% of

recipients); and some think the vaccine is not safe (serious reactions are extremely rare, and proof that the vaccine was the cause is lacking).

The major impact of failure to vaccinate will be felt when today's children grow up. Recall that chickenpox in adults is much more severe than in children: Compared with children, adults have a 10- to 20-fold increased risk of serious complications, including death. Because some children are being vaccinated, the overall incidence of chickenpox is on the decline. As a result, children who remain unvaccinated may still not get chickenpox, and hence may reach adulthood without developing antibodies to the disease. Therefore, if they acquire the disease as adults, it is likely to be severe. The moral to this story is that vaccinating children now will not only protect them from chickenpox during childhood, it will also protect them from serious harm when they grow up.

808

68.3.6 Hepatitis B Vaccine

809

68.3.6.1 Preparations.

Hepatitis B vaccine (HepB) contains *hepatitis B surface antigen* (HBsAg), the primary antigenic protein in the viral envelope. Administration of HepB promotes synthesis of specific antibodies directed against hepatitis B virus. Because HepB is made from a viral component, rather than from a live virus, it cannot cause disease.

HepB is available in pediatric and adult formulations. The pediatric formulation, marketed as *Recombivax HB*, contains 10 mcg of HBsAg/mL. The adult formulation, marketed as *Energix-B*, contains 20 mcg of HBsAg/mL. A combination vaccine for adults, marketed as *Twinrix*, protects against hepatitis A and hepatitis B. In all three products, the HBsAg is produced in yeast using recombinant DNA technology.

68.3.6.2 Efficacy.

Greater than 85% of vaccinees are protected after the second dose of HepB, and more than 90% are protected after the third dose. Although the duration of protection has not been determined with precision, it appears to be at least 5 to 7 years.

68.3.6.3 Adverse Effects and Contraindications.

HepB is one of our safest vaccines. The most common reactions are soreness at the injection site and mild to moderate fever. Acetaminophen or ibuprofen may be used to relieve discomfort, but aspirin should be avoided. The only contraindication to HepB is a prior anaphylactic reaction either to HepB itself or to baker's yeast.

68.3.6.4 Route, Site, and Immunization Schedule.

HepB is injected IM. In neonates and infants, the injection is made into the anterolateral thigh. In adolescents and adults, the injection is made into the deltoid. All vaccinees should receive three doses.

The immunization protocol for *infants* is based on whether the mother is *HBsAg-positive* or *HBsAg-negative* (ie, on whether the mother has laboratory evidence of hepatitis B infection). *All* infants should receive monovalent HepB vaccine soon after birth. The following protocols for infants are recommended:

- *Infants born to mothers who are HBsAg-negative*—Give 5 mcg of Recombivax HB within 12 hours of birth.* Give the second dose between 1 and 2 months of age and the third dose no sooner than 6 months of age.
- *Infants born to mothers who are HBsAg-positive*—Give 5 mcg of Recombivax HB within 12 hours of birth, and give 0.5 mL of *hepatitis B immune globulin* (HBIG) at the same time but at a separate site. (The purpose of the HBIG is to provide immediate protection against hepatitis B acquired from the mother.) Give the second dose of HepB between 1 and 2 months of age, and the third dose no sooner than 6 months of age.
- *Infants born to mothers whose HBsAg status is unknown*—Give 5 mcg of Recombivax HB within 12 hours of birth. Subsequent doses are based on the mother's HBsAg status, which is determined by analyzing a maternal blood sample obtained during delivery. If the mother is HBsAg-positive, the infant should be given HBIG as soon as possible—and no later than 1 week after birth.

Children and adolescents who were not vaccinated against hepatitis B during infancy may begin the three-dose series at any time. Once the first dose is given, the second is given 1 month (or more) later, and the third 4 months (or more) after the first dose and no less than 2 months after the second dose. For children 11 years and older, a two-dose schedule can be used; the second dose is given 4 to 6 months after the first.

* In rare circumstances, the first dose can be delayed—but only if a prescriber's order to withhold the vaccine and a copy of the mother's original HBsAg-negative test result are filed in the infant's medical record.

68.3.7 Hepatitis A Vaccine

68.3.7.1 Preparations.

Hepatitis A vaccine (HepA) is prepared from inactivated hepatitis A virus (HAV). In the United States, two products are available: *Havrix* and *VAQTA*.

68.3.7.2 Efficacy.

Immunization with HepA decreases the risk of clinical disease by 94% to 100%. Protective levels of antibodies are seen in 94% to 100% of adults and children 1 month after the first dose, and in 100% of vaccinees 1 month after the second dose. Protection appears to be long lasting: Among vaccinated children who were followed for 7 years, no cases of hepatitis A were detected.

68.3.7.3 Who Should Be Vaccinated?

Hepatitis A vaccination is recommended for *all* children 12 through 23 months old. In addition, HepA is recommended for

- People at least 1 year old traveling to places with high rates of hepatitis A, including Central or South America, Mexico, the Caribbean islands, Africa, Asia (except Japan), and southern or eastern Europe
- People in communities that have frequent outbreaks of hepatitis A
- Men who have sex with men
- People who use street drugs
- People with chronic liver disease
- People who receive clotting factor concentrates
- People who work with HAV-infected primates or who work with HAV in research labs

68.3.7.4 Adverse Effects.

HepA is extremely safe. By 1999, over 65 million doses had been administered worldwide, causing no serious adverse events that could be definitively linked to the vaccine.

Mild reactions are common. Soreness at the injection site occurs in about 54% of adults and 18% of children. Headache occurs in 14% of adults and 9% of children. Other mild reactions

include loss of appetite and malaise. When mild reactions occur, they usually begin 3 to 5 days after vaccination and last only 1 to 2 days.

68.3.7.5 Route, Site, and Immunization Schedule.

Hepatitis A vaccines should be given IM into the deltoid muscle. Two doses are required. The first can be given at 12 months of age. The second should be given 6 to 12 months after the first (for Havrix) or 6 to 18 months after the first (for VAQTA).

68.3.8 Pneumococcal Conjugate Vaccine

In 2000, the FDA approved a 7-valent *pneumococcal conjugate vaccine* (PCV7) [Prennar] for prevention of invasive pneumococcal disease in infants and children. An unconjugated vaccine—*pneumococcal polysaccharide vaccine* (PPV) [Pneumovax 23]—is also available. However, PPV is approved only for adults and high-risk children over the age of 2 years; PPV does not work in children younger than 2 years.

68.3.8.1 Description.

PCV7 consists of seven pneumococcal capsular polysaccharide antigens that have been conjugated to a protein carrier—specifically, CRM197, a nontoxic variant of diphtheria toxin.

809

810

The protein carrier increases antigenicity, especially in infants. The seven antigens in the vaccine are from the seven serotypes of *Streptococcus pneumoniae* that cause the majority (80%) of invasive pneumococcal infections in American children under the age of 6 years.

68.3.8.2 Efficacy.

Vaccination efficacy was evaluated in a trial that enrolled 37,868 healthy infants. Half received the vaccine, and half received a control injection. Vaccination was 100% effective in preventing invasive disease caused by the *S. pneumoniae* serotypes that the vaccine was designed to protect against. Vaccination was also 89% effective at preventing invasive disease caused by *all* serotypes of *S. pneumoniae*. In addition to preventing invasive pneumococcal disease, vaccination caused a modest reduction in cases of otitis media (see [Chapter 105](#)).

68.3.8.3 Adverse Effects.

PCV7 appears to be very safe. No serious adverse effects have been reported. Mild, self-limited reactions (erythema, swelling, pain, tenderness) occur at the injection site in 10% to 20% of vaccinees. Fever (temperature over 100.3°F) develops in 21%. Irritability, drowsiness, and reduced appetite may also occur.

68.3.8.4 Who Should Be Vaccinated?

The ACIP recommends vaccinating children in the following groups:

- All children under 2 years of age
- All healthy children between their second and fifth birthdays who have not completed the PCV series
- All children between their second and fifth birthdays who have conditions that put them at high risk of serious pneumococcal disease. In this group are children with sickle cell anemia, injury to the spleen, cochlear implants, chronic heart or lung disease, or immunosuppression of any cause (eg, diabetes, cancer, liver disease, HIV infection, use of immunosuppressive drugs).

68.3.8.5 Route, Site, and Immunization Schedule.

Vaccination is done by IM injection into the anterolateral aspect of the thigh (in infants) or into the deltoid muscle of the upper arm (in toddlers and young children). The vaccine is a suspension, and hence must be shaken before use. All doses are 0.5 mL.

68.3.8.5.1 Children Under 2 Years of Age

The number of doses and their timing depend on the child's age when the first dose is given:

- *First dose at age 2 months*—four doses total; one each at ages 2, 4, and 6 months and one between ages 12 and 15 months
- *First dose between ages 7 and 11 months*—three doses total; the first two doses should be given at least 4 weeks apart, and the third should be at least 8 weeks after the second, but not before the child's first birthday
- *First dose between ages 12 and 23 months*—two doses total, given at least 8 weeks apart

68.3.8.5.2 Children Between Their Second and Fifth Birthdays

- Healthy children who have not completed the PCV series should get one dose.
- Children at high risk who have already received three doses should get one additional dose.

- Children at high risk who have received no, one, or two doses should get two doses, given at least 8 weeks apart.

68.3.9 Meningococcal Conjugate Vaccine

In 2005, the FDA approved *Menactra*, the first *meningococcal conjugate vaccine* (MCV). *Menactra* protects against four meningococcal serotypes, and hence its abbreviation is *MCV4*. Approval was originally limited to persons 11 to 55 years old, but now includes persons as young as 2 years old. An unconjugated vaccine—*meningococcal polysaccharide vaccine* (MPSV4) [Menomune]—has been available since the 1970s, but is not very effective in children. Accordingly, MCV4 is currently preferred. An investigational MCV, known as *Menveo*, is more effective than *Menactra* in infants, and hence may be preferred when it is approved.

68.3.9.1 Description.

MCV4 is a tetravalent conjugate vaccine directed against four meningococcal serogroups: A, C, Y, and W-135. Each dose consists of 4 mcg of capsular polysaccharide from each of the four serogroups conjugated with 48 mcg of a protein carrier, specifically, diphtheria toxoid. The carrier protein increases immunogenicity. MCV4 is active against the same serogroups as MPSV4.

68.3.9.2 Efficacy.

The efficacy of MCV4 at preventing meningococcal disease has not been evaluated in clinical trials. However, we do know the vaccine is highly immunogenic. For example, when 423 adolescents were vaccinated, rates of seroconversion for serogroups A, C, Y, and W-135 were 100%, 99%, 98%, and 99%, respectively, as measured by bactericidal antibody assay. FDA approval of MCV4 was based on its documented immunogenicity and the documented ability of other vaccines to prevent meningococcal infection.

68.3.9.3 Adverse Effects.

The most common reactions are local pain (59% in adolescents and 54% in adults), headache (36% and 41%), and fatigue (30% and 35%). Local redness, swelling, and induration are also common.

As of February 25, 2008, the VAERS had received 26 confirmed case reports of *Guillain-Barré syndrome* (GBS) following vaccination with *Menactra*. However, a causal link has not been established. GBS is a serious neurologic disorder that involves inflammatory demyelination of peripheral nerves. Symptoms include symmetric weakness in the arms and legs, sensory

abnormalities, and paralysis of the muscles of respiration. Most patients eventually recover. People with a history of GBS should not receive this vaccine.

68.3.9.4 Who Should Be Vaccinated?

The ACIP recommends MCV4 vaccination for all children and adolescents 11 through 18 years of age. The dose is normally given at 11 to 12 years of age. Children who were not vaccinated at this time should be vaccinated as soon as possible. Vaccination is also recommended for people at increased risk for meningococcal disease, including

- College freshmen living in dormitories
 - U.S. military recruits
 - Microbiologists who are routinely exposed to meningococcal bacteria
 - Anyone traveling to (or living in) a part of the world where meningococcal disease is common
 - Anyone who has an injured spleen, or whose spleen has been removed
 - Anyone who has an immune disorder known as terminal complement component deficiency
-
- Anyone who might have been exposed to meningitis during an outbreak
 - Children 2 to 10 years of age with terminal complement component deficiency, anatomic or functional asplenia, and certain other risk factors

810

811

MCV4 is the preferred vaccine for people 2 to 55 years old in these risk groups, but MPSV4 can be used if MCV4 is not available. MPSV4 should be used for adults over 55 (not because MPSV4 is more effective—but because it is approved for use in this age group, whereas MCV4 is not).

68.3.9.5 Route, Site, and Immunization Schedule.

Vaccination is done by IM injection, preferably into the deltoid muscle of the upper arm. For vaccinees at least 2 years old, one dose of MCV4 is usually sufficient. A booster vaccination may be appropriate for people who remain at high risk.

68.3.10 Influenza Vaccine

Annual vaccination against influenza is now recommended for all children between 6 months and 18 years of age. Properties of IM and intranasal influenza vaccines (composition, efficacy, adverse effects, contraindications, preparations, dosage, route), along with information on adult vaccination, are presented in [Chapter 92](#).

68.3.11 Rotavirus Vaccine

68.3.11.1 Preparations and Efficacy.

In the United States, two rotavirus vaccines are available: RotaTeq, approved in 2006, and Rotarix, approved in 2008. To induce a strong immune response, the viruses in these vaccines must replicate within the infant's gut. Accordingly, administration is oral. RotaTeq and Rotarix differ in composition and dosing schedule.

RotaTeq is a *pentavalent* vaccine directed against the five most common serotypes of human rotavirus, termed G1, G2, G3, G4, and P1A. In trials in the United States and Finland, RotaTeq prevented 74% of *all* rotavirus gastroenteritis cases, and 98% of *severe* cases. Vaccination also reduced the need for diarrhea-related hospitalization by 96%.

Rotarix is a *monovalent* vaccine developed from a rotavirus with the most common serotype found in humans. However, although Rotarix is monovalent, it confers protection against four rotavirus serotypes: G1, G3, G4, and G9. In clinical trials, Rotarix prevented 79% of *all* rotavirus gastroenteritis cases, 90% of *severe* cases, and 96% of diarrhearelated hospitalizations.

68.3.11.2 Safety.

Safety of RotaTeq was evaluated in over 70,000 infants, the largest population ever in a prelicensure trial of vaccine safety. No serious adverse effects were observed. The most common adverse effects were diarrhea (24.1% with RotaTeq vs. 21.3% with placebo), vomiting (15.2% vs. 13.6%), ear infection (14.5% vs. 13%), runny nose and sore throat (6.9% vs. 5.8%), and wheezing and coughing (1.1% vs. 0.7%). Of greatest importance, RotaTeq did not increase the risk of *intussusception*, a rare, life-threatening form of bowel obstruction that occurs when the bowel folds in on itself, like a collapsing telescope. Intussusception is a potential concern because an older rotavirus vaccine—RotaShield—increased the risk of intussusception, and hence was withdrawn.

Safety of Rotarix appears comparable to that of RotaTeq. Testing in over 63,000 infants revealed no increased risk for intussusception. The incidence of other adverse effects was no greater than with placebo.

68.3.11.3 Who Should Be Vaccinated?

The ACIP recommends that all infants receive rotavirus vaccine, beginning around 8 weeks of age.

68.3.11.4 Who Should NOT be Vaccinated?

Infants with moderate to severe diarrhea or vomiting should probably not be vaccinated until they recover. Since rotavirus vaccines contain live viruses, it would seem prudent to use these agents with caution in babies who are immunocompromised. (Neither product has been evaluated in this population.)

68.3.11.5 Preparations, Route, and Immunization Schedule.

RotaTeq is supplied in single-dose, 2-mL vials for oral administration. The vaccination series consists of *three* doses, starting at 6 to 12 weeks of age. The second dose is given 4 to 10 weeks after the first, and the third dose is given 4 to 10 weeks after the second (but no later than 32 weeks of age).

Rotarix is supplied as a powder for suspension in 1 mL of the liquid supplied. Administration is oral. Effective vaccination requires *two* doses (compared with three for RotaTeq). The first dose is given between 6 and 12 weeks of age, and the second is given 4 weeks or more later. The series should be completed by 24 weeks of age.

68.3.12 Human Papillomavirus Vaccine

68.3.12.1 Preparations.

Two HPV vaccines—*Gardasil* and *Cervarix*—are in use worldwide, but only Gardasil is approved in the United States. Approval of Cervarix is expected in 2009.

Gardasil is a quadrivalent vaccine designed to stimulate production of neutralizing antibodies directed at four types of HPV—specifically, types 16 and 18 (which cause 70% of cervical cancers), and types 6 and 11 (which cause 95% of genital warts). The vaccine consists of *virus-like particles* (VLPs), which are virus-sized, empty spheres composed of viral capsid proteins. To the immune system, VLPs look like the actual virus, and hence VLPs can evoke an immune

response. Because VLPs are empty (and hence don't contain viral DNA), VLPs cannot cause infection. Gardasil is available in 0.5 mL, single-use vials.

Like Gardasil, Cervarix is designed to stimulate immunity against HPVs 16 and 18, thereby conferring protection against cervical cancer. However, in contrast to Gardasil, Cervarix does not promote immunity against HPVs 6 and 11, and hence does not protect against genital warts.

68.3.12.2 Indications.

Gardasil is indicated for girls and women 9 to 26 years old to prevent cervical cancer and genital warts (caused by HPV types 6, 11, 16, and 18), plus the following precancerous or dysplastic lesions caused by those HPV types:

- Cervical adenocarcinoma *in situ*
- Cervical intraepithelial neoplasia grade 2 and grade 3
- Vulvar intraepithelial neoplasia grade 2 and grade 3
- Vaginal intraepithelial neoplasia grade 2 and grade 3
- Cervical intraepithelial neoplasia grade 1

Gardasil is the first vaccine licensed in the United States for the specific purpose of protecting against cancer and precancerous lesions.

68.3.12.3 Efficacy.

Gardasil is highly effective, as demonstrated in FUTURE II, a Phase III, randomized, double-blind, placebo-controlled trial. Researchers enrolled 12,167 healthy women, ages 16 to 23, and gave them three IM injections of Gardasil or placebo over a 6-month interval. The result?

811

812

During 2 years of follow-up, Gardasil was nearly 100% effective at preventing precancerous cervical lesions, precancerous vaginal and vulvar lesions, and genital warts caused by HPV types 6, 11, 16, and 18. However, although Gardasil protected against new HPV infection, it didn't eliminate infection that was already present. Furthermore, although Gardasil prevented precancerous cervical lesions, the study period was too short to tell if vaccination prevents cervical cancer. Nonetheless, given that HPV infection causes more than 99% of cervical cancers, it seems highly likely that protection against this cancer will be conferred. At this time, the estimated duration of protection against HPV is 5 to 10 years. Studies are underway to determine if and when booster vaccination may be needed.

68.3.12.4 Is a Pap Test Still Needed?

For two reasons, the answer is a resounding *YES!* First, Gardasil only protects against four types of PVH, leaving vaccinees at risk of cervical cancer caused by other types of HPV. Second, since Gardasil does not eliminate pre-existing HPV infection, vaccinees remain at risk of cancer from infection that was present before the vaccine was given. Therefore, vaccinated women should still undergo routine Pap screening to detect precancerous cervical changes, thereby permitting timely treatment before cancer develops.

68.3.12.5 Safety.

The HPV vaccine appears to be very safe. Injection-site reactions—pain (84%), erythema (25%), swelling (25%), and itching (3%)—although common, are mild and short lived. Fainting has occurred in teenage girls, sometimes resulting in hospitalization. However, the incidence of fainting is no greater than with other vaccines.

What about severe side effects? By 2008, more than 8 million girls and women had been vaccinated, and only a few severe events had been reported, including 27 deaths and 10 confirmed cases of Guillain-Barré syndrome. However, a causal relationship between HPV vaccination and either of these severe effects has not been established.

68.3.12.6 Who Should Be Vaccinated?

Given that HPV infection is sexually transmitted, and that HPV infects males and females, universal vaccination would be required to achieve maximal protection in the community. However, at this time, HPV vaccine is approved only for females.

68.3.12.6.1 Girls 11 to 12 Years Old

The ACIP recommends routine vaccination for all girls 11 to 12 years old. Why girls this young? Because the vaccine only protects against *acquiring* HPV infection; it can't clear infection that already exists. Therefore, vaccination will be most beneficial when done before vaccinees become sexually active, which is the case for most girls in this age group.

Although HPV vaccination is only *recommended* by the ACIP, it is now *mandatory* in some states. However, even in states where vaccination is mandatory, parents who object can easily have their girls opt out, by either submitting a written request or simply making a phone call, depending on local state law. Reasons for objection include expense (about \$360 for the three-dose series), concerns about safety and efficacy (because HPV vaccine is new), and concerns that conferring protection against a sexually transmitted infection might encourage

promiscuity (a concern that has no basis in fact). Parents who are considering withholding vaccination would do well to ask this question: Does protecting my daughter against developing cervical cancer later in life outweigh my concerns about vaccination? If the answer is yes—as I hope it would be—then vaccination should not be withheld.

68.3.12.6.2 Catch-up Vaccination

HPV vaccine is recommended for girls and women 13 to 26 years of age who did not receive the vaccine when they were younger.

68.3.12.6.3 What About Boys?

HPV vaccine is currently approved only for females, although studies in boys are ongoing. From data generated so far, we know the vaccine is safe in boys, and that it produces a good immune response. However, we don't yet know if vaccination will protect boys from genital warts, or will prevent boys from transmitting HPV to their partners.

68.3.12.7 Route, Site, and Immunization Schedule.

The HPV vaccine is injected IM into the deltoid region of the upper arm or the high anterolateral thigh. Three doses are given over a 6-month interval. The first is given at a time selected by the vaccinee and her provider. The second is given 2 months after the first. And the third is given 6 months after the first.

68.3.12.7.1 KEY POINTS

- Vaccines promote synthesis of antibodies directed against bacteria and viruses, whereas toxoids promote synthesis of antibodies directed against toxins that bacteria produce, but not against the bacteria themselves.
- Killed vaccines are composed of whole, killed microbes or isolated microbial components, whereas live vaccines are composed of live microbes that have been weakened or rendered completely avirulent.
- Vaccination is defined as the administration of any vaccine or toxoid.
- Vaccination produces active immunity. Antibodies develop over weeks to months and then persist for years.

- Passive immunity is conferred by administering preformed antibodies (immune globulins). Protection is immediate but lasts only as long as the antibodies remain in the body.
- Thanks to widespread vaccination, five VPDs are virtually gone from the United States, measles and wild-type polio are gone from the Western hemisphere, and smallpox is gone from the planet. Also, the incidence of several other VPDs has been greatly reduced.
- Although vaccines are very safe, mild reactions are common, and serious reactions can occur rarely.
- Several large, high-quality studies have failed to find a causal link between thimerosal-containing vaccines and autism.
- Immunocompromised children are at special risk from live vaccines and should not receive them.
- Measles, mumps, and rubella virus vaccine (MMR) is a combination product composed of three live virus vaccines.
- Rarely, MMR causes thrombocytopenia and anaphylactic reactions. Until recently, anaphylactic reactions were thought to result from allergy to eggs, but now we think they result from allergy to gelatin.

812

- MMR is contraindicated during pregnancy and should be used with caution in children with a history of either thrombocytopenia or anaphylactic reactions to gelatin, eggs, or neomycin.
- Until recently, we had two vaccines for protection against diphtheria, tetanus, and pertussis. One (DTP) contains whole-cell pertussis and the other (DTaP) contains acellular pertussis. DTaP is more effective than DTP and causes fewer and milder side effects. Accordingly, DTaP is recommended for all children. DTP is no longer available.
- Rarely, DTaP causes acute encephalopathy.
- There are two vaccines against polioviruses: oral poliovirus vaccine (OPV, Sabin vaccine) and inactivated poliovirus vaccine (IPV, Salk vaccine). OPV contains live, attenuated viruses, whereas IPV contains inactivated polioviruses.

813

- OPV can cause vaccine-associated paralytic poliomyelitis (VAPP); IPV does not. Because IPV is safer, it has replaced OPV for routine vaccination against polio in the United States.
- *Haemophilus influenzae* type b vaccine is one of our safest vaccines. No serious adverse events have been reported.
- Varicella virus vaccine is composed of live, attenuated varicella viruses.
- All children receiving varicella vaccine are fully protected against severe varicella (chickenpox), although some get mild disease. The children who get mild chickenpox despite vaccination develop far fewer lesions than unvaccinated children, experience less fever, and recover more quickly.
- Varicella vaccine is very safe; no serious adverse events have been reported.
- Varicella vaccine is contraindicated for pregnant women, individuals hypersensitive to neomycin or gelatin, and immunocompromised people.
- Hepatitis B vaccine (HepB) contains hepatitis B surface antigen (HBsAg), the primary antigenic protein in the viral envelope. Administration of HepB promotes synthesis of specific antibodies directed against hepatitis B virus.
- HepB is one of our safest vaccines. The only contraindication is a prior anaphylactic reaction either to HepB itself or to baker's yeast.
- All infants should receive monovalent HepB within 12 hours of birth (except in rare circumstances). Infants whose mothers are HBsAg-positive should also receive hepatitis B immune globulin (HBIG).
- Hepatitis A vaccine is composed of inactivated hepatitis A viruses.
- Pneumococcal conjugate vaccine is the first vaccine for preventing invasive pneumococcal disease in infants and toddlers.
- Meningococcal conjugate vaccine (MCV4), approved in 2005, is more effective in children than meningococcal polysaccharide vaccine (MPSV4), approved in the 1970s.
- Annual influenza vaccination is recommended for all children 6 months to 18 years of age.

- Current rotavirus vaccines—RotaTeq and Rotarix—do not cause intussusception, a life-threatening complication that led to withdrawal of RotaShield, an earlier rotavirus vaccine.
- The HPV vaccine, introduced in 2006, protects against cervical cancer and genital warts.
- The HPV vaccine does not protect against all the types of HPV that can cause cervical cancer, and does not protect against HPV infection that was present prior to vaccination. Accordingly, vaccinated women should still undergo routine Pap screens to detect precancerous cervical lesions, thereby permitting timely treatment before cancer develops.

⁶⁹CHAPTER 68 Immunosuppressants

Immunosuppressive drugs inhibit immune responses. They have two principal applications: (1) prevention of organ rejection in transplant recipients, and (2) treatment of autoimmune disorders (eg, rheumatoid arthritis, systemic lupus erythematosus). At the doses required to suppress allograft rejection, almost all of these drugs are toxic. Two toxicities are of particular concern: (1) increased risk of infection and (2) increased risk of neoplasms. Furthermore, because allograft recipients must take immunosuppressants for life, the risk of toxicity continues lifelong. Sites of action of immunosuppressants are summarized in [Figure 68-1](#).

^{69.1} CALCINEURIN INHIBITORS

Cyclosporine and tacrolimus are the most effective immunosuppressants available. Although cyclosporine and tacrolimus differ in structure, they share the same mechanism: Both drugs inhibit calcineurin, and thereby suppress production of interleukin-2 (IL-2), a compound needed for T-cell proliferation. Their principal use is prevention of organ rejection in transplant recipients. Cyclosporine was developed before tacrolimus and is used more often.

^{69.1.1} Cyclosporine

Cyclosporine [Sandimmune, Gengraf, Neoral] is a powerful immunosuppressant and the drug of choice for preventing organ rejection in recipients of an allogenic transplant.* Major adverse effects are nephrotoxicity and increased risk of infection.

^{69.1.1.1} Mechanism of Action

Cyclosporine acts on helper T lymphocytes to suppress production of IL-2, interferon gamma, and other cytokines. The drug's primary molecular target is a protein known as *cyclophilin*. After binding to cyclophilin, cyclosporine inhibits *calcineurin*, a key enzyme in the pathway that promotes synthesis of IL-2 and other cytokines. In the absence of these compounds, proliferation of B cells and cytotoxic T cells is suppressed. In contrast to methotrexate and other cytotoxic immunosuppressants, cyclosporine does not cause bone marrow suppression.

Figure 68-1 Sites of action of immunosuppressant drugs.

* An allogenic transplant is defined as donor tissue that is genetically distinct from tissues of the recipient, and hence subject to attack by the recipient's immune system.

69.1.1.2 Therapeutic Uses

Cyclosporine is used primarily to prevent rejection of allogenic kidney, liver, and heart transplants. A glucocorticoid (prednisone) is usually given concurrently. Azathioprine, tacrolimus, or sirolimus may be given as well. Additional indications are psoriasis (see [Chapter 104](#)) and rheumatoid arthritis (see [Chapter 72](#)).

814

69.1.1.3 Pharmacokinetics

815

Cyclosporine may be administered orally or IV. Oral administration is preferred; IV therapy is reserved for patients who cannot take the drug orally. Absorption from the GI tract is incomplete (about 30%) and erratic. Accordingly, to avoid toxicity (from high drug levels) and organ rejection (from low drug levels), blood levels of cyclosporine should be measured periodically.

Most cyclosporine in the body is bound. In the blood, the drug is bound to red cells (60% to 70%), white cells (10% to 20%), and plasma lipoproteins. Outside the vascular system, the drug is bound to tissues.

Cyclosporine undergoes extensive metabolism by hepatic microsomal enzymes. Therefore, drugs that increase or decrease the activity of these enzymes can have a significant impact on cyclosporine levels. Excretion of both cyclosporine and its metabolites is via the bile. Practically none of the drug appears in the urine.

69.1.1.4 Adverse Effects

The most common adverse effects are nephrotoxicity, infection, hypertension, tremor, and hirsutism. Of these, nephrotoxicity and infection are the most serious.

69.1.1.4.1 Nephrotoxicity.

Renal damage occurs in up to 75% of patients. Injury manifests as reduced renal blood flow and reduced glomerular filtration rate. These effects are dose dependent and usually reverse following a dosage reduction.

Nephrotoxicity is evaluated by monitoring for elevated blood urea nitrogen (BUN) and serum creatinine. However, be aware that a rise in these values could also indicate rejection of a

kidney transplant. Patients should be informed about the possibility of kidney damage and the importance of periodic tests for BUN and creatinine.

69.1.1.4.2 Infection.

Cyclosporine increases the risk of infection, although less so than the cytotoxic immunosuppressants. Infectious complications occur in 74% of those treated. Patients should be warned about early signs of infection (fever, sore throat) and instructed to report them immediately.

69.1.1.4.3 Hepatotoxicity.

Liver damage occurs in 4% to 7% of patients. Injury is evaluated by monitoring for serum bilirubin and liver transaminases. Signs of liver injury reverse rapidly with a reduction in dosage. Inform the patient about the need for periodic tests of liver function.

69.1.1.4.4 Lymphomas.

Cyclosporine and other immunosuppressants can cause lymphoproliferative diseases. The incidence with cyclosporine alone is low. However, when cyclosporine is combined with other immunosuppressants, the risk of malignant lymphomas increases.

69.1.1.4.5 Other Common Adverse Effects.

Hypertension, indicated by a 10% to 15% increase in blood pressure, develops in about 50% of patients; standard antihypertensive drugs are used for treatment. *Tremor* (21% to 55%) and *hirsutism* (21% to 45%) are also common. Less frequently, patients experience *leukopenia* (6%), *gingival hyperplasia* (4%), *gynecomastia* (4%), *sinusitis* (3% to 7%), and *hyperkalemia*.

69.1.1.4.6 Anaphylactic Reactions.

Anaphylactic reactions are rare, occurring in 1 of every 1000 patients. Signs include flushing, respiratory distress, hypotension, and tachycardia. Anaphylaxis occurs only with IV therapy, not with oral therapy. Patients should be monitored for 30 minutes after infusion onset. If anaphylaxis develops, discontinue the infusion and treat with epinephrine and oxygen.

69.1.1.4.7 Use in Pregnancy and Lactation.

At doses 2 to 5 times those used clinically, cyclosporine is embryotoxic and fetotoxic in rats and rabbits. However, experience to date shows minimal fetal risk in humans. Nonetheless, prudence dictates avoiding the drug during pregnancy, if possible. Patients taking

cyclosporine should be advised to use a mechanical form of contraception (condom, diaphragm) rather than oral contraceptives. Cyclosporine is classified in Food and Drug Administration (FDA) Pregnancy Risk Category C. The drug is excreted in breast milk, and nursing should be avoided.

69.1.1.5 Drug and Food Interactions

Many interactions have been reported. However, only a few appear to have clinical significance. These are considered below.

69.1.1.5.1 Drugs That Can Decrease Cyclosporine Levels.

Drugs that induce hepatic microsomal enzymes can accelerate metabolism of cyclosporine, causing cyclosporine levels to fall. Organ rejection can result. Drugs known to lower cyclosporine levels include *phenytoin*, *phenobarbital*, *carbamazepine*, *rifampin*, *terbinafine*, and *trimethoprim/sulfamethoxazole*. Cyclosporine levels should be monitored and the dosage adjusted accordingly.

69.1.1.5.2 Drugs That Can Increase Cyclosporine Levels.

A variety of drugs can raise cyclosporine levels, thereby increasing the risk of toxicity. Drugs known to increase cyclosporine levels include *azole antifungal drugs* (eg, ketoconazole), *macrolide antibiotics* (eg, erythromycin), and *amphotericin B*. The mechanism is inhibition of cyclosporine metabolism. When any of these drugs is combined with cyclosporine, the dosage of cyclosporine must be reduced.

Some physicians administer ketoconazole concurrently with cyclosporine for the express purpose of permitting a reduction in cyclosporine dosage. By slowing metabolism of cyclosporine, ketoconazole permits cyclosporine dosage to be reduced by up to 88%, while continuing to maintain cyclosporine levels within the therapeutic range. The lowered dosage greatly reduces the cost of treatment—from about \$7000 per year to about \$3000 per year.

69.1.1.5.3 Nephrotoxic Drugs.

Renal damage may be intensified by concurrent use of other nephrotoxic drugs. These include *amphotericin B*, *aminoglycosides*, and *nonsteroidal anti-inflammatory drugs* (NSAIDs).

69.1.1.5.4 Grapefruit Juice.

A compound present in grapefruit juice inhibits metabolism of cyclosporine. As a result, consuming grapefruit juice can raise cyclosporine levels by 50% to 200%, thereby greatly increasing the risk of toxicity.

69.1.1.6 Preparations, Dosage, and Administration

69.1.1.6.1 Preparations and Storage.

Cyclosporine is available under three trade names: *Sandimmune*, *Neoral*, and *Gengraf*. These preparations are NOT bioequivalent and cannot be used interchangeably. In *Neoral* and *Gengraf*, cyclosporine is present as a microemulsion. As a result, absorption is greater than from the *Sandimmune* formulation. As *Sandimmune*, cyclosporine is available in capsules (25 and 100 mg), an oral solution (100 mg/mL), and an IV solution (50 mg/mL). As *Neoral* or *Gengraf*, cyclosporine is available in capsules (25 and 100 mg) and an oral solution (100 mg/mL). To improve palatability, oral solutions can be mixed with plain milk, chocolate milk, or orange juice just before dosing.

69.1.1.6.2 Dosage and Monitoring for Allograft Recipients.

Dosing is complex and depends on the organ transplanted, the formulation employed (*Neoral* or *Gengraf* vs. *Sandimmune*), and other immunosuppressants taken concurrently. The dosages below are representative.

69.1.1.6.2.1 Sandimmune.

Oral therapy is preferred to IV therapy. The initial *oral* dose is 15 mg/kg given 4 to 24 hours prior to surgery. This dose is continued once daily for 1 to 2 weeks. Dosage is then gradually reduced to a maintenance level of 3 to 10 mg/kg/day.

For *intravenous* therapy, 1 mL of concentrate is diluted in 20 to 100 mL of 0.9% sodium chloride or 5% dextrose. The initial dose is 5 to 6 mg/kg (one-third the oral dose) infused over 2 to 6 hours. The solution should be protected from light. Because of the risk of anaphylaxis, epinephrine and oxygen must be immediately available. The patient should be switched to oral therapy as soon as possible.

69.1.1.6.2.2 Neoral and Gengraf.

Dosage depends on the transplanted organ and other immunosuppressive drugs taken concurrently. Typical dosages are 9 mg/kg/day for a kidney transplant, 8 mg/kg/day for a liver transplant, and 7 mg/kg/day for a heart transplant.

69.1.1.6.2.3 Monitoring.

Dosage is adjusted on the basis of nephrotoxicity and cyclosporine trough levels. Blood for drug levels is drawn just prior to the next dose. For patients receiving a kidney transplant, the target level in *whole blood* is 100 to 200 ng/mL.

815

816

69.1.1.6.3 Dosage for Rheumatoid Arthritis.

Rheumatoid arthritis is treated with Neoral or Gengraf. The initial dosage is 1.25 mg/kg twice daily. Dosage may be gradually increased to a maximum of 2 mg/kg twice daily. If there is no response by 16 weeks, cyclosporine should be discontinued.

69.1.1.6.4 Dosage for Psoriasis.

Psoriasis is treated with Neoral or Gengraf. The initial dosage is 1.25 mg/kg twice daily. This may be gradually increased to a maximum of 4 mg/kg twice daily. If the maximum dosage is not effective within 6 weeks, cyclosporine should be discontinued. If a response does occur, the dosage should be reduced to the lowest effective amount for maintenance. Continuous therapy for more than 1 year is not recommended.

69.1.2 Tacrolimus

Tacrolimus [Prograf], also known as FK506, is an alternative to cyclosporine for preventing allograft rejection. The drug is somewhat more effective than cyclosporine, but also more toxic.

69.1.2.1 Therapeutic Use.

Systemic tacrolimus is approved for prophylaxis of organ rejection in patients receiving liver, kidney, or heart transplants. Concurrent use of glucocorticoids is recommended (along with azathioprine or mycophenolate mofetil for heart transplants). Compared with patients receiving cyclosporine, those receiving tacrolimus experience fewer episodes of acute transplant rejection, but twice as many patients discontinue the drug because of toxicity. Tacrolimus is under investigation for use in patients receiving bone marrow, heart, pancreas, and small bowel

transplants. As discussed in [Chapter 104](#), tacrolimus is also used for topical therapy of atopic dermatitis.

69.1.2.2 Mechanism of Action.

Tacrolimus acts much like cyclosporine, although the two drugs are structurally dissimilar. Like cyclosporine, tacrolimus inhibits calcineurin, and thereby prevents helper T cells from producing IL-2, interferon gamma, and other cytokines. The end result is decreased proliferation of B cells and cytotoxic T cells. Tacrolimus and cyclosporine differ only in that cyclosporine must first bind to cyclophilin in order to act, whereas tacrolimus must first bind to an intracellular protein named FKBP-12.

69.1.2.3 Pharmacokinetics.

Tacrolimus may be administered orally or IV. Following oral administration, absorption is slow and incomplete; bioavailability is less than 25%. The drug is metabolized in the liver by an isozyme of cytochrome P450. Excretion is via the bile. Less than 1% is excreted unchanged in the urine. The mean plasma half-life is 8 to 9 hours.

69.1.2.4 Adverse Effects.

Adverse effects are much like those of cyclosporine. As with cyclosporine, nephrotoxicity is the major concern; the incidence is 33% to 40%. Other common reactions include neurotoxicity (headache, tremor, insomnia), GI effects (diarrhea, nausea, vomiting), hypertension, hyperkalemia, hyperglycemia, hirsutism, and gum hyperplasia. Anaphylaxis can occur with IV administration. Like other immunosuppressants, tacrolimus increases the risk of infection and lymphomas.

69.1.2.5 Drug and Food Interactions.

Because tacrolimus is metabolized by CYP3A (an isozyme of cytochrome P450), agents that inhibit CYP3A—erythromycin, ketoconazole, fluconazole, chloramphenicol, and grapefruit juice—can increase tacrolimus levels. Like tacrolimus, NSAIDs can injure the kidneys. Accordingly, NSAIDs should be avoided.

69.1.2.6 Preparations, Dosage, and Administration.

Tacrolimus [Prograf] is supplied in capsules (0.5, 1, and 5 mg) for oral use and in solution (5 mg/mL) for IV use. Oral therapy is preferred. However, initial IV therapy may be needed when initial oral therapy is not tolerated. *Oral* dosages for adults are as follows:

- *Liver transplants*—The initial dosage is 50 to 75 mcg/kg every 12 hours, beginning no sooner than 6 hours after surgery. If treatment is initiated with IV therapy, oral dosing should begin 8 to 12 hours after stopping the infusion. To monitor therapy, trough levels in whole blood should be measured; the desired range is 5 to 20 ng/mL.
- *Kidney transplants*—The initial dosage is 100 mcg/kg every 12 hours. Oral therapy can start within 24 hours after surgery, but not until renal function has recovered. To monitor maintenance therapy, trough levels in whole blood should be measured; the desired ranges are 7 to 20 ng/mL for months 1 through 3, and 5 to 15 ng/mL thereafter.
- *Heart transplants*—The initial dosage is 37.5 mcg/kg every 12 hours, beginning no sooner than 6 hours after surgery. If IV therapy is used initially, oral therapy should begin 8 to 12 hours after the last IV dose. To monitor maintenance therapy, trough levels in whole blood should be measured; the desired ranges are 10 to 20 ng/mL for months 1 through 3, and 5 to 15 ng/mL thereafter.

69.2 SIROLIMUS

69.2.1 Actions and Therapeutic Use.

Sirolimus [Rapamune] is an immunosuppressant approved only for preventing renal transplant rejection. The drug should be used in conjunction with cyclosporine and glucocorticoids. Owing to severe adverse effects and no proof of efficacy, sirolimus should not be used following liver or lung transplantation.

Sirolimus is structurally similar to tacrolimus, but works by a somewhat different mechanism. Both drugs form a complex with a regulatory protein known as FKBP-12. The ultimate result is suppression of T-cell activation and proliferation. However, there is a difference: Whereas responses to tacrolimus (and cyclosporine too) involve inhibition of calcineurin, responses to sirolimus do not.

69.2.2 Pharmacokinetics.

Sirolimus is rapidly but incompletely absorbed. Food reduces the *rate* of absorption but increases the *extent*. In the blood, most of the drug is sequestered in erythrocytes. As a result, concentrations in plasma are considerably lower than in whole blood. Sirolimus undergoes extensive metabolism by CYP3A4 (the 3A4 isozyme of cytochrome P450). Excretion is via the bile. The half-life is prolonged—2.5 days.

69.2.3 Adverse Effects.

Like all other immunosuppressants, sirolimus increases the risk of *infection*. Accordingly, patients should avoid sources of contagion. In addition, for 12 months after transplant surgery, patients should take medicine to prevent *Pneumocystis pneumonia* (PCP), an infection caused by *Pneumocystis jiroveci* (formerly thought to be *Pneumocystis carinii*). Also, for 3 months after transplant surgery, patients should take medicine to prevent infection with cytomegalovirus.

Sirolimus *raises levels of cholesterol and triglycerides*. In clinical trials, about 50% of patients required treatment with lipid-lowering drugs. Exercise caution in patients with pre-existing hyperlipidemias.

Sirolimus, combined with cyclosporine, poses a significant risk of *renal injury*. Renal function should be monitored.

Severe complications have developed in liver and lung recipients. Liver recipients treated with sirolimus plus cyclosporine or tacrolimus have developed hepatic artery thrombosis, resulting in graft rejection or death. Lung recipients have developed bronchial anastomotic dehiscence; some cases were fatal.

Other side effects include rash, acne, anemia, thrombocytopenia, joint pain, diarrhea, and hypokalemia. In addition, sirolimus increases the risk of lymphocele (a complication of renal transplant surgery). In contrast to cyclosporine, sirolimus is not neurotoxic, and, in contrast to tacrolimus, it is not diabetogenic.

69.2.4 Use in Pregnancy and Lactation.

In rats, sirolimus can cause fetal death and reduced birth weight, but does not cause fetal malformations. Effects in pregnant women have not been studied systematically. At this time, sirolimus is categorized in FDA Pregnancy Risk Category C, and hence should be avoided during pregnancy. Women should initiate effective contraception before starting sirolimus, and continue it for at least 12 weeks after stopping sirolimus. Sirolimus is excreted into breast milk, and hence breast-feeding should be avoided.

69.2.5 Drug and Food Interactions.

Levels of sirolimus can be raised or lowered by drugs that inhibit or induce CYP3A4, thereby posing a risk of toxicity or treatment failure. Drugs that *induce* CYP3A4, and thereby *decrease* sirolimus levels, include carbamazepine, phenytoin, phenobarbital, rifabutin, and rifapentine.

Drugs that *inhibit* CYP3A4, and thereby *increase* sirolimus levels, include verapamil, nicardipine,

816

azole antifungal agents (eg, ketoconazole), macrolide antibiotics (eg, erythromycin), and HIV-protease inhibitors (eg, saquinavir). Because cyclosporine, tacrolimus, and sirolimus are metabolized by CYP3A4, they can compete with each other for metabolism, and can thereby raise each other's levels.

Sirolimus can reduce the immune response to all vaccines. In addition, the drug can render patients vulnerable to infection from live virus vaccines, which must be avoided.

High-fat foods can increase sirolimus absorption by about 35%. To minimize variability, patients should take all doses consistently (ie, all with food or all without food)

Grapefruit juice can inhibit the metabolism of sirolimus, causing its level to rise. Accordingly, taking sirolimus with grapefruit juice should be avoided.

69.2.6 Monitoring.

Routine monitoring of sirolimus blood levels is not required. However, monitoring *is* recommended for pediatric patients, patients with liver disease, and patients taking strong inducers or inhibitors of CYP3A4. Monitoring is also recommended whenever the dosage of cyclosporine (taken concurrently with sirolimus) is raised or lowered substantially.

69.2.7 Preparations, Dosage, and Administration.

Sirolimus is available in tablets (1 and 2 mg) and a 1-mg/mL oral solution. The treatment program should include cyclosporine and glucocorticoids. Sirolimus dosing should begin as soon as possible after transplant surgery. The recommended regimen consists of a 6-mg loading dose followed by 2-mg daily maintenance doses. For patients who weigh less than 40 kg (but are at least 13 years old), the loading dose is 3 mg/m² and the maintenance dosage is 1 mg/m² once a day. For all patients, maintenance doses should be taken 4 hours after taking cyclosporine, should be taken consistently with respect to food intake (ie, either with food or without food), and should *not* be taken with grapefruit juice. In patients with liver impairment, maintenance doses (but not the loading dose) should be reduced by 33%.

69.3 GLUCOCORTICOIDS

Glucocorticoids (eg, prednisone) are used widely to suppress immune responses. Applications range from suppression of allograft rejection to treatment of asthma to therapy of autoimmune disorders, such as rheumatoid arthritis, systemic lupus erythematosus, and multiple sclerosis.

Glucocorticoids have multiple effects on elements of the immune system. They cause lysis of antigen-activated lymphocytes, suppression of lymphocyte proliferation, and sequestration of

lymphocytes at extravascular locations. In addition, they reduce production of IL-2 by monocytes and lymphocytes, and they reduce the responsiveness of T lymphocytes to interleukin-1.

Immunosuppressive doses are large. For example, to prevent organ rejection, an initial dose of 0.5 to 2 mg/kg of prednisone is employed. To treat episodes of acute organ rejection, 500 to 1500 mg of IV methylprednisolone is given.

Because large doses are employed, the full range of glucocorticoid adverse effects can be expected. These include increased risk of infection, thinning of the skin, bone dissolution with resultant fractures, impaired growth in children, and suppression of the hypothalamic-pituitary-adrenal axis.

The pharmacology of glucocorticoids is discussed at length in [Chapter 71](#) (Glucocorticoids in Nonendocrine Diseases).

69.4 CYTOTOXIC DRUGS

Cytotoxic drugs suppress immune responses by killing B and T lymphocytes that are undergoing proliferation. With the exception of mycophenolate mofetil, these drugs are nonspecific. That is, they are toxic to all proliferating cells. As a result, they can cause bone marrow suppression, GI disturbances, reduced fertility, and alopecia (hair loss). Neutropenia and thrombocytopenia from bone marrow suppression are of particular concern. Because of their serious adverse effects, the cytotoxic drugs are usually reserved for patients who have not responded to safer immunosuppressants (ie, cyclosporine, tacrolimus, and glucocorticoids).

69.4.1 Azathioprine

69.4.1.1 Mechanism of Action.

Azathioprine [Imuran] suppresses cell-mediated and humoral immune responses by inhibiting the proliferation of B and T lymphocytes. Azathioprine is a prodrug that undergoes conversion to its active form—mercaptopurine—in the body. Mercaptopurine suppresses cell proliferation by inhibiting DNA synthesis. Hence, the drug acts selectively during the S phase of the cell cycle. As discussed in [Chapter 101](#), mercaptopurine itself is used to treat cancer.

69.4.1.2 Therapeutic Uses.

Prior to the advent of cyclosporine, azathioprine (combined with prednisone) was the principal drug employed to suppress rejection of renal transplants. Today, azathioprine is generally used as an adjunct to cyclosporine and glucocorticoids to help suppress transplant rejection. In addition, the drug is approved for severe refractory rheumatoid arthritis in nonpregnant adults (see [Chapter 72](#)). Azathioprine has been used investigationally to treat various autoimmune

diseases, including myasthenia gravis, systemic lupus erythematosus, Crohn's disease, and ulcerative colitis.

69.4.1.3 Adverse Effects and Drug Interactions.

Although uncommon at usual therapeutic doses, *neutropenia* and *thrombocytopenia* from bone marrow suppression can be serious concerns. Accordingly, complete blood counts should be performed at baseline and periodically thereafter. Azathioprine is *mutagenic* and *teratogenic* in animals, and hence should be avoided during pregnancy. Long-term therapy is associated with an increased incidence of *neoplasms*.

Allopurinol delays conversion of mercaptopurine to inactive products, and thereby increases the risk of toxicity. If allopurinol and azathioprine are used concurrently, the dose of azathioprine must be reduced by about 70%.

69.4.1.4 Preparations, Dosage, and Administration.

Azathioprine [Imuran] is available in 50-mg tablets for oral dosing, and as a powder to be reconstituted with sterile water for IV use. For patients receiving a kidney transplant, therapy is initiated with a single daily dose of 3 to 5 mg/kg, usually beginning on the day of surgery. Daily maintenance doses range from 1 to 3 mg/kg. Oral administration is preferred to IV.

69.4.2 Cyclophosphamide

Cyclophosphamide [Cytoxan, Neosar], an anticancer drug, is discussed at length in [Chapter 101](#). Discussion here is limited to its immunosuppressant use. Cyclophosphamide is a prodrug that is converted to its active form by the liver. The active form is an alkylating agent that cross-links DNA, leading to cell injury and death. Immunosuppressant effects result from a decrease in the number and activity of B and T lymphocytes. Toxicity to other cells produces adverse effects, including neutropenia (from bone marrow suppression), hemorrhagic cystitis, and sterility in males and females. Cyclophosphamide has been used for its immunosuppressant actions to treat rheumatoid arthritis, systemic lupus erythematosus, and multiple sclerosis. The drug is as effective as azathioprine for suppressing rejection of kidney transplants.

69.4.3 Methotrexate

Methotrexate [Rheumatrex, Trexall], developed as an anticancer agent (see [Chapter 101](#)), was later found to be effective in psoriasis (see [Chapter 104](#)), and arthritis (see [Chapter 72](#)) and other autoimmune disorders. Immunosuppressant effects result from suppression of B and T lymphocytes secondary to interference with folate metabolism. The doses employed for immunosuppression are lower than those employed to treat cancer. As a result, toxicities differ

with the two applications: In cancer chemotherapy, bone marrow suppression, ulcerative stomatitis, and renal damage are primary concerns, whereas in immunosuppressive therapy, hepatic fibrosis and cirrhosis are primary concerns.

69.4.4 Mitoxantrone

Like methotrexate, mitoxantrone [Novantrone] was developed to treat cancer (see [Chapter 101](#)), and then later used for immunosuppression, owing to its toxic effects on macrophages and B and T lymphocytes. As an immunosuppressant, mitoxantrone has only one indication: reduction of neurologic disability and clinical relapse in patients with multiple sclerosis. Mitoxantrone is a dangerous drug reserved for patients unresponsive to safer agents. The basic pharmacology of the drug and its use in multiple sclerosis are discussed in [Chapter 23](#).

817

818

69.4.5 Mycophenolate Mofetil

69.4.5.1 Therapeutic Use.

Mycophenolate mofetil [CellCept, Myfortic] is approved for prophylaxis of organ rejection in patients receiving allogenic heart, liver, or kidney transplants. The drug should be combined with cyclosporine and glucocorticoids.

69.4.5.2 Mechanism of Action.

Following oral administration, mycophenolate mofetil is rapidly converted to mycophenolic acid (MPA), its active form. MPA then acts on B and T lymphocytes to inhibit inosine monophosphate dehydrogenase, an enzyme required for *de novo* synthesis of purines. Since these cells are uniquely dependent on *de novo* synthesis for proliferation (other cells acquire needed purines via salvage pathways), MPA causes selective inhibition of B and T lymphocyte proliferation.

69.4.5.3 Pharmacokinetics.

With oral administration, mycophenolate mofetil undergoes nearly complete absorption, followed by rapid and nearly complete hydrolysis to MPA. MPA is converted in the liver to an inactive metabolite, which is then excreted in the urine. The half-life of MPA is about 18 hours.

69.4.5.4 Adverse Effects.

Major adverse effects include diarrhea, vomiting, severe neutropenia, and sepsis (primarily cytomegalovirus viremia). As with other immunosuppressive drugs, there is an increased risk of infection and malignancies, especially lymphomas. Very rarely, patients have developed

progressive multifocal leukoencephalopathy, a severe infection of the brain. However, a causal relationship has not been established.

69.4.5.5 Drug Interactions.

Absorption of mycophenolate can be decreased by antacids that contain magnesium and aluminum hydroxides and by cholestyramine, a drug that lowers blood cholesterol. Accordingly, mycophenolate should not be given simultaneously with these drugs.

69.4.5.6 Use in Pregnancy.

When given to pregnant rats in doses at or below those used clinically, mycophenolate causes fetal malformations and fetal resorption. Controlled studies in women have not been performed. Because of the serious risk of fetal toxicity, the drug should be avoided during pregnancy. Before initiating treatment, pregnancy should be ruled out. During therapy, women of child-bearing age should use *two* reliable forms of contraception.

69.4.5.7 Preparations, Dosage, and Administration.

Administration is PO or IV. For oral dosing, mycophenolate mofetil [CellCept, Myfortic] is available in 250-mg capsules, 500-mg immediate-release tablets, 180- and 360-mg delayed-release tablets, and a 200-mg/mL suspension. For IV dosing, the drug is available as a lyophilized powder [CellCept] to be reconstituted to a 6-mg/mL solution. Intravenous administration is reserved for patients who cannot take the drug orally, and should be done by *slow infusion* (over 2 hours or longer). Adult dosages are as follows:

- *Kidney transplant*—1 gm twice daily, IV or PO
- *Heart transplant*—1.5 gm twice daily, IV or PO
- *Liver transplant*—1 gm twice daily IV or 1.5 gm twice daily PO

Dosing should begin within 24 hours of transplant surgery. All patients who receive IV therapy initially should switch to oral therapy within 14 days. As a rule, oral dosing should be done on an empty stomach to increase drug availability.

69.5 ANTIBODIES

Antibodies directed against components of the immune system can suppress immune responses. Five preparations are considered here. Four of these—muromonab-CD3, basiliximab, daclizumab, and lymphocyte immune globulin—are used to suppress allograft rejection in transplant recipients.

Pharmacology for Nursing Care, 7th Edition

The fifth preparation—Rh_o(D) immune globulin (RhIG)—is used to prevent reactions to Rh-positive blood in Rh-negative women.

69.5.1 Muromonab-CD3

69.5.1.1 Actions and Uses.

Muromonab-CD3 [Orthoclone OKT3] is a monoclonal antibody, developed in mice, that binds to the CD3 site on human T lymphocytes. Upon binding, the antibody blocks T-cell function. All T cells—both those in the circulation and those in tissues—are affected. Muromonab-CD3 is used to prevent acute rejection of kidney, heart, and liver transplants. In addition, the drug is given to deplete T cells from bone marrow prior to bone marrow transplantation.

69.5.1.2 Adverse Effects.

Relatively mild reactions are common. Among these are fever (73%), chills (59%), dyspnea (21%), chest pain (14%), and nausea and vomiting (12%). These effects are most intense on the first day and then rapidly subside.

In some patients, potentially fatal *anaphylactoid reactions* have occurred. Manifestations include pulmonary edema, cardiovascular collapse, and cardiac or respiratory arrest. Accordingly, patients should be monitored closely. Also, the drug should be used only in facilities with equipment and staffing for cardiopulmonary resuscitation.

69.5.1.3 Preparations, Dosage, and Administration.

Muromonab-CD3 [Orthoclone OKT3] is supplied in solution (1 mg/mL) for IV administration. The usual dosage is 5 mg/day for 10 to 14 days. Administration is by IV bolus. The preparation should be drawn through a filter before injection. Treatment is begun following diagnosis of acute transplant rejection. To minimize first-dose adverse reactions, the patient should be pretreated with an IV glucocorticoid. The wholesale cost for a course of treatment averages \$7000.

69.5.2 Basiliximab and Daclizumab

69.5.2.1 Actions and Uses.

Basiliximab [Simulect] and daclizumab [Zenapax] are monoclonal antibodies, developed in mice, that bind to the receptor for IL-2 on T lymphocytes. By doing so, they block activation of T cells by IL-2.

Both drugs have the same indication: prophylaxis of *acute* organ rejection following *renal* transplantation. Both drugs must be combined with cyclosporine and a glucocorticoid. In clinical trials, these drugs helped reduce the incidence of acute organ rejection during the first 6 months after transplant surgery, but had little or no impact on graft survival after 1 year.

69.5.2.2 Adverse Effects.

Basiliximab and daclizumab are generally well tolerated. The incidence and severity of adverse effects is much lower than with muromonab-CD3. In contrast to other immunosuppressants, basiliximab and daclizumab do not increase the risk of opportunistic infections. Furthermore, no cancers have been observed 1 year after treatment.

Rarely, these drugs cause severe, acute *hypersensitivity reactions*, including anaphylaxis. Accordingly, medications for managing hypersensitivity should be immediately available. If a severe hypersensitivity reaction occurs, these drugs should be permanently discontinued.

In a cardiac transplantation trial, mortality rates were *increased* by adding *daclizumab* (7% vs. 5% with placebo). All patients were also receiving cyclosporine, mycophenolate, and glucocorticoids. Increased mortality appeared to result from increased infection.

69.5.2.3 Preparations, Dosage, and Administration.

Basiliximab. Basi-liximab [Simulect] is available as a powder to be reconstituted for IV administration. Treatment consists of two 20-mg doses, given by either (1) IV bolus or (2) IV infusion over 20 to 30 minutes. The first dose is given within 2 hours *prior* to transplant surgery. The second is given 4 days later. The wholesale cost for the two doses is about \$2500.

69.5.2.3.1 Daclizumab.

Daclizumab [Zenapax] is available in a concentrated solution (25 mg/5 mL) that must be diluted in 50 mL of 0.9% saline for IV infusion. Treatment consists of five doses (1 mg/kg each) infused over 15 minutes. The first dose is given within 24 hours prior to transplant surgery. The next four doses are given 2, 4, 6, and 8 weeks later. The wholesale cost for a course of treatment is about \$6000.

69.5.3 Lymphocyte Immune Globulin, Antithymocyte Globulin (Equine)

69.5.3.1 Basic Pharmacology.

Lymphocyte immune globulin [Atgam] is prepared by immunizing horses with human T lymphocytes. Therapeutic effects result from a decrease in the number and activity of thymus-

derived lymphocytes. Lymphocyte immune globulin has two approved uses: (1) preventing rejection of renal transplants and (2) treating aplastic anemia. Investigational uses include treatment of multiple sclerosis and myasthenia gravis, and suppressing rejection of liver, bone marrow, and heart transplants. Lymphocyte immune globulin is usually employed in combination with glucocorticoids and azathioprine. Because these other immunosuppressants are present, immune reactions to this horse-derived drug are generally mild (chills, fever, leukopenia, skin reactions). However, anaphylactic reactions can occur. Accordingly, epinephrine and facilities for respiratory support should be immediately available.

69.5.3.2 Preparations, Dosage, and Administration.

Lymphocyte immune globulin is supplied in solution (50 mg/mL) for IV administration. The concentrate should be diluted in saline solution as per the manufacturer's instructions. The infusion apparatus should have an in-line filter. To minimize phlebitis, a vein with high flow should be employed. Monitor the patient for anaphylaxis. Each dose should be infused over 4 or more hours. Dosages for adults are as follows:

- *Prevention of renal allograft rejection*—15 mg/kg/day for 14 days, followed by alternate-day dosing for 14 more days, to make a total of 21 doses over 28 days.
- *Treatment of aplastic anemia*—10 to 20 mg/kg/day for 8 to 14 days followed, if needed, by alternate-day dosing for up to a total of 21 doses.

69.5.4 Rh₀(D) Immune Globulin

Rh₀(D) immune globulin (RhIG) is a concentrated preparation of immune globulin that contains antibodies to Rh₀(D). RhIG is given to prevent development of antibodies to Rh₀(D) in Rh₀(D)-negative women following exposure to Rh₀(D)-positive blood. Such exposure can occur in association with a Rh₀(D)-positive pregnancy (as a result of the pregnancy itself, full-term delivery, spontaneous or induced abortion, or amniocentesis). RhIG suppresses the immune response of Rh-negative women to Rh-positive blood cells. In many medical centers, RhIG is administered routinely at 28 weeks of gestation to all Rh₀(D)-negative women.

Undesired reactions are uncommon and mild. Temperature may rise slightly. RhIG is contraindicated for Rh-positive women and must not be administered to newborns.

RhIG [RhoGAM, BayRho-D Full Dose] is supplied in vials and pre-filled syringes for IM injection. Prevention of anti-Rh₀(D) antibody formation is most successful if the drug is administered twice: at 28 weeks of gestation and again within 72 hours after delivery.

69.5.4.1

KEY POINTS

- Immunosuppressants are used to prevent organ rejection in allograft recipients and to treat autoimmune disorders (eg, rheumatoid arthritis).
- Allograft recipients must take immunosuppressants for life.
- Immunosuppressants increase the risk of infection and lymphomas.
- Cyclosporine and tacrolimus are the most effective immunosuppressants available.
- Cyclosporine and tacrolimus are used primarily in allograft recipients.
- Cyclosporine causes kidney injury in up to 75% of patients.
- Renal damage from cyclosporine can be intensified by other nephrotoxic drugs, including amphotericin B, aminoglycosides, and NSAIDs.
- Drugs that inhibit hepatic microsomal enzymes can increase cyclosporine levels, and drugs that induce these enzymes can decrease cyclosporine levels.
- Grapefruit juice inhibits cyclosporine metabolism, and can thereby greatly increase cyclosporine levels.
- Like cyclosporine, tacrolimus causes renal damage, and hence should not be combined with other nephrotoxic drugs.
- Ketoconazole, fluconazole, grapefruit juice, and other agents that inhibit metabolism of tacrolimus can elevate its levels.
- Immunosuppressant applications of glucocorticoids include suppression of transplant rejection and treatment of rheumatoid arthritis and other autoimmune disorders.
- Prolonged use of glucocorticoids can cause osteoporosis, thinning of the skin, increased risk of infection, impaired growth in children, and adrenal insufficiency (secondary to suppression of the hypothalamic-pituitary-adrenal axis).
- Cytotoxic immunosuppressants (eg, azathioprine) decrease immune responses by killing B and T lymphocytes.
- Cytotoxic immunosuppressants (except mycophenolate mofetil) injure all proliferating cells. As a result, these drugs can cause bone marrow suppression (neutropenia, thrombocytopenia), GI disturbances, reduced fertility, and alopecia.

- Immune responses can be suppressed with muromonab-CD3, basiliximab, and other antibodies directed against components of the immune system.

Summary of Major Nursing Implications*

CYCLOSPORINE

Preadministration Assessment

Therapeutic Goal

Prevention of allograft rejection

Baseline Data

Obtain baseline data on kidney function (serum creatinine, BUN), liver function (aspartate aminotransferase, alanine aminotransferase, serum amylase, bilirubin, alkaline phosphatase), and serum potassium levels.

Identifying High-Risk Patients

Cyclosporine has the following *contraindications*: hypersensitivity to cyclosporine or its intravenous vehicle (polyoxyethylated castor oil), pregnancy, recent inoculation with a live virus vaccine, and chickenpox or herpes zoster (or recent contact with a person with either infection).

Use with *caution* in patients taking potassium-sparing diuretics and in those with intestinal malabsorption, hypertension, hyperkalemia, active infection, and renal or hepatic dysfunction.

Implementation: Administration

Routes

Oral, intravenous.

Preparations

Cyclosporine is available under three trade names: Sandimmune, Neoral, and Gengraf. Sandimmune has lower bioavailability than Neoral or Gengraf, and hence is not interchangeable with them.

Patient Education for Oral Administration

Dispense the oral liquid into a glass container using the specially calibrated pipette. Mix well with diluent and drink immediately. Rinse the container with diluent and drink to ensure ingestion of the complete dose. Dry the outside of the pipette and return to its cover for storage.

To improve palatability, mix the concentrated drug solution with plain milk, chocolate milk, or orange juice just before dosing.

Intravenous Dosage and Administration

Dilute 1 mL of concentrate in 20 to 100 mL of 0.9% sodium chloride or 5% dextrose. Protect from light. Administer the initial dose (5 to 6 mg/kg) slowly—over 2 to 6 hours. Because of the risk of anaphylactic reactions, monitor the patient closely for 30 minutes after beginning administration. Have epinephrine and oxygen available. Switch to oral therapy as soon as possible.

Dosage Adjustment

Adjust dosage on the basis of nephrotoxicity and cyclosporine trough levels. Draw blood for drug levels just prior to the next dose. The target level is 100 to 200 ng/mL in whole blood.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Graft tenderness or fever may indicate rejection. In renal transplant recipients, elevated BUN and elevated serum creatinine in conjunction with low cyclosporine may indicate rejection. Therapeutic failure can be confirmed with ultrasound, a biopsy, or renal flow scan.

Minimizing Adverse Effects

Nephrotoxicity.

Cyclosporine can cause a dosedependent reduction in kidney function. Monitor for elevation of serum creatinine and BUN. **Inform outpatients about the importance of undergoing periodic tests of kidney function.**

69.5.4.2...

Infection.

Cyclosporine increases the risk of infection. **Inform patients about early signs of infection (fever, sore throat), and instruct them to report these immediately.**

69.5.4.2...

Hepatotoxicity.

Cyclosporine causes reversible liver damage. Monitor for elevation of serum bilirubin and liver transaminases. **Inform patients about the need for periodic tests of liver function.**

69.5.4.2...

Hirsutism.

Cyclosporine promotes hair growth. **Assure the patient that this effect is reversible.**

69.5.4.2...

Use in Pregnancy and Lactation.

Cyclosporine is embryotoxic. **Advise women of child-bearing age to use a mechanical form of contraception (diaphragm, condom) and to avoid oral contraceptives. Cyclosporine is excreted in breast milk; warn patients against breast-feeding.**

69.5.4.2...

Anaphylactic Reactions.

See **Intravenous Dosage and Administration.**

69.5.4.2...

Minimizing Adverse Interactions

69.5.4.2...

Drugs That Can Decrease Cyclosporine Levels.

Phenytoin, phenobarbital, carbamazepine, rifampin, terbinafine, and trimethoprim/sulfamethoxazole can reduce cyclosporine levels, leading to organ rejection. Monitor cyclosporine levels and increase the dosage as needed.

69.5.4.2...

Drugs That Can Increase Cyclosporine Levels

Azole antifungal drugs (eg, ketoconazole), *macrolide antibiotics* (eg, erythromycin), and *amphotericin B* can elevate cyclosporine levels, thereby increasing the risk of toxicity. Monitor cyclosporine levels and reduce the dosage as needed.

69.5.4.2...

Nephrotoxic Drugs

*Amphotericin B, aminoglycosides, **and** NSAIDs* increase the risk of cyclosporine-induced kidney damage. Monitor renal function.

69.5.4.2...

Grapefruit Juice.

Grapefruit juice inhibits cyclosporine metabolism, and can thereby increase cyclosporine levels. Toxicity may result.

* Patient education information is highlighted as **blue text**.

⁷⁰CHAPTER 69 Antihistamines

Histamine is an endogenous compound found in specialized cells throughout the body. The substance plays an important role in allergic reactions and regulation of gastric acid secretion. The antihistamines, one of our most widely used families of drugs, block histamine's actions.

In order to understand the antihistamines, we must first understand histamine itself. Accordingly, the chapter begins with a discussion of histamine, emphasizing its contribution to allergic responses. Discussion of the antihistamines follows.

^{70.1}HISTAMINE

Histamine is a locally acting substance with prominent and varied effects. In the vascular system, histamine dilates small blood vessels and increases capillary permeability. In the bronchi, histamine produces constriction. In the stomach, histamine stimulates secretion of acid. In the central nervous system (CNS), histamine acts as a neurotransmitter. Despite this impressive spectrum of actions, clinical applications for histamine itself are limited. Currently, use of histamine is restricted to diagnostic procedures. However, although its clinical utility is minimal, histamine is still of great interest owing to its involvement in two common pathologic states: allergic disorders and peptic ulcer disease.

^{70.1.1} Distribution, Synthesis, Storage, and Release

^{70.1.1.1} Distribution.

Histamine is present in practically all tissues. Levels are especially high in the skin, lungs, and GI tract. The histamine content of plasma is low.

^{70.1.1.2} Synthesis and Storage.

In the periphery, histamine is synthesized and stored in two types of cells: *mast cells* and *basophils*. Mast cells are present in the skin and other soft tissues; basophils are present in the blood. In both mast cells and basophils, histamine is stored in structures called secretory granules. (In addition to histamine, secretory granules contain other substances that, like histamine, are mediators of allergic reactions.)

In the CNS, histamine is produced by neurons with cell bodies in the posterior hypothalamus and with axonal projections to the frontal and temporal cortices and other brain regions.

70.1.1.3 Release.

Release of histamine from mast cells and basophils is produced by allergic and nonallergic mechanisms.

70.1.1.3.1 Allergic Release.

The initial requirement for allergic release of histamine is the production of antibodies of the immunoglobulin E class. These antibodies are generated in response to exposure to specific allergens (eg, pollens, insect venoms, certain drugs). Following synthesis, the antibodies become attached to the outer surface of mast cells and basophils ([Fig. 69-1](#)). When the individual is re-exposed to the allergen, the allergen becomes bound by the antibodies. As indicated in [Figure 69-1](#), binding of allergen to adjacent antibodies creates a bridge between those antibodies. By a mechanism that is not fully understood, this bridging process mobilizes intracellular calcium. The calcium, in turn, causes the histamine-containing storage granules to fuse with the cell membrane and disgorge their contents into the extracellular space. Note that allergic release of histamine requires *prior exposure* to the allergen; an allergic reaction cannot occur during initial contact with an allergen.

70.1.1.3.2 Nonallergic Release.

A number of agents (certain drugs, radiocontrast media, plasma expanders) can act directly on mast cells to trigger histamine release. With these agents, no prior sensitization is needed. Cell injury can also cause direct release.

70.1.2 Physiologic and Pharmacologic Effects

Histamine acts primarily through two types of receptors, named H₁ and H₂. As discussed below, responses to activation of these receptors differ.

70.1.2.1 Effects of H₁ Stimulation

70.1.2.1.1 Vasodilation.

Activation of H₁ receptors causes dilation of small blood vessels (arterioles and venules). Vasodilation is prominent in the skin of the face and upper body, causing the area to become warm and flushed. If extensive vasodilation occurs, total peripheral resistance declines and blood pressure falls.

70.1.2.1.2 Increased Capillary Permeability.

Histamine₁ stimulation increases capillary permeability. How? By causing capillary endothelial cells to contract, which creates openings between these cells through which fluid, protein, and platelets can escape. Escape of fluid and protein into the interstitial space produces edema. If loss of intravascular fluid is substantial, blood pressure may fall.

821

822

Figure 69-1 Release of histamine by allergen-antibody interaction.(IgE = immunoglobulin E.)

70.1.2.1.3 Bronchoconstriction.

Histamine₁ activation causes constriction of the bronchi. If histamine is administered to an individual with asthma, severe bronchoconstriction will follow. However, although *exogenous* histamine can induce bronchial constriction, histamine is not the cause of bronchoconstriction that occurs during a spontaneous asthma attack. Consequently, antihistamines are of no use for treating asthma.

70.1.2.1.4 CNS Effects.

In the CNS, H₁ receptors have a role in cognition, memory, and the cycle of sleeping and waking. In addition, H₁ receptors appear to have a role in seizure suppression, modulation of neurotransmitter release, and regulation of energy and endocrine homeostasis.

70.1.2.1.5 Other Effects.

Activation of H₁ receptors on sensory nerves produces *itching* and *pain*. Histamine₁ activation also promotes *secretion of mucus*.

70.1.2.2 Effects of H₂ Stimulation

The major response to activation of H₂ receptors is *secretion of gastric acid*. Histamine acts directly on parietal cells of the stomach to promote acid release. Although acetylcholine and gastrin also help regulate acid release, histamine has a dominant role. We know this because, in the presence of H₂ blockade, acetylcholine and gastrin are unable to elicit acid secretion.

70.1.3 Role of Histamine in Allergic Responses

Allergic reactions are mediated by histamine and other compounds (eg, prostaglandins, leukotrienes, tryptase). The intensity of an allergic reaction is determined by which mediator is involved.

70.1.3.1 Mild Allergy.

The symptoms of mild allergy (eg, rhinitis, itching, localized edema) are caused largely by histamine, acting at H₁ receptors. As a result, mild allergic conditions (eg, hay fever, acute urticaria, mild transfusion reactions) are generally responsive to antihistamine therapy.

70.1.3.2 Severe Allergic Reactions (Anaphylaxis).

Severe allergic reactions manifest as *anaphylactic shock*, a syndrome characterized by bronchoconstriction, hypotension, and edema of the glottis. Although histamine is involved in anaphylaxis, it plays a minor role; other substances (eg, leukotrienes) are the principal mediators. Since histamine has little to do with producing anaphylaxis, it follows that antihistamines are of little help as treatment. The drug of choice for anaphylaxis is *epinephrine*. The rationale for using epinephrine is discussed in [Chapter 17](#).

70.2 THE TWO TYPES OF ANTIHISTAMINES: H₁ ANTAGONISTS AND H₂ ANTAGONISTS

Antihistamines fall into two basic categories: H₁ receptor antagonists and H₂ receptor antagonists. The H₁ antagonists produce selective blockade of H₁ receptors. The H₂ antagonists produce selective blockade of H₂ receptors. The principal use of H₁ blockers is treatment of mild allergic disorders. The principal use of H₂ blockers is treatment of gastric and duodenal ulcers. Because H₂ antagonists do not block H₁ receptors, these drugs are of no use for treating allergies. In this chapter, we focus on H₁ antagonists. The H₂ blockers, which are important and widely used, are discussed in [Chapter 77](#) (Drugs for Peptic Ulcer Disease).

70.3 H₁ ANTAGONISTS I: BASIC PHARMACOLOGY

The H₁ antagonists are the classic antihistamines. These agents were in use long before H₂ blockers came along. In fact, before H₂ blockers became available, the term *H₁ antagonist* did not exist; the drugs that we now call H₁ antagonists or H₁ blockers were simply referred to as *antihistamines*. Because of its historic use, the term *antihistamines* is still employed as a synonym for the subgroup of histamine antagonists that produce selective H₁ blockade. In this chapter, we respect tradition and continue to use the term *antihistamine* interchangeably with H₁ blocker and H₁ antagonist.

Although all H₁ antagonists available have similar antihistaminic actions, these drugs differ significantly in side effects. Because of these differences, selection of a prototype to represent the group is not feasible. Hence, rather than structuring discussion around one prototypic drug, we discuss the H₁ antagonists collectively. Differences among individual antihistamines are addressed as appropriate.

822

823

70.3.1 Classification of H₁ Antagonists

The H₁ antagonists fall into two major groups: *first-generation* H₁ antagonists and *second-generation* H₁ antagonists. The principal difference between the groups is that first-generation antihistamines are highly sedating, whereas second-generation antihistamines are not.

70.3.2 Mechanism of Action

Histamine₁ blockers bind selectively to H₁-histaminic receptors, thereby blocking the actions of histamine at these sites. H₁ antagonists do not block H₂ receptors. Also, they do not block release of histamine from mast cells or basophils.

It should be noted that, although interaction of the classic antihistamines with *histaminic* receptors is limited to the H₁ receptor subtype, these drugs can also bind to *nonhistaminic* receptors. Of particular significance is the ability of certain antihistamines to bind to and block *muscarinic* receptors. This action underlies several important side effects.

70.3.3 Pharmacologic Effects

70.3.3.1 Peripheral Effects.

The major therapeutic effects of the H₁ antagonists can be attributed to preventing the actions of histamine at H₁ receptors. In arterioles and venules of the skin, H₁ blockers inhibit the dilator actions of histamine, and thereby reduce localized flushing. In capillary beds, the antihistamines prevent histamine-induced increases in permeability, and thereby reduce edema. By blocking histamine at sensory nerves, H₁ antagonists reduce itching and pain. Blockade of H₁ receptors in mucous membranes suppresses secretion of mucus.

70.3.3.2 Effects on the CNS.

Antihistamines can cause both excitation and depression of the CNS. At *therapeutic doses*, antihistamines produce CNS *depression*: reaction time is slowed, alertness is diminished, and drowsiness is likely. These effects are more pronounced with some antihistamines than with others. With most second-generation antihistamines (eg, fexofenadine), CNS depression is negligible.

Overdose with antihistamines can produce *CNS stimulation*. Convulsions frequently result. Very young children are especially sensitive to CNS stimulation by these drugs.

70.3.3.3 Other Pharmacologic Effects.

Blockade of muscarinic cholinergic receptors by antihistamines can produce typical *anticholinergic* responses. These are discussed below under *Adverse Effects*. Several antihistamines can suppress nausea and vomiting (see below under *Motion Sickness*).

70.3.4 Therapeutic Uses

All of the H₁ antagonists are useful in treating allergic disorders. Some are also indicated for other conditions (eg, motion sickness, insomnia).

70.3.4.1 Mild Allergy.

Antihistamines can reduce symptoms of mild allergies. In people with *seasonal allergic rhinitis* (also known as hay fever or rose fever), H₁ blockers can reduce sneezing, rhinorrhea, and itching of the eyes, nose, and throat (although they can't reduce nasal congestion). In patients with *acute urticaria*, these drugs can reduce redness, itching, and edema. The antihistamines can also reduce symptoms of *allergic conjunctivitis* and urticaria associated with *mild transfusion reactions*. In all of these conditions, benefits result from H₁ receptor blockade—not from preventing allergen-induced release of histamine from mast cells and basophils. Because mild allergic reactions may be mediated by substances in addition to histamine, antihistamines often fail to produce complete relief.

70.3.4.2 Severe Allergy.

As noted, the major symptoms of anaphylaxis (hypotension, laryngeal edema, bronchospasm) are caused by mediators other than histamine. Hence, although antihistamines may be employed as adjuncts in patients with anaphylaxis, their benefits are limited.

70.3.4.3 Motion Sickness.

Some antihistamines, such as promethazine [Phenergan] and dimenhydrinate [Dramamine], are labeled for use in motion sickness. Benefits derive from blocking H₁ receptors and muscarinic receptors in the neuronal pathway leading from the vestibular apparatus of the inner ear to the vomiting center of the medulla. Motion sickness and its treatment are discussed in [Chapter 79](#). The antihistamines employed for motion sickness, along with their dosages, are listed in [Table 79-1](#).

70.3.4.4 Insomnia.

The ability of antihistamines to cause CNS drowsiness has been exploited in the treatment of insomnia. Practically every over-the-counter (OTC) sleep aid contains an H₁ antagonist (diphenhydramine or pyrilamine) as its active ingredient. However, although antihistamines can induce sleep when used in sufficient dosage, the doses recommended for OTC preparations are usually too low to be effective.

70.3.4.5 Common Cold.

Despite their widespread presence in cold remedies, antihistamines are of practically no value against the common cold. These drugs neither prevent colds nor shorten their duration. Moreover, since histamine does not mediate symptoms of colds, H₁ blockade cannot even provide symptomatic relief. The only benefit these drugs may offer is a moderate reduction in rhinorrhea, an effect that derives from their *anticholinergic* properties, not from H₁ blockade.

70.3.5 Adverse Effects

All of the H₁ blockers can produce undesired effects. As a rule, these responses are more of a nuisance than a source of serious discomfort or danger. Frequently, side effects subside with continued drug use. Because individual antihistamines differ in their abilities to produce particular side effects ([Table 69-1](#)), adverse responses can be minimized by judicious drug selection.

70.3.5.1 Sedation.

Sedation is the most common side effect of the antihistamines, and can lead to serious consequences. For students, sedation can impair learning and memory. For drivers, sedation greatly increases the risk of an accident. In fact, the degree of impairment seen with antihistamines equals that seen when blood levels of alcohol exceed the legal limit. Worse yet, impairment can occur without feeling tired. Accordingly, patients should be advised to exercise extreme caution when driving or performing other hazardous activities. They should also be warned against using alcohol and other CNS depressants. Why? Because these agents will intensify the depressant effects of the H₁ antagonist. Fortunately, tolerance to sedation often develops within a few days or weeks. If a preparation with a long half-life is being used, daytime sedation can be minimized by administering the entire daily dose at night.

The second-generation antihistamines exert little or no sedative effect. Why? Because they can't cross the blood-brain barrier, and hence cannot alter CNS function.

For patients who experience disabling sedation with a first-generation H₁ antagonist, therapy with a second-generation (nonsedating) antihistamine is likely to help. Unfortunately, the nonsedating agents are more expensive than the first-generation agents. The sedative properties of individual antihistamines are indicated in [Table 69-1](#).

70.3.5.2 Nonsedative CNS Effects.

In addition to sedation, antihistamines can cause dizziness, incoordination, confusional states, and fatigue. The elderly are especially sensitive to these actions. In some patients, paradoxical excitation occurs, resulting in insomnia, nervousness, tremors, and even convulsions. CNS stimulation is most common in children and following overdose.

70.3.5.3 Gastrointestinal Effects.

Gastrointestinal disturbances are common. Responses include nausea, vomiting, loss of appetite, and diarrhea or constipation. These reactions can be minimized by administering antihistamines with meals.

70.3.5.4 Anticholinergic Effects.

The H₁ antagonists possess weak atropine-like properties. These antimuscarinic actions can produce drying of mucous membranes in the mouth, nasal passages, and throat. Cholinergic blockade may also result in urinary hesitancy, constipation, and palpitations. If dry mouth becomes distressing, discomfort can be minimized by sucking on hard (sugarless) candy and by taking frequent sips of fluid. Antihistamines should be used with caution in patients with asthma, because thickening of bronchial secretions may impair breathing. Care should also be exercised in patients with other conditions that may be exacerbated by muscarinic blockade (eg, urinary retention, prostatic hypertrophy, hypertension). The antimuscarinic efficacy of individual H₁ blockers is indicated in [Table 69-1](#). As you can see, the second-generation antihistamines are the least anticholinergic.

70.3.5.5 Cardiac Dysrhythmias.

Potentially fatal cardiac dysrhythmias (torsades de pointes, ventricular fibrillation, and others) have occurred rarely in patients taking *astemizole* [Hismanal] or *terfenadine* [Seldane], two second-generation antihistamines. These drugs promote dysrhythmias by prolonging the QT interval, but only when their levels are excessive. Because of their potential for serious harm, terfenadine and astemizole were withdrawn from the market.

70.3.6 Drug Interactions: CNS Depressants

Alcohol and other CNS depressants (eg, barbiturates, benzodiazepines, opioids) can intensify the depressant effects of H₁ antagonists. Patients should be advised against drinking alcoholic beverages. If medications with CNS-depressant properties are combined with H₁ blockers, dosage of the depressant may need to be lowered.

70.3.7 Use in Pregnancy and Lactation

70.3.7.1 Pregnancy.

The margin of safety of antihistamines in pregnancy is unknown. There have been reports of fetal malformation, but direct involvement of H₁ antagonists has not been proved. Given the uncertainty over the safety of these drugs, it is recommended that antihistamines be used only when clearly necessary, and only when the benefits of treatment outweigh the potential risks to the fetus. Antihistamines should be avoided late in the third trimester, because newborns are particularly sensitive to the adverse actions of these drugs.

70.3.7.2 Lactation.

The H₁ antagonists can be excreted in breast milk, thereby posing a risk to the nursing infant. Since infants, and especially newborns, are unusually sensitive to antihistamines, these drugs should be avoided by women who are breast-feeding.

824

825

TABLE 69-1 Pharmacologic Effects of H₁ Antagonists*

Drug	H ₁ -Blocking Activity	Sedative Effects	Anticholinergic Effects
First-Generation Agents			
Alkylamines			
Brompheniramine	+++	+	++
Chlorpheniramine	++	+	++
Dexchlorpheniramine	+++	+	++
Ethanolamines

* ± + low to none, ++ low, +++ moderate, ++++ high.

† Promethazine can cause fatal respiratory depression in patients under 2 years old, and hence is contraindicated for this group.

‡ May cause excitation.

70.3.8 Acute Toxicity

Although the antihistamines have a large margin of safety, acute poisoning is nonetheless common, owing to the widespread availability of these drugs. CNS effects are prominent, especially anticholinergic reactions. Specific symptoms and treatment are described below.

70.3.8.1 Symptoms.

The anticholinergic actions of H₁ blockers produce symptoms resembling those of atropine poisoning (dilated pupils, flushed face, hyperpyrexia, tachycardia, dry mouth, urinary retention). In children, CNS excitation is prominent, manifesting as hallucinations, incoordination, ataxia, and convulsions. In extreme cases, intoxication progresses to coma, cardiovascular collapse, and death.

70.3.8.2 Treatment.

There is no specific antidote to antihistamine poisoning. Hence, treatment is directed at drug removal and managing symptoms. Absorption can be minimized by giving activated charcoal (to adsorb the drug), followed by a cathartic (to hasten its export from the GI tract). Convulsions can be treated with IV phenytoin. Anticonvulsants that have CNS-depressant properties must be avoided. Hyperthermia can be reduced by applying ice packs or by giving sponge baths.

70.4 H₁ ANTAGONISTS II: PREPARATIONS

70.4.1 First-Generation H₁ Antagonists

The first-generation (sedating) H₁ antagonists can be grouped into five major categories (see [Table 69-1](#)). As indicated in the table, these groups differ in antihistaminic efficacy and the ability to cause sedation and muscarinic blockade. Given these differences, it is often possible, through judicious drug selection, to produce effective H₁ blockade while minimizing undesired effects.

Sedation can be a significant problem. Among the first-generation agents, CNS depression is most prominent with the ethanolamines (eg, diphenhydramine) and phenothiazines (eg, promethazine), and least prominent with the alkylamines (eg, chlorpheniramine). For many patients, the alkylamines can provide effective H₁ blockade while causing only a modest reduction in alertness. If sedation remains excessive with an alkylamine, a second-generation agent should be tried.

As indicated in [Table 69-1](#), most first-generation agents have significant anticholinergic properties. As a result, they can cause dry mouth, urinary hesitancy, and other typical anticholinergic side effects.

All of the H₁ blockers can be administered by mouth. In addition, some can be given parenterally or by rectal suppository. Routes and dosages for individual H₁ antagonists are summarized in [Table 69-2](#).

70.4.2 Second-Generation (Nonsedating) H₁ Antagonists

Six second-generation antihistamines are available: azelastine, cetirizine, levocetirizine, fexofenadine, loratadine, and desloratadine. The second-generation agents differ from the first-generation agents in that they cross the blood-brain barrier poorly, and hence produce much less sedation than the first-generation drugs. Synergism with alcohol and other CNS depressants is low. Nonetheless, combined use with these drugs should be avoided. In addition to lacking sedative effects, the second-generation agents are largely devoid of anticholinergic actions. When these drugs were introduced, they all required a prescription and their prices were very high. Several second-generation drugs are now available over the counter, and prices are falling. Since all of these drugs are very similar, initial selection can usually be based on price. If a cheaper agent proves ineffective, a more expensive agent can be tried.

825

826

TABLE 69-2 Some H₁ Antagonists: Trade Names, Routes, and Dosage

Generic Name	Trade Names	Routes	Usual Adult Oral Dosage
First-Generation Agents			
Alkylamines			
Brompheniramine	Brovex, others	PO	4 mg q 4–6 h
Chlorpheniramine	Chlor-Trimeton, others	PO	4 mg q 4–6 h
Dexchlorpheniramine	Generic only	PO	2 mg q 4–6 h
Ethanolamines			
Clemastine	Tavist Allergy, Dayhist-1	PO	1.34 mg q 12 h
Diphenhydramine	Benadryl, others	PO, IV, IM	25–50 mg q 6–8 h
Phenothiazines			
Promethazine [*]	Phenergan, others	PO, IV, IM, R [†]	12.5–25 mg q 6–24 h
Piperazines			
Hydroxyzine	Vistaril	PO	25–100 mg q 4–8 h
Piperidines			
Cyproheptadine	Generic only	PO	4 mg q 6–8 h
Phenindamine	Nolahist	PO	25 mg q 4–6 h
Second-Generation (Nonsedating) Agents			
Azelastine	Astelin	Nasal spray	See text
Cetirizine [‡]	Zyrtec	PO	See text
Levocetirizine [‡]	Xyzal	PO	See text
Fexofenadine	Allegra, Allegra ODT	PO	See text
Loratadine	Alavert, Claritin, Tavist ND	PO	See text
Desloratadine	Clarinex, Clarinex RediTabs	PO	5 mg q 24 h

* Promethazine is contraindicated in children under 2 years old owing to a risk of fatal respiratory depression.

† R = rectal suppository.

‡ Cetirizine and levocetirizine have mild sedating effects.

70.4.2.1 Fexofenadine.

Fexofenadine [Allegra, Allegra ODT] is approved for oral therapy of seasonal allergic rhinitis and for chronic idiopathic urticaria. Of the second-generation antihistamines now available,

fexofenadine appears to offer the best combination of efficacy and safety. In clinical trials, the incidence of drowsiness and other side effects was nearly the same as with placebo.

Fexofenadine has a half-life of 14.4 hours and is excreted unchanged in the urine. The drug is available in standard tablets (30, 60, and 180 mg) and a suspension (6 mg/mL), both marketed as *Allegra*, and in orally disintegrating tablets (30 mg), marketed as *Allegra ODT*. Dosages depend on the drug formulation and patient age as follows:

- *Standard tablets*—patients 12 years and older, 60 mg twice daily or 180 mg once daily; children 6 to 11 years, 30 mg twice daily
- *ODT tablets*—children 6 to 11 years, 30 mg twice daily
- *Suspension*—children 2 to 11 years, 30 mg twice daily; children 6 months to 2 years, 15 mg twice daily

For all formulations, dosage should be reduced in patients with renal impairment.

70.4.2.2 Cetirizine.

Cetirizine [Zyrtec, Zyrtec-D] is indicated for allergic rhinitis and chronic idiopathic urticaria. Administration is oral, and food delays absorption. Cetirizine is eliminated by a combination of hepatic metabolism and renal excretion. Its half-life is 8.3 hours. Although cetirizine is generally well tolerated, it can cause drowsiness (14%), fatigue (6%), and dryness of the mouth, nose, and throat (5%). Cetirizine—and levocetirizine, its active isomer—cause more sedation than the other second-generation antihistamines, but less sedation than the first-generation drugs. Cetirizine is available in standard tablets (5 and 10 mg), chewable tablets (5 and 10 mg), and a syrup (1 mg/mL). The recommended dosage for adults and for children 6 years and older is 5 or 10 mg once a day. The dosage for children ages 2 to 5 years is 2.5 mg once a day initially, and may be increased to either 5 mg once a day or 2.5 mg twice a day. Dosage should be reduced in patients with significant hepatic or renal impairment.

70.4.2.3 Levocetirizine.

Levocetirizine [Xyzal] is the levo (active) isomer of cetirizine, and shares that drug's indications: allergic rhinitis and chronic idiopathic urticaria. Like cetirizine, levocetirizine is more sedating than the other second-generation antihistamines, but less sedating than the first-generation agents. The most common side effects are drowsiness, fatigue, muscle weakness, and dry mouth. Alcohol and other CNS depressants can intensify sedation, and hence should be avoided. Although levocetirizine is classified in Food and Drug Administration Pregnancy Category B (it has no teratogenic effects in animals), use in pregnancy should probably be

avoided, as should use during breast-feeding. Levocetirizine is eliminated primarily by renal excretion, and hence must not be given to patients with *severe* renal impairment (creatinine clearance less than 10 mL/min). Levocetirizine is supplied in scored 5-mg tablets that can be administered without regard to meals. To minimize sedation, dosing should be done in the evening. The dosage for patients 12 years and older is 5 mg once daily; dosage should be reduced for those with *mild to moderate* renal impairment. The dosage for children 6 to 11 years is 2.5 mg daily; children with *any degree* of renal impairment should not use the drug.

70.4.2.4 Loratadine.

Loratadine [Claritin, Tavist ND, Alavert, others] is approved only for seasonal allergic rhinitis. Like other second-generation antihistamines, the drug is generally well tolerated. However, in clinical trials, 8% of patients experienced drowsiness, and 12% experienced headache. Loratadine is administered orally, and food delays absorption. The drug undergoes extensive hepatic metabolism and has a half-life of 8 to 28 hours. Loratadine is available in four formulations: a syrup (1 mg/mL), 10-mg standard tablets, 10-mg orally disintegrating tablets [Alavert, others], and 10-mg rapidly disintegrating tablets [Claritin Reditabs] designed to dissolve on the tongue. The recommended dosage for adults and for children 6 years and older is 10 mg once a day. The dosage for children ages 2 to 5 years is 5 mg (of the syrup) once a day. For patients with significant hepatic or renal impairment, dosing should be done every other day.

70.4.2.5 Desloratadine.

Desloratadine [Clarinet, Clarinet Reditabs] is the major active metabolite of loratadine. The two drugs differ primarily in that desloratadine has a longer half-life (27 hours vs. 8.4 hours). However, although desloratadine has a longer half-life, there is no proof that its *effects* persist longer. Approved indications are seasonal allergic rhinitis, perennial allergic rhinitis, and chronic idiopathic urticaria. Desloratadine has no significant drug interactions and, at the recommended dosage, the incidence of adverse effects is similar to that of placebo. There is no indication that desloratadine prolongs the QT interval or poses a risk of dysrhythmias. About 7% of patients metabolize desloratadine very slowly, causing its effects to be more intense. Desloratadine is available in 5-mg standard tablets, 5-mg rapidly disintegrating tablets [Clarinet Reditabs], and a syrup (2.5 mg/5 mL). The recommended dosage for adults and children over 12 years is 5 mg once a day. Taking higher doses offers no increase in benefits, but does increase the risk of drowsiness. For patients with liver or renal impairment, the manufacturer recommends reducing the initial dosage to 5 mg every other day.

70.4.2.6 Azelastine.

For two reasons, azelastine [Astelin] is unique among the second-generation agents. First, azelastine is administered by nasal spray, whereas the others are given by mouth. Second, in addition to blocking receptors for histamine, azelastine blocks the *release* of histamine and other mediators from mast cells. For patients with allergic or vasomotor rhinitis (the drug's only indications), azelastine is as effective as oral antihistamines and intranasal glucocorticoids. Azelastine causes mild sedation and hence should not be combined with alcohol. During clinical trials, the most common side effect was a bitter taste, which occurred in 20% of patients. Other side effects include headache (14.8%); drowsiness (11.5%); pharyngitis (3.8%); dry mouth, nose, and throat (2.8%); and nausea, vomiting, and bowel changes (2.8%). The recommended dosage for adults and children 12 years and older is 2 sprays (270 mcg) per nostril twice a day. The dosage for children ages 5 to 11 years is one spray per nostril twice a day.

70.4.2.6.1

KEY POINTS	
▪ Histamine is synthesized and stored in mast cells and basophils. ▪ Histamine release may be triggered by allergic and nonallergic mechanisms.	826
▪ There are two major classes of histamine receptors, called H₁ receptors and H₂ receptors. ▪ Activation of H₁ receptors causes vasodilation, increased capillary permeability, pain, itching, bronchoconstriction, and CNS effects. ▪ Activation of H₂ receptors causes release of gastric acid from parietal cells of the stomach. ▪ Histamine is an important mediator of mild allergic reactions, but is only a minor contributor to severe (anaphylactic) reactions. ▪ There are two major classes of histamine receptor antagonists: H₁ receptor antagonists, which are used to treat mild allergic reactions, and H₂ receptor antagonists, which are used to treat gastric and duodenal ulcers (see Chapter 77). ▪ Histamine₁ receptor antagonists relieve allergic symptoms by blocking histamine receptors on small blood vessels, capillaries, and sensory nerves. These drugs do not block release of histamine from mast cells and basophils.	827

- There are two major classes of H₁ receptor antagonists, known as first-generation H₁ receptor antagonists and second-generation H₁ receptor antagonists.
- First-generation H₁ receptor antagonists frequently cause sedation and anticholinergic effects; second-generation agents rarely cause either.
- CNS depression from first-generation H₁ receptor antagonists can be intensified by alcohol and other drugs with CNS-depressant actions.

70.4.2.6.2

Summary of Major Nursing Implications*

70.4.2.6.2.1

H₁ RECEPTOR ANTAGONISTS

70.4.2.6.2....

First-Generation Antihistamines

Brompheniramine

Chlorpheniramine

Clemastine

Cyproheptadine

Dexchlorpheniramine

Diphenhydramine

Hydroxyzine

Phenindamine

Promethazine

70.4.2.6.2....

Second-Generation Antihistamines

Azelastine

Cetirizine

Desloratadine

Fexofenadine

Levocetirizine

Loratadine

70.4.2.6.2....

Preadministration Assessment

70.4.2.6.2....

Therapeutic Goal

70.4.2.6.2....

Oral Therapy

Relief of symptoms of mild to moderate allergic disorders (eg, allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria and angioedema).

70.4.2.6.2....

Parenteral Therapy

Treatment of allergic reactions to blood or plasma; adjunctive therapy of anaphylaxis.

70.4.2.6.2....

Identifying High-Risk Patients

Antihistamines are *contraindicated* during the third trimester of pregnancy and for nursing mothers and newborn infants.

Exercise *caution* when treating young children, the elderly, and patients with conditions that may be aggravated by muscarinic blockade, including asthma, urinary retention, open-angle glaucoma, hypertension, and prostatic hypertrophy.

70.4.2.6.2....

Implementation: Administration

70.4.2.6.2....

Routes

Except for azelastine, all H₁ blockers can be administered orally. Some can also be administered by injection, rectal suppository, or nasal spray (see [Table 69-2](#)).

70.4.2.6.2....

Administration

Advise patients to take oral antihistamines with food if GI upset occurs.

Warn patients not to crush or chew enteric-coated preparations.

70.4.2.6.2....

Ongoing Evaluation and Interventions

70.4.2.6.2....

Minimizing Adverse Effects

70.4.2.6.2....

Sedation

For most patients, a first-generation antihistamine in the alkylamine group (see [Table 69-1](#)) can provide effective H₁ blockade with only modest sedation. If sedation is excessive with an alkylamine, a second-generation antihistamine (eg, fexofenadine) can be used. With long-acting antihistamines, daytime sedation can be minimized by administering the entire daily dose in the evening. **Caution the patient to exercise extreme caution when driving or doing other hazardous activities.**

70.4.2.6.2....

Anticholinergic Effects

Advise patients that dryness of the mouth and throat can be reduced by sucking on hard (sugarless) candy and by taking frequent sips of liquids. Other atropine-like responses (urinary hesitancy, tachycardia, constipation) are not usually problems. Second-generation antihistamines have minimal anticholinergic effects.

70.4.2.6.2....

Gastrointestinal Distress

Advise the patient that GI disturbances (nausea, vomiting) can be minimized by taking antihistamines with meals.

70.4.2.6.2....

Effects in the Elderly

Older patients are especially sensitive to CNS and anticholinergic effects. Be alert for CNS effects (eg, dizziness, incoordination, confusion, fatigue) and exaggerated anticholinergic effects (eg, dry mouth, urinary hesitancy, constipation).

70.4.2.6.2....

Minimizing Adverse Interactions

70.4.2.6.2....

CNS Depressants

Alcohol and other CNS depressants can intensify the depressant actions of the H₁ antagonists. **Warn the patient against drinking alcohol.** Dosages of CNS depressants (eg, barbiturates, benzodiazepines, opioids) may need to be reduced. Second-generation antihistamines have minimal CNS-depressant effects and hence are less likely to potentiate the actions of CNS depressants.

70.4.2.6.2....

Managing Toxicity

There is no specific antidote to antihistamine overdose, and hence treatment is directed at minimizing absorption and managing symptoms. To reduce absorption, give activated charcoal. Treat hyperthermia with ice packs or cooling sponge baths. Control convulsions with IV phenytoin.

* Patient education information is highlighted as **blue text**.

⁷¹CHAPTER 70 Cyclooxygenase Inhibitors: Nonsteroidal Anti-inflammatory Drugs and Acetaminophen

The family of cyclooxygenase inhibitors consists of aspirin and related drugs. Most of these agents have useful effects: they can suppress inflammation, relieve pain, and reduce fever. In addition, aspirin—and only aspirin—can protect against myocardial infarction (MI) and stroke. All of these effects are produced through one central mechanism: inhibition of cyclooxygenase, the enzyme responsible for synthesis of prostanoids (prostaglandins and related compounds). This same mechanism underlies their principal adverse effects: gastric ulceration, bleeding, and renal impairment. Cyclooxygenase inhibition also underlies MI and stroke, which can occur with most of these drugs, but *not* with aspirin.

^{71.1}MECHANISM OF ACTION

All of the drugs discussed in this chapter work by inhibiting *cyclooxygenase* (COX), the enzyme that converts arachidonic acid into *prostanoids*: *prostaglandins* and related compounds (prostacyclin, thromboxane A₂ [TXA₂]). To understand the drugs that inhibit COX, we must first understand COX itself.

Cyclooxygenase is found in all tissues and helps regulate multiple processes. At sites of tissue injury, COX catalyzes the synthesis of prostaglandin E₂ (PGE₂) and prostaglandin I₂ (PGI₂, aka prostacyclin), which promote inflammation and sensitize receptors to painful stimuli. In the stomach, COX promotes synthesis of PGE₂ and PGI₂, which help protect the gastric mucosa. Three mechanisms are involved: reduced secretion of gastric acid, increased secretion of bicarbonate and cytoprotective mucus, and maintenance of submucosal blood flow. In platelets, COX promotes synthesis of TXA₂, which stimulates platelet aggregation. In blood vessels, COX promotes synthesis of prostacyclin, which causes vasodilation. In the kidney, COX catalyzes synthesis of PGE₂ and PGI₂, which promote vasodilation and thereby maintain renal blood flow. In the brain, COX-derived prostaglandins mediate fever and contribute to perception of pain. In the uterus, COX-derived prostaglandins help promote contractions at term. It is important to appreciate that prostaglandins, prostacyclin, and TXA₂ act *locally*; these compounds do not affect sites distant from where they were made.

Cyclooxygenase has two forms, named cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). Cyclooxygenase-1 is found in practically all tissues, where it mediates “housekeeping” chores.

Pharmacology for Nursing Care, 7th Edition

Important among these are protecting the gastric mucosa, supporting renal function, and promoting platelet aggregation. In contrast, COX-2 is produced mainly at sites of *tissue injury*, where it mediates inflammation and sensitizes receptors to painful stimuli. Cyclooxygenase-2 is also present in the *brain* (where it mediates fever and contributes to perception of pain), the *kidney* (where it supports renal function), *blood vessels* (where it promotes vasodilation), and the *colon* (where it can contribute to colon cancer). Because COX-1 primarily mediates beneficial processes, whereas COX-2 primarily mediates harmful processes, COX-1 has been dubbed the “good COX” and COX-2 the “bad COX.” Some important functions of COX-1 and COX-2 are summarized in [Table 70-1](#).

Having established the roles of COX-1 and COX-2, we can now predict the effects of drugs that inhibit these enzymes. Inhibition of COX-1 (good COX) results largely in harmful effects:

- Gastric erosion and ulceration
- Bleeding tendencies
- Renal impairment

Inhibition of COX-1 also has one very beneficial effect:

- Protection against myocardial infarction and stroke (secondary to reduced platelet aggregation)

Inhibition of COX-2 (bad COX) results largely in beneficial effects:

- Suppression of inflammation
- Alleviation of pain
- Reduction of fever
- Protection against colorectal cancer

Inhibition of COX-2 also has two adverse effects:

- Renal impairment
- Promotion of MI and stroke (secondary to suppressing vasodilation)

828

TABLE 70-1 Cyclooxygenase-1 and Cyclooxygenase-2: Functions and Effect of Inhibition

Location	COX Isoform	COX Reaction Product	Response to COX Reaction Product	Effect of COX Inhibition
Stomach	COX-1	PGE ₂ , PGI ₂	Gastric protection: Increased bicarbonate secretion Increased mucus production Decreased acid secretion Maintenance of submucosal blood flow	Gastric ulceration
Platelets	COX-1	TXA ₂	Platelet aggregation	Bleeding tendencies Protection against MI
Blood vessels	COX-2	Prostacyclin	Vasodilation	Vasoconstriction (which can promote MI)
Kidney	COX-1, COX-2	PGE ₂ , PGI ₂	Maintenance of renal function: Renal vasodilation Maintenance of renal perfusion	Renal impairment
Injured tissue	COX-2	PGE ₂	Inflammation Pain	Reduced inflammation Analgesia
Brain	COX-2	??	Fever Pain	Reduced fever Analgesia
Colon/rectum	COX-2	??	Colorectal cancer promotion	Colorectal cancer protection
COX-1 = cyclooxygenase-1, COX-2 = cyclooxygenase-2, MI = myocardial infarction, PGE ₂ = prostaglandin E ₂ , PGI ₂ = prostaglandin I ₂ , (prosta-cyclin), TXA ₂ = thromboxane A ₂ .				

71.2 CLASSIFICATION OF CYCLOOXYGENASE INHIBITORS

The cyclooxygenase inhibitors fall into two major categories: (1) drugs that have anti-inflammatory properties and (2) drugs that lack anti-inflammatory properties. Agents in the first group are referred to as *nonsteroidal anti-inflammatory drugs* (NSAIDs). Representative members include aspirin,

ibuprofen [Advil, Motrin, others], naproxen [Aleve, others], and celecoxib [Celebrex]. The second class consists of just one drug: *acetaminophen* [Tylenol, others]. Acetaminophen can reduce pain and fever but cannot suppress inflammation.

The NSAIDs can be subdivided into two groups: (1) *first-generation NSAIDs* (conventional NSAIDs, traditional NSAIDs) and (2) *second-generation NSAIDs* (selective COX-2 inhibitors, coxibs). The first-generation agents inhibit COX-1 *and* COX-2. The second-generation agents inhibit COX-2 only. Because the first-generation agents inhibit both COX isoforms, they are unable to suppress pain and inflammation without posing a risk of serious side effects (gastric ulceration, bleeding, renal impairment). In contrast, because of their selectivity for COX-2, the second-generation NSAIDs, *in theory*, can suppress pain and inflammation while (possibly) causing fewer adverse effects than the first-generation NSAIDs. However, *in reality*, COX-2 inhibitors appear even less safe than the first-generation agents, owing to an increased risk of myocardial infarction (MI) and stroke.

[Table 70-2](#) summarizes the principal indications and adverse effects of the first-generation NSAIDs, second-generation NSAIDs, and acetaminophen.

71.3 FIRST-GENERATION NSAIDs

The first-generation NSAIDs, which inhibit COX-1 and COX-2, are a large and widely used family of drugs. In the United States, more than 70 million prescriptions are written annually and more than 30 billion tablets are sold over the counter. The traditional NSAIDs are used to treat inflammatory disorders (eg, rheumatoid arthritis, osteoarthritis, bursitis), alleviate mild to moderate pain, suppress fever, and relieve dysmenorrhea. Because they cannot inhibit COX-2 without inhibiting COX-1, first-generation NSAIDs cannot suppress inflammation without posing a risk of serious harm: NSAID-induced ulcers are responsible for more than 100,000 hospitalizations and at least 16,500 deaths each year. Aspirin, the oldest member of the family, will serve as our prototype for the group.

71.3.1 Aspirin

Aspirin is an important drug whose effectiveness is frequently underappreciated. Given that aspirin is available without prescription, widely advertised in the media, and used somewhat casually by the general public, you may be surprised to hear that aspirin is a highly valuable and effective medication. The drug provides excellent relief of mild to moderate pain, reduces fever, protects against thrombotic disorders, and remains a drug of choice for rheumatoid arthritis and other inflammatory conditions. You may also be surprised to hear that aspirin can cause serious

toxicity, especially gastric ulceration. Despite the introduction of many new NSAIDs, aspirin remains one of the most widely used members of the group and is the standard against which the others must be compared.

71.3.1.1 Chemistry

Aspirin belongs to a chemical family known as *salicylates*. All members of this group are derivatives of salicylic acid (Fig. 70-1). Aspirin is produced by substituting an acetyl group onto salicylic acid. Because of this acetyl group, aspirin is commonly known as *acetylsalicylic acid*, or simply ASA.

829

830

TABLE 70-2 Principal Indications and Adverse Effects of the Four Major Types of Cyclooxygenase Inhibitors

	First-Generation NSAIDs: Aspirin	First-Generation NSAIDs: All Others	Second-Generation NSAIDs (Coxibs)	Acetaminophen
Indications				
Inflammation	Yes	Yes	Yes	No
Pain	Yes	Yes	Yes	Yes
Fever	Yes	Yes	No	Yes
Prevention of MI and stroke	Yes	No	No	No
Adverse Effects				
Gastric ulceration	Yes	Yes	Yes*	No
Renal impairment	Yes	Yes	Yes	No
Bleeding	Yes	Yes	No	No
MI and stroke	No	Yes	Yes	No
Liver damage with overdose	No	No	No	Yes

* Despite their selectivity for cyclooxygenase-2, coxibs can still cause gastric ulceration, although it may be less than with other NSAIDs.

Figure 70-1 Structural formulas of aspirin and related salicylates.

71.3.1.2 Mechanism of Action

Aspirin is a nonselective inhibitor of cyclooxygenase. Most beneficial effects—reductions of inflammation, pain, and fever—result from inhibiting COX-2. One beneficial effect—protection against myocardial infarction (MI) and ischemic stroke—results from inhibiting COX-1. Major adverse effects—gastric ulceration, bleeding, and renal impairment—result from inhibiting COX-1.

It is important to note that aspirin is an *irreversible* inhibitor of cyclooxygenase. In contrast, all other NSAIDs are *reversible* (competitive) inhibitors. Because inhibition of cyclooxygenase by aspirin is irreversible, duration of action depends on how quickly specific tissues can synthesize

new molecules of COX-1 and COX-2. With other NSAIDs, effects decline as soon as drug levels fall.

71.3.1.3 Pharmacokinetics

71.3.1.3.1 Absorption.

Aspirin is absorbed rapidly and completely following oral administration. The principal site of absorption is the small intestine. When administered by rectal suppository, aspirin is absorbed slowly and blood levels are lower than with oral dosing.

71.3.1.3.2 Metabolism.

Aspirin has a very short half-life (15 to 20 minutes) because of rapid conversion to *salicylic acid*, an *active* metabolite. The rate of inactivation of salicylic acid depends on the amount present: At low therapeutic levels, salicylic acid has a half-life of approximately 2 hours, but at high therapeutic levels, the half-life may exceed 20 hours.

71.3.1.3.3 Distribution.

Salicylic acid is extensively bound to plasma albumin. At therapeutic levels, binding is between 80% and 90%. Aspirin undergoes distribution to all body tissues and fluids, including breast milk, fetal tissues, and the central nervous system (CNS).

71.3.1.3.4 Excretion.

Salicylic acid and its metabolites are excreted by the kidneys. Excretion of salicylic acid is highly dependent on urinary pH. Accordingly, by raising the pH of urine from 6 to 8, we can increase the rate of excretion fourfold.

71.3.1.3.5 Plasma Drug Levels.

Low therapeutic doses of aspirin produce plasma salicylate levels in the range of 100 mcg/mL. Anti-inflammatory doses produce salicylate levels of about 400 mcg/mL. Signs of salicylism (toxicity) begin when plasma salicylate levels exceed 200 mcg/mL. Severe toxicity occurs at levels above 400 mcg/mL.

71.3.1.4 Therapeutic Uses

71.3.1.4.1 Suppression of Inflammation.

Aspirin is an initial drug of choice for rheumatoid arthritis, osteoarthritis, and juvenile arthritis. Aspirin is also indicated for other inflammatory disorders, including rheumatic fever, tendinitis, and bursitis. The dosages employed to suppress inflammation are considerably larger than dosages used for analgesia or reduction of fever. The use of aspirin and other NSAIDs to treat arthritis is discussed further in [Chapter 72](#).

830

The precise mechanisms by which aspirin decreases inflammation have not been established. We do know that prostanoids contribute to several, but not all, components of the inflammatory process. Hence, inhibition of COX-2 provides a partial explanation of anti-inflammatory effects. Other possible mechanisms include modulation of T-cell function, suppression of inflammatory cell infiltration, and stabilization of lysosomes.

831

71.3.1.4.2 Analgesia.

Aspirin is used widely to relieve mild to moderate pain. The degree of analgesia produced depends on the type of pain. Aspirin is most active against joint pain, muscle pain, and headache. For some forms of postoperative pain, aspirin can be more effective than opioids. However, aspirin is relatively ineffective against severe pain of visceral origin. In contrast to opioid analgesics, aspirin produces neither tolerance nor physical dependence. In addition, aspirin is safer than opioids.

Aspirin relieves pain primarily through actions in the periphery. At sites of injury, prostanoids sensitize pain receptors to mechanical and chemical stimulation. Aspirin reduces pain by inhibiting COX-2, thereby suppressing prostanoid production. In addition to this peripheral mechanism, aspirin works in the CNS to help relieve pain.

71.3.1.4.3 Reduction of Fever.

Aspirin is a drug of choice for reducing temperature in febrile *adults*. However, because of the risk of Reye's syndrome (see below), *aspirin should not be used to treat fever in children*. Although aspirin readily reduces fever, it will not lower normal body temperature, nor will it lower temperature that has become elevated in response to physical activity or to a rise in environmental temperature.

How does aspirin reduce fever? Body temperature is regulated by the hypothalamus, which maintains a balance between heat production and heat loss. Fever occurs when the set point of the hypothalamus becomes elevated, causing the hypothalamus to increase heat production and decrease heat loss. Set-point elevation is triggered by local synthesis of prostaglandins in response to endogenous pyrogens (fever-promoting substances). Aspirin lowers the set point by inhibiting COX-2, and thereby inhibits pyrogen-induced synthesis of prostaglandins.

71.3.1.4.4 Dysmenorrhea.

Aspirin can provide relief from primary dysmenorrhea. Benefits derive from inhibiting prostaglandin synthesis in uterine smooth muscle. (Prostaglandins promote uterine contraction, and hence suppression of prostaglandin synthesis relieves cramping.) Some of the newer aspirin-like drugs (eg, ibuprofen, naproxen) are superior to aspirin for dysmenorrhea. The efficacy of the newer drugs is attributed to a greater ability to inhibit COX in the uterus.

71.3.1.4.5 Suppression of Platelet Aggregation.

Synthesis of TXA₂ in platelets promotes aggregation. Aspirin suppresses platelet aggregation by causing *irreversible* inhibition of COX-1, the enzyme that makes TXA₂. Because platelets lack the machinery to synthesize new COX-1, the effects of a single dose persist for the life of the platelet (about 8 days).

There is a large body of evidence demonstrating that aspirin, through its antiplatelet actions, can benefit a variety of patients. Accordingly, in 1999, the Food and Drug Administration (FDA) recommended wider use of aspirin for antiplatelet effects. Professional labeling now recommends daily aspirin for men and women with the following:

- *Ischemic stroke* (to reduce the risk of death and nonfatal stroke)
- *Transient ischemic attacks* (to reduce the risk of death and nonfatal stroke)
- *Acute MI* (to reduce the risk of vascular mortality)
- *Previous MI* (to reduce the combined risk of death and nonfatal MI)
- *Chronic stable angina* (to reduce the risk of MI and sudden death)
- *Unstable angina* (to reduce the combined risk of death and nonfatal MI)

- *Angioplasty and other revascularization procedures* (in patients who have a pre-existing condition for which aspirin is already indicated)

According to a 2007 review published in JAMA—*Aspirin Dose for the Prevention of Cardiovascular Disease*—a dose of 75 to 81 mg/day for these indications is adequate. Higher doses, which are commonly prescribed in these circumstances, offer no greater protection, but will increase the risk of GI bleeding.

In addition to these applications, aspirin can be taken by healthy people for *primary prevention* of MI and stroke. However, benefits differ for men and women. In men, daily aspirin reduces the risk of a first MI, but does not reduce the risk of a first stroke. In women, benefits depend on age, as shown by results of the Women's Health Study, published in 2005. Specifically, for women in their 40s and 50s, taking 100 mg of aspirin every other day reduces the risk of a first stroke, but does *not* reduce the risk of a first MI. By contrast, in women 65 and older, the same regimen reduces the risk of MI *and* stroke. Why do benefits differ between middle-aged women and older women? It may be that older women are simply at higher risk, and hence protection is more easily shown. Why do benefits differ between men and women? One possibility is that the dosage used in the Women's Health Study was lower than the dosages used in studies involving men. Differences in benefits for men and women are summarized in [Table 70-3](#). In light of these data, the American Heart Association now recommends that all women *with heart disease* take 75 to 325 mg of aspirin daily, and that most healthy women older than 65 take 81 mg daily. Aspirin is *not* advised for healthy women younger than 65.

Of note, about 25% of patients appear to be resistant to the antiplatelet effects of aspirin. The mechanism of resistance has not been determined. Antiplatelet effects of aspirin are discussed further in [Chapter 51](#).

71.3.1.4.6 Cancer Prevention.

71.3.1.4.6.1 Colorectal Cancer.

There is good evidence that regular use of aspirin decreases the risk of colorectal cancer—
but only at doses that increase the risk of bleeding. In 2003, researchers reported that, in
patients with a history of colorectal cancer, short-term use of aspirin (325 mg/day) reduces
the development of new colorectal adenomas (precancerous polyps). Results from the
Nurses' Health Study, reported in 2005, showed that regular use of aspirin (and probably

831

832

other NSAIDs) reduces the risk of colorectal cancer itself. However, to see a significant reduction, aspirin must be taken long term (at least 10 years), and, for maximum benefits, the dosage must be high (over 650 mg/day). This dosage is much greater than the dosage needed to prevent cardiovascular disease, and hence poses a significant risk of bleeding. In fact, for every one or two cancers prevented, aspirin would cause eight additional serious bleeds. At this time, it is not clear that the benefit of cancer protection outweighs the risk of bleeding and other adverse events. Accordingly, in 2007, the U.S. Preventive Services Task Force (USPSTF) recommended against routine use of aspirin and other NSAIDs to prevent colorectal cancer. How might aspirin protect against colorectal cancer? Probably by inhibiting COX-2. This statement is based on the observation that aspirin reduces the risk of colon cancers that have high levels of COX-2, but does *not* reduce the risk of colon cancers that have little or no COX-2.

TABLE 70-3 Effect of Low-Dose Aspirin on the Risk of Myocardial Infarction (MI) and Ischemic Stroke in Men and Women

Cardiovascular Event	Patient Population		
	Men	Women 40–60 Years Old	Women 65 and Older
First MI	Decrease	No decrease	Decrease
First stroke	No decrease	Decrease	Decrease
Second MI or stroke	Decrease	Decrease	Decrease

71.3.1.4.6.2

Other Cancers.

Available data suggest that aspirin may protect against cancers of the prostate, breast, and ovary. In a study involving men over the age of 60, daily use of aspirin and other NSAIDs was associated with a 50% decrease in the incidence of prostate cancer. In a study involving 2884 women, aspirin appeared to reduce the risk of breast cancer, especially among women with hormone receptor–positive tumors, and among those who took 7 or more aspirin tablets a week. In another study, taking aspirin at least 3 times a week for at least 6 months was associated with a 40% reduction in the incidence of ovarian cancer. It is important to note that the results from the Women's Health Study, released in 2005, showed that *low-dose* aspirin offered *no* protection against cancer of the breast, colon, or any other tissue.

71.3.1.4.7 Protection Against Alzheimer's Disease.

There is mounting evidence that aspirin and other NSAIDs, taken in moderate doses, may delay the onset of Alzheimer's disease. However, these drugs are of no benefit once the disease is established (see [Chapter 22](#)).

71.3.1.5 Adverse Effects

When administered short term in analgesic or antipyretic (fever-reducing) doses, aspirin rarely causes serious adverse effects. However, toxicity is common when treating inflammatory disorders, which require high-dose long-term treatment.

71.3.1.5.1 Gastrointestinal Effects.

The most common side effects are *gastric distress*, *heartburn*, and *nausea*. These reactions can be reduced by taking aspirin with food or a full glass of water.

Occult GI bleeding occurs often. In most cases, the amount of blood lost each day is insignificant. However, with chronic aspirin use, cumulative blood loss can result in anemia.

Long-term aspirin—even in low doses—can cause life-threatening *gastric ulceration*, *perforation*, and *bleeding*. Ulcers result from (1) increased secretion of acid and pepsin, (2) decreased production of cytoprotective mucus and bicarbonate, (3) decreased submucosal blood flow, and (4) the direct irritant action of aspirin on the gastric mucosa. The first three effects occur secondary to inhibition of COX-1. Direct injury to the stomach is most likely with aspirin preparations that dissolve slowly: Because of slow dissolution, particulate aspirin becomes entrapped in folds of the stomach wall, causing prolonged exposure to high concentrations of the drug. Because aspirin-induced ulcers are often asymptomatic, perforation and upper GI hemorrhage can occur without premonitory signs. (Hemorrhage is due in part to erosion of the stomach wall and in part to suppression of platelet aggregation.) Factors that increase the risk of ulceration include (1) advanced age, (2) a history of peptic ulcer disease, (3) previous intolerance to aspirin or other NSAIDs, (4) cigarette smoking, and (5) a history of alcohol abuse. Because alcohol intensifies the irritant effects of aspirin, alcohol should not be consumed.

What can we do to *prevent* ulcers? According to an expert panel—convened in 2008 by the American College of Gastroenterology, the American Heart Association, and the American

College of Cardiology—prophylaxis with a *proton pump inhibitor* (PPI) is recommended for patients at risk, including those with a history of peptic ulcers, the elderly, and those taking glucocorticoids. Proton pump inhibitors (eg, omeprazole, lansoprazole) reduce ulcer generation by suppressing production of gastric acid. Since many ulcers are caused by infection with *Helicobacter pylori* (see [Chapter 77](#)), the panel recommends that patients with ulcer histories undergo testing and treatment for *H. pylori* before starting long-term aspirin use. *Treatment* of NSAID-induced ulcers is discussed in [Chapter 77](#).

71.3.1.5.2 Bleeding.

Aspirin promotes bleeding by inhibiting platelet aggregation. Taking just 2 aspirin tablets can double bleeding time for about 1 week. (Recall that platelets are unable to replace aspirin-inactivated cyclooxygenase, and hence bleeding time is prolonged for the life of the platelet.) Because of its effects on platelets, *aspirin is contraindicated for patients with bleeding disorders* (eg, hemophilia, vitamin K deficiency, hypoprothrombinemia). In order to minimize blood loss during parturition and elective surgery, *high-dose* aspirin should be discontinued at least 1 week before these procedures. There is no need to stop aspirin prior to procedures with a low risk of bleeding (eg, dental, dermatologic, or cataract surgery). In most cases, use of *low-dose* aspirin to protect against thrombosis should *not* be interrupted for elective surgery and dental procedures. Caution is needed when aspirin is used in conjunction with anticoagulants.

In patients taking daily aspirin, high blood pressure increases the risk of a brain bleed (ie, hemorrhagic stroke), even though aspirin protects against ischemic stroke. To reduce risk of hemorrhagic stroke, blood pressure should be 150/90 mm Hg (and preferably lower) before starting daily aspirin.

71.3.1.5.3 Renal Impairment.

Aspirin can cause acute, reversible impairment of renal function, resulting in salt and water retention and edema. Clinically significant effects are most likely in patients with additional risk factors: advanced age, preexisting renal impairment, hypovolemia, hepatic cirrhosis, or heart failure. Aspirin impairs renal function by inhibiting COX-1, thereby depriving the kidney of prostaglandins needed for normal function.

Development of renal impairment is signaled by reduced urine output, weight gain despite use of diuretics, and a rapid rise in serum creatinine and blood urea nitrogen. If any of these is

observed, aspirin should be withdrawn immediately. In most cases, kidney function then returns to baseline level.

The risk of acute renal impairment can be reduced by identifying high-risk patients and treating them with the smallest dosages possible.

In addition to its acute effects on renal function, aspirin may pose a risk of renal papillary necrosis and other types of renal injury when used long term.

71.3.1.5.4 Salicylism.

Salicylism is a syndrome that begins to develop when aspirin levels climb just slightly above therapeutic. Overt signs include *tinnitus* (ringing in the ears), *sweating*, *headache*, and *dizziness*. Acid-base disturbance may also occur (see below). If salicylism develops, aspirin should be withheld until symptoms subside; therapy should then resume, but with a small reduction in dosage. In some cases, development of tinnitus can be used to adjust aspirin dosage: When tinnitus occurs, the maximum acceptable dose has been achieved. However, this guideline may be inappropriate for older patients, because they may fail to develop tinnitus even when aspirin levels become toxic.

832

833

Acid-base disturbance results from the effects of aspirin on respiration. When administered in high therapeutic doses, aspirin acts on the CNS to stimulate breathing. The resultant increase in CO₂ loss produces *respiratory alkalosis*. In response, the kidneys excrete more bicarbonate. As a result, plasma pH returns to normal and a state of *compensated respiratory alkalosis* is produced.

71.3.1.5.5 Reye's Syndrome.

This syndrome is a rare but serious illness of childhood that has a mortality rate of 20% to 30%. Characteristic symptoms are encephalopathy and fatty liver degeneration.

Epidemiologic data published in 1980 suggested a relationship between Reye's syndrome and use of aspirin by children who have influenza or chickenpox. Although a direct causal link between aspirin and Reye's syndrome was never established, the Centers for Disease Control and Prevention recommended that *aspirin (and other NSAIDs) be avoided by children and teenagers suspected of having influenza or chickenpox*. In response to this recommendation, aspirin was removed from most products intended for children, and use of aspirin by children declined sharply. As a result, Reye's syndrome essentially vanished: The incidence declined from a high of 555 cases in 1980 to no more than 2 cases per year between 1994 and 1997. If

a child with chickenpox or influenza needs an analgesic/antipyretic, acetaminophen can be used safely.

71.3.1.5.6 Adverse Effects Associated with Use During Pregnancy.

Aspirin poses risks to the pregnant patient and the developing fetus. Accordingly, the drug is classified in *FDA Pregnancy Risk Category D: there is evidence of human fetal risk, but the potential benefits from use of the drug during pregnancy may outweigh the potential for harm*. The principal risks to pregnant women are (1) anemia (from GI blood loss), and (2) postpartum hemorrhage. In addition, by inhibiting prostaglandin synthesis, aspirin may suppress spontaneous uterine contractions, and may thereby prolong labor.

Aspirin crosses the placenta and may adversely affect the fetus. Since prostaglandins help keep the ductus arteriosus patent, inhibition of prostaglandin synthesis by aspirin may induce premature closure of the ductus arteriosus. Aspirin use has also been associated with low birth weight, stillbirth, renal toxicity, intracranial hemorrhage in preterm infants, and neonatal death.

71.3.1.5.7 Hypersensitivity Reactions.

Hypersensitivity develops in about 0.3% of aspirin users. Reactions are most likely in adults with a history of asthma, rhinitis, and nasal polyps. Hypersensitivity reactions are uncommon in children. The aspirin hypersensitivity reaction begins with profuse, watery rhinorrhea and may progress to generalized urticaria, bronchospasm, laryngeal edema, and shock. Despite its resemblance to severe anaphylaxis, this reaction is not allergic and is not mediated by the immune system. Because individuals who react to aspirin are also sensitive to most other NSAIDs, it is thought that hypersensitivity reactions are in some way related to inhibition of cyclooxygenase. However, it is not clear why the reaction is limited to those adults who have the predisposing conditions noted above. As with severe anaphylactic reactions, *epinephrine* is the treatment of choice. Hypersensitivity to aspirin is a contraindication to using other drugs with aspirin-like properties.

71.3.1.5.8 Cardiovascular Events.

In contrast to all other NSAIDs, aspirin does *NOT* increase the risk of thrombotic events, including myocardial infarction and ischemic stroke. In fact, when taken in low doses, aspirin *protects* against these events.

71.3.1.6 Summary of Precautions and Contraindications

Aspirin is contraindicated in patients with *peptic ulcer disease*, *bleeding disorders* (eg, hemophilia, vitamin K deficiency, hypoprothrombinemia), and *hypersensitivity to aspirin itself or other NSAIDs*. In addition, the drug should be used with extreme caution by *pregnant women and by children who have chickenpox or influenza*. Caution should also be exercised when treating *elderly patients*, *patients who smoke cigarettes*, and *patients with H. pylori infection, heart failure, hepatic cirrhosis, hypovolemia, renal dysfunction, asthma, hay fever, chronic urticaria, nasal polyps*, or a *history of alcoholism*. Aspirin should be withdrawn 1 week prior to elective surgery or the anticipated date of parturition.

71.3.1.7 Drug Interactions

Because of its widespread use, aspirin has been reported to interact with many other medications. However, most of these interactions have little clinical significance. Significant interactions are discussed below.

71.3.1.7.1 Anticoagulants: Warfarin and Heparin.

The most important interactions of aspirin occur with anticoagulants. Because aspirin suppresses platelet function and can decrease prothrombin production, aspirin will intensify the anticoagulant effects of warfarin and heparin. Furthermore, since aspirin can initiate gastric bleeding, augmenting anticoagulant effects can increase the risk of gastric hemorrhage. Accordingly, the combination of aspirin with anticoagulants must be used with care—even when aspirin is taken in low doses to reduce the risk of thrombotic events.

71.3.1.7.2 Glucocorticoids.

Like aspirin, glucocorticoids promote gastric ulceration. As a result, the risk of ulcers is greatly increased when these drugs are combined—as may happen when treating arthritis. To reduce the risk of gastric ulceration, patients can be given a proton pump inhibitor for prophylaxis.

71.3.1.7.3 Alcohol.

Combining alcohol with aspirin and other NSAIDs increases the risk of gastric bleeding. To alert the public to this risk, the FDA now requires that labels for aspirin include the following

statement: *Alcohol Warning: If you consume three or more alcoholic drinks every day, ask your doctor whether you should take aspirin or other pain relievers/fever reducers. Aspirin [and related drugs] may cause stomach bleeding.* A similar label is required for all other NSAIDs and acetaminophen.

71.3.1.7.4 Ibuprofen.

There is evidence that ibuprofen (an NSAID) can reduce the antiplatelet effects of aspirin. How? By blocking access of aspirin to COX-1 in platelets. This interaction is important: In patients taking low-dose aspirin to prevent MI or ischemic stroke, ibuprofen could negate aspirin's benefits. At least three analgesics—acetaminophen, diclofenac, and celecoxib—have little or no impact on aspirin's cardioprotective actions, and hence would be good alternatives to ibuprofen when pain relief is needed. Of course, high doses of aspirin itself could also be used.

833

834

71.3.1.7.5 ACE Inhibitors and ARBs.

Like aspirin, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) can impair renal function. In susceptible patients, combining aspirin with drugs in either class can increase the risk of acute renal failure. High-dose aspirin should be avoided in patients taking these drugs. However, low-dose aspirin taken for antiplatelet effects should be continued.

71.3.1.8 Acute Poisoning

Aspirin overdose is a common cause of poisoning. Although rarely fatal in adults, aspirin poisoning may be lethal in children. The lethal dose for adults is 20 to 25 gm. In contrast, as little as 4 gm may be enough to kill a child.

71.3.1.8.1 Signs and Symptoms.

Initially, aspirin overdose produces a state of compensated respiratory alkalosis—the same state seen in mild salicylism. As poisoning progresses, respiratory excitation is replaced by respiratory depression. Acidosis, hyperthermia, sweating, and dehydration are prominent, and electrolyte imbalance is likely. Stupor and coma result from effects in the CNS. Death usually results from respiratory failure. The mechanisms that underlie these clinical manifestations are described below.

Many symptoms of aspirin overdose occur secondary to uncoupling of oxidative phosphorylation, the process by which the energy released during the oxidation of carbohydrates, fats, and proteins is used to form ATP from ADP. When oxidative phosphorylation becomes uncoupled, energy from metabolism of carbohydrates and other nutrients can no longer be transferred to ATP and stored. The consequences of this uncoupling are threefold: (1) Production of CO₂ is increased (secondary to the increased rates of metabolism that take place in futile attempts to form needed ATP). (2) There is increased production of lactic and pyruvic acids (as by-products of increased metabolism). (3) Production of heat is increased because the energy that would normally be used to make ATP is released in the form of heat. Increased heat production is responsible for hyperthermia and dehydration, two of the more serious consequences of aspirin overdosage.

The acidosis that characterizes aspirin poisoning results from multiple causes. Respiratory acidosis occurs because CO₂ production is increased and because toxic levels of salicylate act on the CNS to decrease respiration, thereby allowing even more CO₂ to accumulate.

Respiratory acidosis remains uncompensated because bicarbonate stores become depleted during the initial phase of poisoning. Superimposed on respiratory acidosis is true metabolic acidosis. Metabolic acidosis results from (1) the acidity of aspirin and its metabolites, (2) increased production of lactic and pyruvic acids, and (3) accumulation of acidic products of metabolism (eg, sulfuric and phosphoric acids) because of aspirin-induced impairment of renal excretion.

Acidosis is intensified by the following cycle: (1) Because of the pH partitioning effect, acidosis promotes penetration of salicylate into the CNS. (2) Increased entry of salicylate deepens respiratory depression. (3) Deepening of respiratory depression increases accumulation of CO₂, thereby increasing acidosis. (4) Increasing acidosis causes even more salicylate to enter the CNS, producing even further deepening of respiratory depression. This cycle continues until respiration ceases.

71.3.1.8.2

Treatment.

Aspirin poisoning is an acute medical emergency that requires hospitalization. The immediate threats to life are respiratory depression, hyperthermia, dehydration, and acidosis. Treatment is largely supportive. If respiration is inadequate, mechanical ventilation should be instituted. External cooling (eg, sponging with tepid water) can help reduce hyperthermia. Intravenous fluids are administered to correct dehydration; the composition of these fluids is determined

by electrolyte and acid-base status. Slow infusion of bicarbonate is given to reverse acidosis. Several measures (eg, gastric lavage, giving activated charcoal) can reduce further GI absorption of aspirin. Alkalinization of the urine with bicarbonate accelerates excretion of aspirin and salicylate. If necessary, hemodialysis or peritoneal dialysis can be used to remove salicylates.

71.3.1.9 Formulations

Aspirin is available in several formulations, including plain and buffered tablets, enteric-coated preparations, and tablets used to produce a buffered solution. These different formulations reflect efforts to increase rates of absorption and decrease gastric irritation. For the most part, the clinical utility of the more complex formulations is no greater than that of plain aspirin tablets.

71.3.1.9.1 Aspirin Tablets, Plain.

All brands are essentially the same with respect to analgesic efficacy, time of onset, and duration of action. Some of the less expensive tablets have greater particle size, which results in slower dissolution and prolonged contact with the gastric mucosa. These effects can augment gastric irritation. Over time, aspirin in tablets decomposes and emits an odor of vinegar (acetic acid); these tablets should be discarded.

71.3.1.9.2 Aspirin Tablets, Buffered.

The amount of buffer in buffered aspirin tablets is too small to produce significant elevation of gastric pH. An equivalent effect on pH can be achieved by taking plain aspirin tablets with food or a glass of water. Buffered aspirin tablets are no different from plain tablets with respect to analgesic effects and incidence of gastric distress. Buffered tablets may dissolve faster than plain tablets, resulting in a somewhat faster onset.

71.3.1.9.3 Buffered Aspirin Solution.

A buffered aspirin solution is produced by dissolving effervescent aspirin tablets [Alka-Seltzer] in a glass of water. This solution has considerable buffering capacity due to its high content of sodium bicarbonate. Effects on gastric pH are sufficient to decrease the incidence of gastric irritation and bleeding. In addition, aspirin absorption is accelerated and peak blood levels are increased. Unfortunately, these benefits come with a price. The sodium content of buffered aspirin solution can be detrimental to individuals on a sodium-restricted diet. Also,

absorption of bicarbonate can elevate urinary pH, which will accelerate aspirin excretion. Lastly, this highly buffered preparation is expensive. Because of this combination of benefits and drawbacks, the buffered aspirin solution is well suited for occasional use but is generally inappropriate for long-term therapy.

71.3.1.9.4 Enteric-Coated Preparations.

Enteric-coated preparations dissolve in the intestine rather than the stomach, thereby reducing gastric irritation. Unfortunately, absorption from these formulations can be delayed and erratic. Patients should be advised not to crush or chew them.

71.3.1.9.5 Timed-Release Tablets.

Timed-release tablets offer no advantage over plain aspirin tablets. Since the half-life of salicylic acid is long to begin with, and since aspirin produces irreversible inhibition of cyclooxygenase, timed-release tablets cannot increase duration of action.

71.3.1.9.6 Rectal Suppositories.

Rectal suppositories have been employed for patients who cannot take aspirin orally. Absorption can be variable, resulting in plasma drug levels that are insufficient in some patients and excessive in others. Also, rectal irritation can occur. Because of these undesirable properties, aspirin suppositories are not generally recommended.

71.3.1.10 Dosage and Administration

Aspirin is almost always administered by mouth. Gastric irritation can be minimized by administering aspirin with a glass of water or food. Dosage depends on the age of the patient and the condition being treated. Adult and pediatric dosages for major indications are summarized in [Table 70-4](#).

71.3.2 Nonaspirin First-Generation NSAIDs

In attempts to produce an aspirin-like drug with fewer GI, renal, and hemorrhagic effects than aspirin, the pharmaceutical industry has produced a large number of drugs with actions much like those of aspirin. In the United States, over 20 nonaspirin NSAIDs are available ([Table 70-5](#)). Like aspirin, all other first-generation NSAIDs inhibit both COX-1 and COX-2. However, in contrast to aspirin, which causes *irreversible* inhibition of cyclooxygenase, the other traditional NSAIDs

cause *reversible* inhibition. All of these drugs have anti-inflammatory, analgesic, and antipyretic properties. In addition, they all can cause gastric ulceration, bleeding, and renal impairment—although the intensity of these effects may be less with some agents. Patients who are hypersensitive to aspirin are likely to experience cross-hypersensitivity with other NSAIDs. For most NSAIDs, safety during pregnancy has not been established, and hence use by pregnant women is discouraged.

TABLE 70-4 Aspirin Dosage

Indication	Adult Dosage	Pediatric Dosage [*]
Aches and pains; fever	325–650 mg every 4 hr	2–3 yr old: 160 mg
		4–5 yr old: 240 mg
		6–8 yr old: 325 mg
		9–10 yr old: 405 mg
		11 yr old: 485 mg
		Over 11 yr old: 650 mg
		All of the above doses are administered every 4 hr
Acute rheumatic fever	5–8 gm/day in divided doses	100 mg/kg/day (initially), then 75 mg/kg/day for 4–6 wk
Rheumatoid arthritis	3.6–5.4 gm/day in divided doses	90–130 mg/kg/day in divided doses every 4–6 hr
Suppression of platelet aggregation		
Initial therapy	325 mg once a day	
Chronic therapy	80 mg once a day	

* Owing to the risk of Reye's syndrome, aspirin is usually avoided in patients less than 18 years old.

The principal indications for the nonaspirin NSAIDs are rheumatoid arthritis and osteoarthritis. In addition, certain NSAIDs are used to treat fever, bursitis, tendinitis, mild to moderate pain, and dysmenorrhea (see [Table 70-5](#)).

In contrast to aspirin, the nonaspirin NSAIDs *do not* protect against MI and stroke; in fact, they *increase* the risk of thrombotic events. For the NSAIDs as a group, the increase in cardiovascular risk is relatively low—about 12%. Risk is highest with indomethacin (71%), sulindac (41%), and meloxicam (37%). However, although the increase in risk with these drugs appears high, it pales in comparison with smoking, which increases cardiovascular risk by 200% to 300%. To minimize cardiovascular risk, nonaspirin NSAIDs should be used in the lowest effective dosage for the shortest time needed. Also, these drugs should not be used prior to coronary artery bypass graft (CABG) surgery or for 14 days after. Other measures to reduce risk are discussed below under *AHA Statement on COX Inhibitors in Chronic Pain*.

Although individual NSAIDs differ chemically, pharmacokinetically, and to some extent pharmacodynamically, all are very similar clinically: They all produce essentially equivalent antirheumatic effects and they all present a similar risk of serious adverse effects (gastric ulceration, bleeding, renal impairment, MI, and stroke). However, for reasons that are not understood, individual patients may respond better to one agent than another. Furthermore, individual patients may tolerate one NSAID better than another. Therefore, in order to optimize therapy for each patient, trials with more than one NSAID may be needed.

71.3.2.1 Nonacetylated Salicylates: Magnesium Salicylate, Sodium Salicylate, and Salsalate

71.3.2.1.1 Similarities to Aspirin.

The nonacetylated salicylates are similar to aspirin (an acetylated salicylate) in most respects. Like aspirin, these drugs inhibit COX-1 and COX-2 and are employed to treat arthritis, moderate pain, and fever. The most common adverse effects are GI disturbances. As with aspirin, these drugs should not be given to children with chickenpox or influenza owing to the possibility of precipitating Reye's syndrome.

71.3.2.1.2 Contrasts with Aspirin.

In contrast to aspirin, the nonacetylated salicylates cause little or no suppression of platelet aggregation. As a result, these drugs cannot protect against MI and stroke, and may actually increase risk.

Because of its sodium content, *sodium salicylate* should be avoided in patients on a sodium-restricted diet (eg, patients with hypertension or heart failure).

Magnesium salicylate may accumulate to toxic levels in patients with chronic renal insufficiency, and hence should be avoided by these people.

Salsalate is a prodrug that breaks down to release two molecules of salicylate in the alkaline environment of the small intestine. Because the stomach is not exposed to salicylate, salsalate produces less gastric irritation than aspirin.

71.3.2.1.3 Preparations, Dosage, and Administration

Magnesium salicylate [Magan, others] is supplied in caplets (467, 500, and 580 mg) and tablets (545 and 600 mg) for oral administration. The usual dosage is 650 mg every 4 hours or 1090 mg every 8 hours. The maximum dosage is 4800 mg/day, administered in three or four doses.

Sodium salicylate (generic) is supplied in enteric-coated tablets (325 and 650 mg) for oral use. The usual dosage is 325 to 650 mg every 4 hours.

Salsalate [Disalcid, others] is supplied in capsules (500 mg) and tablets (500 and 750 mg) for oral use. The usual dosage is 3000 mg/day in divided doses.

Choline salicylate, formerly available as Arthropan, has been withdrawn from the market.

71.3.2.2 Ibuprofen

Ibuprofen [Advil, Motrin, others] is the prototype of the propionic acid derivatives. Other members of the family are listed in [Table 70-5](#) and discussed individually below. Like aspirin, ibuprofen inhibits cyclooxygenase and has anti-inflammatory, analgesic, and antipyretic actions. The drug is used to treat fever, mild to moderate pain, and arthritis. In addition, ibuprofen appears superior to most other NSAIDs for relief of primary dysmenorrhea, presumably because it produces good inhibition of cyclooxygenase in uterine smooth muscle. In clinical trials, ibuprofen was highly effective at promoting closure of the ductus arteriosus in preterm infants, a condition for which indomethacin is the current treatment of choice.

Ibuprofen is generally well tolerated, and the incidence of adverse effects is low. The drug produces less gastric bleeding than aspirin and causes less inhibition of platelet aggregation. Consequently, ibuprofen is among the safer NSAIDs for use with anticoagulants. Very rarely, ibuprofen has been associated with Stevens-Johnson syndrome, a severe hypersensitivity reaction that causes blistering of the skin and mucous membranes, and can result in scarring,

blindness, and even death. Like other nonaspirin NSAIDs, ibuprofen may pose a risk of MI and stroke.

Ibuprofen, by itself, is available in five *oral formulations*: (1) standard tablets (100, 200, 400, 600, and 800 mg); (2) chewable tablets (50 and 100 mg); (3) capsules (200 mg); (4) a 20-mg/
mL oral suspension [Children's Advil, Children's Motrin, PediaCare Fever]; and (5) a 40-mg/
mL oral suspension [Pediatric Advil Drops, Infant's Motrin, Pedia-Care Fever]. Administration
with meals or milk can reduce gastric distress.

TABLE 70-5 Clinical Pharmacology of the Oral Nonsteroidal Anti-Inflammatory Drugs

Drug	Maximum Daily Dosage (mg)	Plasma Half-Life (hr)	Major Indications*				
			Arthritis	Moderate Pain	Fever	Dysmenorrhea	Bursitis/Tendinitis
First-Generation NSAIDs							
Salicylates							
Aspirin (many trade names)	8000	0.2–0.3	A	A	A

Second-Generation NSAIDs (COX-2 Inhibitors)						
Celecoxib [Celebrex]	800	11	A	A	A	

* A = FDA-approved indication; I = nvestigational use.

† Half-life increases with increasing dosage.

‡ Diclofenac is also available in two *topical* formulations, sold as Voltaren Gel and Flector Patch (see text).

§ Ketorolac is approved only for *acute* pain; use should not exceed 5 days.

Dosages for *adults* are

- *Arthritis*—1.2 to 3.2 gm/day administered in three or four divided doses
- *Primary dysmenorrhea*—400 mg every 4 to 6 hours
- *Mild to moderate pain*—400 mg every 4 hours

Dosages for *children* are

- *Juvenile arthritis*—30 to 40 mg/kg/day in three or four divided doses.

- *Fever reduction*—5 mg/kg (for temperatures up to 102.5°F) or 10 mg/kg (for temperatures above 102.5°F). The total daily dose should not exceed 40 mg/kg.

An *intravenous formulation* (10 mg/mL), sold as NeoProfen, is available to close a patent ductus arteriosus in premature infants. Treatment consists of an initial dose (10 mg/kg infused over 15 minutes) followed by two more doses (5 mg/kg each) given 24 and 48 hours later.

Ibuprofen is also available in a fixed-dose combination with oxycodone, sold as Combunox, for short-term oral therapy of moderate to severe pain.

71.3.2.3 Fenopfen

Fenopfen [Nalfon] belongs to the propionic acid family of NSAIDs. Like other NSAIDs, the drug inhibits synthesis of prostanoids, thereby causing anti-inflammatory, analgesic, and antipyretic effects. Fenopfen is indicated for arthritis and mild to moderate pain. The most common adverse effects are GI disturbances. Fenopfen is supplied in tablets (600 mg) and capsules (200 and 300 mg). The usual dosage for rheumatoid arthritis is 300 to 600 mg 3 or 4 times a day. The maximum daily dosage is 3.2 gm.

71.3.2.4 Flurbiprofen

Flurbiprofen [Ansaid] is chemically related to ibuprofen and the other derivatives of propionic acid. The drug is approved for arthritis and has been used investigationally for bursitis, tendinitis, moderate pain, fever, and primary dysmenorrhea. The most common adverse effects are GI disturbances (dyspepsia, nausea, diarrhea, abdominal pain). The risk of serious GI effects (ulceration, perforation, hemorrhage) may be greater than with ibuprofen. Like other NSAIDs, flurbiprofen can exacerbate renal impairment and may pose a risk of MI and stroke. The drug is supplied in tablets (50 and 100 mg) for oral use. The usual dosage for rheumatoid arthritis is 200 to 300 mg/day administered in two to four divided doses.

836

71.3.2.5 Ketoprofen

Ketoprofen (formerly available as Orudis and Oruvail) belongs to the propionic acid family of NSAIDs. The drug inhibits synthesis of prostanoids and has anti-inflammatory, analgesic, and antipyretic effects. Indications are rheumatoid arthritis, osteoarthritis, mild to moderate pain, and primary dysmenorrhea. The most common adverse effects are dyspepsia (11.5%), nausea, vomiting, and abdominal pain. Ketoprofen is supplied in standard capsules (50 and 75 mg) and

837

extended-release capsules (100, 150, and 200 mg). The usual dosage for rheumatoid arthritis is 150 to 300 mg/day administered in three or four divided doses. The dosage for moderate pain or primary dysmenorrhea is 25 to 50 mg every 6 to 8 hours.

71.3.2.6 Naproxen

71.3.2.6.1 Actions and Uses.

Naproxen [Aleve, Anaprox, Naprelan, Naprosyn], which belongs to the propionic acid family of NSAIDs, is highly selective for COX-1. The drug has a prolonged half-life (see [Table 70-5](#)), and hence can be administered less frequently than other propionic acid derivatives (eg, ibuprofen). Naproxen is approved for arthritis, bursitis, tendinitis, primary dysmenorrhea, fever, and mild to moderate pain. Like other NSAIDs, the drug acts primarily by inhibiting cyclooxygenase.

71.3.2.6.2 Adverse Effects.

Naproxen is among the better tolerated NSAIDs. The most common adverse effects are GI disturbances. Like other NSAIDs, the drug can compromise renal function and may increase the risk of MI and stroke. However, because naproxen is COX-1 selective, the risk of MI and stroke appears lower than with other traditional NSAIDs. Bleeding time can be prolonged secondary to reversible inhibition of platelet aggregation.

71.3.2.6.3 Preparations, Dosage, and Administration.

Naproxen is supplied in standard tablets (200, 250, 375, and 500 mg) sold as Aleve, Anaprox, and Naprosyn; delayed-release enteric-coated tablets (375 and 500 mg) sold as EC-Naprosyn; controlled-release tablets (375 and 500 mg) sold as Naprelan; and an oral suspension (25 mg/mL) sold as Naprosyn and Naproxen. The usual dosage for rheumatoid arthritis is 250 to 500 mg twice daily. The dosage for mild to moderate pain is 500 mg initially followed by 250 mg every 6 to 8 hours.

71.3.2.7 Naproxen Plus Lansoprazole

For patients at high risk for gastric ulcers, naproxen tablets are co-packaged with lansoprazole capsules under the trade name *Prevacid NapraPAC*. Lansoprazole protects against ulcers by inhibiting the proton pump that generates gastric acid. Two combinations of naproxen/lansoprazole are available: 375 mg/15 mg and 500 mg/15 mg. Each morning before eating, the

patient takes 15 mg of lansoprazole plus either 375 mg or 500 mg naproxen, followed in the evening by 375 mg or 500 mg of naproxen alone.

71.3.2.8 Oxaprozin

Oxaprozin [Daypro] belongs to the propionic acid family of NSAIDs. Approved uses are rheumatoid arthritis and osteoarthritis. As with other NSAIDs, benefits derive from inhibiting synthesis of prostanoids. Like other propionic acid derivatives, oxaprozin is generally well tolerated. The drug has an unusually long half-life (42 to 50 hours), and hence can be administered just once a day. Oxaprozin is available in 600-mg tablets and caplets. The dosage for arthritis is 1200 mg once a day. The maximum dosage is 1800 mg/day.

71.3.2.9 Diclofenac

71.3.2.9.1 Oral.

Oral diclofenac [Voltaren, Cataflam] is approved for rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, mild pain, and primary dysmenorrhea. As with other NSAIDs, anti-inflammatory, analgesic, and antipyretic effects result from inhibiting cyclooxygenase. Diclofenac is well absorbed following oral administration, but undergoes extensive (40% to 50%) metabolism on its first pass through the liver. In the blood, about 99.5% of the drug is protein bound, primarily to albumin. Diclofenac is metabolized by the liver and excreted in the urine.

The most common adverse effects are abdominal pain, dyspepsia, and nausea. By impairing renal function, diclofenac can cause fluid retention, which can exacerbate hypertension and heart failure. The risk of liver dysfunction is greater than with other NSAIDs. Accordingly, patients should receive periodic tests of liver function, and should be instructed to report manifestations of liver injury (eg, jaundice, fatigue, nausea). Like other NSAIDs, diclofenac may pose a risk of MI and stroke.

Diclofenac is supplied in standard tablets (50 mg) as Cataflam and enteric-coated delayed-release tablets (25, 50, 75, and 100 mg) as Voltaren. The dosage for rheumatoid arthritis is 150 to 200 mg/day administered in two or three divided doses. The dosage for osteoarthritis is 100 to 150 mg/day administered in two or three divided doses.

71.3.2.9.2 Topical.

Two topical formulations of diclofenac—*Voltaren Gel* and *Flector Patch*—are now available. Voltaren Gel is for osteoarthritis. Flector Patch is for minor pain. A third topical formulation—*Solaraze*—is used for actinic keratoses (see [Chapter 104](#)). Topical diclofenac is more expensive than oral diclofenac, and there is no proof of equivalent efficacy. With topical therapy, blood levels are only about 5% of those seen with oral therapy, and hence the risk of systemic toxicity is low. Whether topical diclofenac shares the drug interactions of oral diclofenac has not been determined.

Voltaren Gel (1% diclofenac sodium) is the first prescription topical NSAID for treating pain and inflammation. Application is done to the knees, elbows, and other amenable joints. For joints of the lower extremity (knees, ankles, feet), the dosage is 4 gm of gel applied 4 times a day. For joints of the upper extremity (elbows, wrists, hands), the dosage is 2 gm of gel applied 4 times a day. Total body exposure should not exceed 32 gm/day. Treated areas should be protected from sunlight. Local dermatitis is the principal adverse effect.

Flector Patch (1.3% diclofenac epolamine) is the first prescription NSAID patch indicated for pain of strains, sprains, and contusions. One patch is applied over the injury twice a day—but only to skin that is intact. The patch should not be worn while bathing or showering. Local reactions—pruritus, dermatitis, burning—are the principal adverse effects.

71.3.2.10 Diclofenac Plus Misoprostol

Oral diclofenac, in combination with misoprostol, is available under the trade name *Arthrotec*. Misoprostol is a prostaglandin analog that can protect against NSAID-induced ulcers. The combination product is approved for patients with rheumatoid arthritis or osteoarthritis who are at high risk for NSAID-induced gastric or duodenal ulcers. In patients with arthritis, the combination is as effective as diclofenac alone and produces significantly less GI ulceration. The most bothersome side effect is diarrhea (caused by misoprostol). Misoprostol can induce uterine contraction, and hence the product is contraindicated for use during pregnancy. Diclofenac/misoprostol is supplied in two strengths: 50 mg/200 mcg and 75 mg/200 mcg. For rheumatoid arthritis, the usual dosage is 50 mg/200 mcg 3 or 4 times a day.

71.3.2.11 Diflunisal

Diflunisal [Dolobid] is a derivative of salicylic acid. However, unlike the salicylates, diflunisal is not converted to salicylic acid in the body. The drug is indicated for mild to moderate pain, rheumatoid arthritis, and osteoarthritis. Like other NSAIDs, the drug inhibits prostaglandin synthesis and can cause GI disturbances, suppression of platelet aggregation, and renal impairment, and may increase the risk of MI and stroke. Diflunisal has a prolonged half-life (11 to 15 hours), and hence can be administered only 2 or 3 times a day. Diflunisal is supplied in tablets (250 and 500 mg) for oral use. For treatment of arthritis and mild to moderate pain, the initial dose is 500 to 1000 mg. Maintenance doses of 250 to 500 mg are administered every 8 to 12 hours.

71.3.2.12 Etodolac

Etodolac (formerly available as Lodine) is indicated for rheumatoid arthritis, osteoarthritis, and moderate pain. The drug has been used investigationally to treat bursitis and tendinitis. Like other NSAIDs, etodolac produces many of its effects by suppressing the synthesis of prostanoids. The most common adverse effects are dyspepsia (10%), nausea, vomiting, diarrhea, and abdominal pain. Etodolac may cause less gastric ulceration and bleeding than other NSAIDs. The drug is supplied in standard tablets (400 and 500 mg), extended-release tablets (400, 500, and 600 mg), and capsules (200 and 300 mg). The recommended dosage for arthritis is 800 to 1200 mg/day in divided doses. The dosage for moderate pain is 200 to 400 mg every 6 to 8 hours.

71.3.2.13 Indomethacin

71.3.2.13.1 Actions and Uses.

Indomethacin [Indocin] is an effective anti-inflammatory agent approved for arthritis, bursitis, tendinitis, and, as discussed in [Chapter 73](#), acute gouty arthritis. In addition, the drug can be given IV to preterm infants to promote closure of the ductus arteriosus. Although indomethacin is able to reduce pain and fever, it is not routinely used for these effects, owing to its potential for toxicity.

71.3.2.13.2 Adverse Effects.

Untoward effects are seen in 35% to 50% of patients, causing about 20% to discontinue treatment. The most common adverse effect is severe frontal headache, which occurs in 25% to 50% of patients. Other CNS effects (dizziness, vertigo, confusion) are also common. Seizures and psychiatric changes (eg, depression, psychosis) have occurred. Mild GI reactions (nausea, vomiting, indigestion) develop in 3% to 9% of users. More severe GI effects (ulceration with perforation, hemorrhage) may also occur. Hematologic reactions (neutropenia, thrombocytopenia, aplastic anemia) have occurred but are rare. Indomethacin suppresses platelet aggregation.

837

71.3.2.13.3 Precautions and Contraindications.

838

Because of its adverse effects, indomethacin is generally contraindicated for infants and children under the age of 14, patients with peptic ulcer disease, and women who are pregnant or breast-feeding. Caution is required in patients with epilepsy and psychiatric disorders, in patients involved in hazardous activities, and in patients receiving anticoagulant therapy.

71.3.2.13.4 Pharmacokinetics.

Indomethacin is well absorbed following oral administration and distributes to all body fluids and tissues. The drug is metabolized in the liver. Metabolites and parent drug are excreted in the urine and feces.

71.3.2.13.5 Preparations, Dosage, and Administration.

Indomethacin [Indocin] is available in standard capsules (25 and 50 mg), sustained-release capsules (75 mg), an oral suspension (5 mg/mL), and rectal suppositories (50 mg). For treatment of rheumatoid arthritis, the initial dosage is 25 mg 2 or 3 times a day. The maximum daily dosage is 200 mg. Gastrointestinal reactions can be reduced by administering indomethacin with meals. Dosages for gout are presented in [Chapter 73](#).

71.3.2.14 Ketorolac

71.3.2.14.1 Actions and Uses.

Ketorolac (formerly available as Toradol) is a powerful analgesic with minimum anti-inflammatory actions. Pain relief is equivalent to that produced by morphine and other

opioids. Although ketorolac lacks the serious adverse effects associated with opioids (respiratory depression, tolerance, dependence, abuse potential), it nonetheless has serious adverse effects of its own. Accordingly, use should be short term and restricted to managing acute pain of moderate to severe intensity. Ketorolac is not indicated for chronic pain or for treatment of minor aches and discomfort. The usual indication is postoperative pain, for which ketorolac can be as effective as morphine. Like other NSAIDs, ketorolac suppresses prostaglandin synthesis. This action is thought to underlie analgesic effects.

71.3.2.14.2 Pharmacokinetics.

Ketorolac is administered orally and parenterally (IM or IV). With parenteral administration, analgesia begins within 30 minutes, peaks in 1 to 2 hours, and persists 4 to 6 hours. The drug is eliminated by hepatic metabolism and urinary excretion. In young adults, ketorolac has a half-life of 4 to 6 hours. The half-life may be prolonged in the elderly and those with renal impairment.

71.3.2.14.3 Adverse Effects and Contraindications.

Ketorolac can cause all of the adverse effects associated with other NSAIDs, including peptic ulcers, GI bleeding or perforation, prolonged bleeding time, renal impairment, hypersensitivity reactions, suppression of uterine contractions, and premature closure of the ductus arteriosus. Concurrent use with other NSAIDs increases the risk of these effects and is therefore contraindicated. Other contraindications include active peptic ulcer disease, history of peptic ulcer disease or recent GI bleeding, advanced renal impairment, confirmed or suspected intracranial bleeding, use prior to major surgery, history of NSAID hypersensitivity reactions, and use during labor and delivery.

71.3.2.14.4 Preparations, Dosage, and Administration.

Ketorolac is available in 10-mg tablets for oral use, and solution (15 and 30 mg/mL) for IM or IV administration. Therapy should begin with parenteral treatment, followed by oral treatment, if needed. Because of the risks associated with prolonged use, treatment (parenteral plus oral) should not exceed 5 days.

Parenteral therapy can be accomplished with one injection or with several. When a single injection is used, the IM dose is 30 or 60 mg, and the IV dose is 15 or 30 mg. When multiple injections are given, the dosage (IM or IV) is 15 or 30 mg every 6 hours. In all cases, the smaller dosage option is employed for patients over 65 years, patients with impaired kidney

function, and patients who weigh less than 50 kg (110 pounds). Intravenous doses should be administered over 15 seconds or longer. Intramuscular injections should be done slowly and deep in the muscle. Treatment should not exceed 5 days.

Oral ketorolac is indicated only as a follow-up to parenteral therapy. Initial oral doses are based on preceding parenteral doses. The usual oral maintenance dosage is 10 mg every 4 to 6 hours. Combined oral and parenteral treatment should not exceed 5 days.

71.3.2.15 Mefenamic Acid

Mefenamic acid [Ponstel] is indicated for relief of primary dysmenorrhea and moderate pain. The principal adverse effect is diarrhea, which can be severe. Mefenamic acid is supplied in 250-mg capsules. The dosage for primary dysmenorrhea is 500 mg initially followed by 250 mg every 6 hours. The drug should be administered with food or milk to reduce gastric distress. Duration of treatment is usually 2 to 3 days.

71.3.2.16 Meclofenamate

Meclofenamate is indicated for rheumatoid arthritis, osteoarthritis, mild to moderate pain, and dysmenorrhea. As with other NSAIDs, benefits derive from inhibiting cyclooxygenase. Therapeutic effects are no better than with other NSAIDs, but adverse GI effects are greater: 3% to 9% of patients experience nausea, vomiting, abdominal pain, and cramps; worse yet, 10% to 33% develop diarrhea. Because of this poor benefit/risk profile, meclofenamate is not a drug of first choice. Meclofenamate is available in 50- and 100-mg capsules. Dosages are as follows: arthritis, 200 to 400 mg/day in three or four divided doses; moderate pain, 50 mg every 4 to 6 hours; and dysmenorrhea, 100 mg 3 times a day for up to 6 days.

71.3.2.17 Nabumetone

Nabumetone (formerly available as Relafen) is a prodrug that undergoes conversion to its active form (6-MNA) in the liver. In contrast to most traditional NSAIDs, 6-MNA inhibits COX-2 more than COX-1. Although nabumetone has antipyretic, analgesic, and anti-inflammatory properties, the drug is approved only for osteoarthritis and rheumatoid arthritis. Principal adverse effects are diarrhea (14%), abdominal cramps (13%), dyspepsia (12%), and nausea (3% to 9%). Nabumetone causes much less GI ulceration than other first-generation NSAIDs, possibly because it preferentially inhibits COX-2. Nabumetone is supplied in 500- and 750-mg tablets. Administration with food increases the rate of absorption. Treatment of arthritis is begun

with a single dose of 1000 mg. After this, the daily dosage is 1500 to 2000 mg administered in one or two doses. Dosage should be reduced in patients with renal impairment.

71.3.2.18 Piroxicam

Piroxicam [Feldene] has anti-inflammatory, analgesic, and antipyretic properties, but is approved only for rheumatoid arthritis and osteoarthritis. The drug's most outstanding feature is its long half-life (about 50 hours). Because piroxicam is eliminated so slowly, therapeutic effects can be maintained with once-a-day dosing. In general, piroxicam is better tolerated than aspirin. Undesired effects are seen in 11% to 46% of patients, causing between 4% and 12% to discontinue therapy. Gastrointestinal reactions are most common, occurring in about 20% of patients. The incidence of gastric ulceration is about 1%. Like aspirin, piroxicam inhibits platelet aggregation and prolongs bleeding time. The drug is supplied in 10- and 20-mg capsules for oral use. The usual dosage is 20 mg once a day.

71.3.2.19 Sulindac

Sulindac [Clinoril] is a prodrug that undergoes conversion to its active form after dosing. The drug is approved for rheumatoid arthritis, osteoarthritis, tendinitis, bursitis, and acute gouty arthritis. Principal adverse effects are abdominal distress, dyspepsia, nausea, vomiting, and diarrhea. Gastric ulceration is less common than with some other NSAIDs. Like other NSAIDs, sulindac causes reversible inhibition of platelet aggregation, prolongs bleeding time, and impairs renal function. The drug is supplied in 150- and 200-mg oral tablets. The usual dosage is 150 mg administered twice daily with meals. The maximum daily dosage is 400 mg.

71.3.2.20 Tolmetin

Tolmetin (formerly available as Tolectin) is approved for rheumatoid arthritis and osteoarthritis. The drug has analgesic and antipyretic properties but is not employed to relieve fever or pain unrelated to inflammation. Adverse effects occur in 25% to 40% of patients, causing between 5% and 10% to discontinue treatment. Gastrointestinal effects (nausea, vomiting, indigestion) are most common. Gastric ulceration has occurred, but less frequently than with aspirin. Nonetheless, caution should be exercised in patients with a history of peptic ulcer disease. Hypersensitivity reactions are more common than with aspirin. Effects on the CNS (headache, dizziness, anxiety, drowsiness) are less severe and less frequent than with indomethacin. Unlike most other NSAIDs, tolmetin does not augment the effects of warfarin, an oral anticoagulant. The drug is supplied in tablets (200 and 600 mg) and capsules (400 mg). For rheumatoid

arthritis, the initial dosage is 400 mg 3 times a day. The maximum daily dosage is 2 gm. Gastrointestinal distress can be minimized by administering tolmetin with food.

71.3.2.21 Meloxicam

Meloxicam [Mobic] is a relatively new drug with some COX-2 selectivity. Like other NSAIDs, the drug has analgesic, anti-inflammatory, and antipyretic actions. Approved indications are osteoarthritis, rheumatoid arthritis, and pauciarticular/polyarticular-course juvenile rheumatoid arthritis (JRA). For osteoarthritis, meloxicam is as effective as first-generation NSAIDs. Direct comparison with true COX-2 inhibitors (eg, celecoxib) has not been made. Despite its COX-2 selectivity, meloxicam has a side effect profile like that of the first-generation NSAIDs.

Gastrointestinal effects (abdominal pain, constipation, diarrhea, dyspepsia, flatulence, nausea, and vomiting) occur in 20% to 25% of patients. More serious effects—GI ulceration, bleeding, perforation, and death—have also occurred. Meloxicam does not suppress platelet aggregation.

838

839

The drug has a long half-life (15 to 20 hours) and undergoes elimination in the urine (50%) and feces (50%). Meloxicam is available in tablets (7.5 and 15 mg) and an oral solution (7.5 mg/5 mL). Both formulations can be administered with or without food. Because of its long half-life, meloxicam can be administered just once a day. The recommended dose for initial and maintenance therapy of osteoarthritis and rheumatoid arthritis is 7.5 mg a day. For patients with JRA, the recommended daily dosage is 0.125 mg/kg (but no more than 7.5 mg).

71.4 SECOND-GENERATION NSAIDs (COX-2 INHIBITORS, COXIBS)

The COX-2 inhibitors, also known as coxibs, were developed on the theory that selective inhibition of COX-2 should be able to suppress pain and inflammation while posing little or no risk of gastric ulceration. To some degree, theory and reality agree: Coxibs are just as effective as traditional NSAIDs at suppressing inflammation and pain, and they pose a somewhat lower risk of GI side effects. However, even with coxibs, patients can develop clinically significant gastroduodenal ulceration and bleeding. Furthermore, like traditional NSAIDs, coxibs can impair renal function, and can thereby cause hypertension and edema. Coxibs also increase the risk of MI and stroke.

The coxib story reads like a Greek tragedy. Following their introduction in December 1998, coxibs were prescribed for millions of patients, with hopes of relieving inflammation and pain while minimizing GI side effects. At their peak, combined annual sales for the three available coxibs exceeded \$5 billion. Within a few years, however, the story began to change. Protection from ulcers turned out to be less than hoped for, and evidence of serious cardiovascular risk began to emerge.

Pharmacology for Nursing Care, 7th Edition

By 2005, two coxibs—rofecoxib and valdecoxib—had been withdrawn from the market, and sales of the one remaining agent—celecoxib—had sharply declined.

71.4.1 Celecoxib

71.4.1.1 Therapeutic Use

Celecoxib [Celebrex], approved in December 1998, was the first selective COX-2 inhibitor to reach the market. The drug is indicated for osteoarthritis, rheumatoid arthritis, ankylosing spondylitis, acute pain, and dysmenorrhea. In addition, celecoxib is approved for a rare genetic disorder known as familial adenomatous polyposis, which predisposes to developing colorectal cancer. For patients with arthritis, celecoxib is equal to naproxen (an NSAID) at relieving joint pain, stiffness, and swelling. Owing to concerns about cardiovascular safety, celecoxib is considered a last-choice drug for long-term management of pain (see below under *AHA Statement on COX Inhibitors in Chronic Pain*).

It is important to note that celecoxib does *not* provide the cardiovascular benefits of aspirin. Why? Because celecoxib does not inhibit COX-1 in platelets, and hence does not suppress platelet aggregation.

71.4.1.2 Mechanism of Action

Celecoxib causes selective inhibition of COX-2, the COX isoform whose products mediate inflammation and pain. At therapeutic doses, celecoxib does not inhibit COX-1, the COX isoform whose products protect the stomach, help maintain renal function, and promote platelet aggregation.

71.4.1.3 Pharmacokinetics

Celecoxib is well absorbed following oral administration. Plasma levels peak in 3 hours. Binding to plasma proteins is extensive (97%). The drug undergoes hepatic metabolism followed by renal excretion. The half-life is 11 hours.

71.4.1.4 Adverse Effects

In premarketing trials, celecoxib was well tolerated. The discontinuation rate owing to adverse effects was 7.1% for celecoxib versus 6.1% for placebo. The most common complaints were *dyspepsia* (8.8% vs. 6.2% for placebo) and *abdominal pain* (4.1% vs. 2.8% for placebo).

Celecoxib does not decrease platelet aggregation and hence does not promote bleeding. Possible cardiovascular events are the biggest concern.

71.4.1.4.1 Gastroduodenal Ulceration.

Because celecoxib does not inhibit COX-1, the isoform of COX that protects the stomach, a low incidence of gastroduodenal ulceration would be expected. Some data support this expectation; others do not. When celecoxib was first approved, conclusions about its safety were based on 6-month data from the Celecoxib Arthritis Safety Study (CLASS), which indicated that celecoxib caused less GI toxicity than conventional NSAIDs (diclofenac, naproxen, ibuprofen). However, longer term (12-month) data from the same study showed *no difference* in GI toxicity between celecoxib and conventional NSAIDs. Other studies have shown that, compared with patients taking conventional NSAIDs, those taking celecoxib had a lower incidence of endoscopically detectable ulcers and a lower incidence of hospitalization for GI bleeding. What's the bottom line? Celecoxib *may* be safer than conventional NSAIDs, especially when used short term. However, convincing data of superior safety are lacking. Like traditional NSAIDs, celecoxib can be combined with a PPI to reduce GI complications.

71.4.1.4.2 Cardiovascular Events.

There is strong evidence that coxibs, like other nonaspirin NSAIDs, increase the risk of MI, stroke, and other serious cardiovascular events. In the Adenoma Prevention with Celecoxib (APC) trial, patients who took 400 mg or 800 mg of celecoxib a day experienced more major fatal or nonfatal cardiovascular events than did patients who took placebo. With two other coxibs—rofecoxib and valdecoxib—cardiovascular risk is even greater than with celecoxib, and hence these drugs have been removed from the market (see below). To minimize risk, celecoxib should be used in the lowest effective dosage for the shortest time needed. Also, the drug should be avoided in patients with existing heart disease and those who have just undergone CABG surgery, and should be used with caution in patients with cardiovascular risk factors, such as hypertension, diabetes, and dyslipidemia. Other measures to reduce risk are discussed below under *AHA Statement on COX Inhibitors in Chronic Pain*.

Why is the risk of MI and stroke increased? First, because celecoxib does not inhibit COX-1, platelet aggregation is not suppressed. Second, because celecoxib inhibits COX-2 in blood vessels, vasoconstriction is increased. These two factors—unimpeded platelet aggregation and increased vasoconstriction—increase the likelihood of vessel blockage once the process of thrombosis has begun.

71.4.1.4.3 Renal Impairment.

Like conventional NSAIDs, celecoxib can impair renal function, thereby posing a risk to patients with hypertension, edema, heart failure, or pre-existing kidney disease. Renal impairment apparently results from inhibiting COX-2.

839

71.4.1.4.4 Sulfonamide Allergy.

Celecoxib contains a sulfur molecule and hence can precipitate an allergic reaction in patients allergic to sulfonamides. Accordingly, the drug should be avoided by patients with sulfa allergy.

840

71.4.1.4.5 Use in Pregnancy.

Celecoxib and other NSAIDs can cause premature closure of the ductus arteriosus. Accordingly, these drugs are contraindicated during the third trimester of pregnancy.

71.4.1.5 Drug Interactions

71.4.1.5.1 Warfarin.

Celecoxib may increase the anticoagulant effects of warfarin, and may thereby increase the risk of bleeding. Celecoxib itself does not inhibit platelet aggregation and does not promote bleeding. However, the drug may enhance the anticoagulant effects of warfarin (perhaps by increasing warfarin levels). Celecoxib may be combined with warfarin, but effects of warfarin should be monitored closely, especially during the first few days of treatment.

71.4.1.5.2 Other Interactions.

Information on the interactions of celecoxib with other drugs is limited. Celecoxib may decrease the diuretic effects of furosemide as well as the antihypertensive effects of ACE inhibitors. Conversely, celecoxib may increase levels of lithium (a drug for bipolar disorder). Levels of celecoxib may be increased by fluconazole (an antifungal drug).

71.4.1.6 Preparations, Dosage, and Administration

Celecoxib [Celebrex] is available in capsules (100, 200, and 400 mg). To minimize cardiovascular risk, the drug should be used in the lowest effective dosage for the shortest time needed. Approved dosages are as follows:

- *Osteoarthritis*—100 mg twice daily or 200 mg once daily
- *Rheumatoid arthritis*—100 or 200 mg twice daily
- *Acute pain*—On day 1, 400 mg initially plus another 200 mg if needed; on all subsequent days, 200 mg twice daily as needed
- *Primary dysmenorrhea*—Same as for acute pain
- *Familial adenomatous polyposis*—400 mg twice daily, taken with food

71.4.2 Rofecoxib and Valdecoxib

Rofecoxib [Vioxx] and valdecoxib [Bextra] have been withdrawn from the market. Both drugs greatly increase the risk of serious cardiovascular events. In addition, valdecoxib poses a risk of severe skin reactions.

Rofecoxib was approved in May 1999 and withdrawn in September 2004. Concern about the drug began in March 2000, when data from the Vioxx Gastrointestinal Outcomes Research (VIGOR) trial showed that patients who took rofecoxib experienced more MIs and other thrombotic events (eg, unstable angina, ischemic stroke, transient ischemic attacks) than did patients who took naproxen. However, it wasn't clear from these data whether rofecoxib actively promoted MI or naproxen protected against MI. Any doubts about the cardiovascular risks of rofecoxib were eliminated in September 2004, when data from the Adenomatous Polyp Prevention On Vioxx (APPROVE) trial showed that, in patients who took rofecoxib for more than 18 months, rates of MI and stroke were significantly greater than in patients who took a placebo. In response to the APPROVE data, the manufacturer—Merck—voluntarily withdrew rofecoxib from the market worldwide. By that time, however, more than 100 million prescriptions had been written in the United States alone, possibly resulting in thousands of excess cardiovascular deaths.

Valdecoxib was approved in November 2001 and withdrawn in April 2005. Why? Because of cardiovascular and hypersensitivity risks. Like other coxibs, valdecoxib increases the risk of

cardiovascular events. In a study involving patients recovering from CABG surgery, those who took valdecoxib experienced more cardiovascular events (MI, stroke, deep vein thrombosis, pulmonary embolism) than did those who took a placebo. Valdecoxib can also cause severe skin reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis, both of which can be fatal. Because of these risks, and because valdecoxib has no demonstrated advantage over other NSAIDs, the FDA asked the manufacturer (Pfizer) to suspend sales in the United States.

71.5 ACETAMINOPHEN

Acetaminophen [Tylenol, many others] is like aspirin in some respects but different in others. Acetaminophen has *analgesic* and *antipyretic* properties equivalent to those of aspirin. However, in contrast to aspirin and the other NSAIDs, *acetaminophen is devoid of clinically useful anti-inflammatory and antirheumatic actions*. In addition, acetaminophen does not suppress platelet aggregation, does not cause gastric ulceration, and does not decrease renal blood flow or cause renal impairment. However, acetaminophen overdose can cause severe liver injury. In the United States, acetaminophen is used more than any other analgesic.

71.5.1 Mechanism of Action

Differences between the effects of acetaminophen and aspirin are thought to result from selective inhibition of cyclooxygenase, the enzyme needed to make prostaglandins and related compounds. Whereas aspirin can inhibit cyclooxygenase in both the CNS and the periphery, inhibition by acetaminophen is limited to the CNS; acetaminophen has only minimal effects on cyclooxygenase at peripheral sites. By decreasing prostaglandin synthesis in the CNS, acetaminophen is able to reduce fever and pain. The inability of acetaminophen to inhibit prostaglandin synthesis outside the CNS may explain the absence of anti-inflammatory effects, gastric ulceration, and adverse effects on the kidneys and platelets.

71.5.2 Pharmacokinetics

Acetaminophen is readily absorbed following oral dosing and undergoes wide distribution. Most of each dose is metabolized by the liver, and the metabolites are excreted in the urine. The plasma half-life of the drug is approximately 2 hours.

Acetaminophen can be metabolized by two pathways; one is major and the other is minor ([Fig. 70-2](#)). In the major pathway, acetaminophen undergoes conjugation with glucuronic acid and other compounds to form nontoxic metabolites. In the minor pathway, acetaminophen is oxidized by a cytochrome P450-containing enzyme into a highly reactive and toxic compound. At

therapeutic doses, practically all of the drug is converted to nontoxic compounds via the major pathway. Only a small fraction is converted into the toxic metabolite via the minor pathway. Under normal conditions, the toxic metabolite undergoes rapid conversion to a nontoxic form; glutathione is required for the conversion. When an overdose of acetaminophen is taken, a larger than normal amount is processed via the minor pathway, and hence a large quantity of the toxic metabolite is produced. As the liver attempts to detoxify the metabolite, glutathione is rapidly depleted, and further detoxification stops. As a result, the toxic metabolite accumulates, causing damage to the liver (see below).

71.5.3 Adverse Effects

Adverse effects are extremely rare at therapeutic doses. Acetaminophen does not cause gastric ulceration or renal impairment and does not inhibit platelet aggregation. In addition, there is no evidence linking acetaminophen with Reye's syndrome. Individuals who are hypersensitive to aspirin only rarely experience cross-hypersensitivity with acetaminophen. Overdose can cause severe *liver injury* (see below).

840

841

Figure 70-2 Metabolism of acetaminophen.

Data from the Nurses' Health Study show an association between daily use of *acetaminophen* (500 mg or more/day) and development of *hypertension*. However, a causal relationship has not been established. Nonetheless, it would be prudent to monitor blood pressure in women who take acetaminophen daily. The mechanism by which acetaminophen might raise blood pressure in women is unknown.

71.5.4 Drug Interactions

71.5.4.1 Alcohol.

Regular alcohol consumption increases the risk of liver injury from acetaminophen—but only if acetaminophen dosage is excessive. Three mechanisms are involved. First, alcohol induces synthesis of the P450-containing enzyme in the minor metabolic pathway, thereby increasing production of acetaminophen's toxic metabolite (see [Fig. 70-2](#)). Second, stores of glutathione are depleted in chronic alcoholics. As a result, the liver is unable to convert the toxic metabolite to a nontoxic form ([Fig. 70-2](#)). Third, chronic alcohol abusers often have pre-existing liver damage, which renders them less able to tolerate injury from acetaminophen.

Does alcohol increase the risk of liver damage from acetaminophen taken in *therapeutic* doses? Probably not. Although *anecdotal* reports suggest that low-dose acetaminophen can cause liver injury in alcohol users, the results of a randomized controlled trial indicate otherwise: In alcoholics given therapeutic doses of acetaminophen, indices of liver damage were no greater than in alcoholics given a placebo. These data suggest that, even for people who consume alcohol in large amounts, *low* (therapeutic) doses of acetaminophen are safe. Nonetheless, some authorities recommend that, if you drink alcohol on a regular basis, you should consume no more than 2 gm of acetaminophen a day (one-half the normal maximum).

Although therapeutic doses of acetaminophen may be safe for alcohol drinkers, *high* doses certainly are not. Accordingly, to alert the public to the potential risk of combining alcohol with acetaminophen, the FDA requires that acetaminophen labels bear the following statement: *Alcohol Warning: If you consume three or more alcoholic drinks every day, ask your doctor whether you should take acetaminophen or other pain relievers/fever reducers.*

71.5.4.2 Warfarin.

There is evidence that acetaminophen may increase the risk of bleeding in patients taking warfarin (an oral anticoagulant), which is surprising. Why? Because unlike NSAIDs, acetaminophen does not suppress platelet aggregation, and hence should not promote bleeding. How, then, might acetaminophen cause a problem? The best guess is that acetaminophen may inhibit warfarin metabolism, which would cause warfarin levels to rise. Although this interaction has not been proved, caution is advised. Accordingly, for patients taking more than 1 gram of acetaminophen daily for several days, responses to warfarin should be monitored closely. Occasional use of acetaminophen is not a concern.

71.5.5 Therapeutic Uses

Acetaminophen is indicated for relief of pain and fever. Because of its lack of association with Reye's syndrome, acetaminophen is preferred to NSAIDs for use by children suspected of having chickenpox or influenza. Because it does not cause GI injury, acetaminophen is preferred to NSAIDs for patients with peptic ulcer disease. In addition, acetaminophen may be a safe alternative to aspirin for patients who have experienced aspirin hypersensitivity reactions. Because of its weak anti-inflammatory actions, acetaminophen is *not* useful for treating arthritis or rheumatic fever.

71.5.6 Acute Toxicity: Liver Damage

Overdose with acetaminophen can cause severe liver injury and death. In the United States, acetaminophen overdose—intentional or unintentional—is the leading cause of acute liver failure, accounting for about 50% of all cases. Risk of liver injury is increased by fasting, chronic alcohol use, and taking more than 4 gm of acetaminophen a day.

71.5.6.1 Signs and Symptoms.

The principal feature of acetaminophen overdose is *hepatic necrosis*. Severe poisoning can progress to hepatic failure, coma, and death. Early symptoms of poisoning (nausea, vomiting, diarrhea, sweating, abdominal discomfort) belie the severity of intoxication. It is not until 48 to 72 hours after drug ingestion that overt indications of hepatic injury appear.

71.5.6.2 Treatment.

Liver damage can be minimized by giving *acetylcysteine* [Mucomyst, Acetadote], a specific antidote to acetaminophen. Acetylcysteine reduces injury by substituting for depleted glutathione in the reaction that converts the toxic metabolite of acetaminophen to its nontoxic form. When given within 8 to 10 hours of acetaminophen overdose, acetylcysteine is 100% effective at preventing severe liver injury. However, it can still provide significant protection when administered as long as 24 hours after poisoning has occurred. Acetylcysteine may be administered PO or IV.

For oral therapy, acetylcysteine is supplied in solution (100 and 200 mg/mL), sold as *Mucomyst*, and should be diluted to 50 mg/mL with water, fruit juice, or a cola beverage. Conventional treatment consists of a loading dose (140 mg/kg) followed by 17 more doses (70 mg/kg) given

every 4 hours for 72 hours. However, a recent study indicates that, for most patients, treatment can be stopped after just 20 hours. Acetylcysteine has an extremely unpleasant odor and may induce vomiting.

For intravenous therapy, acetylcysteine is supplied in solution (200 mg/mL), sold as *Acetadote*, and should be diluted in 5% dextrose. Three doses are given. The first dose—150 mg/kg (in 200 mL of 5% dextrose)—is infused over 15 minutes to 1 hour. The second dose—50 mg/kg (in 500 mL of 5% dextrose)—is infused over 4 hours. And the third dose—100 mg/kg (in 1000 mL of 5% dextrose)—is infused over 16 hours. Rarely, IV acetylcysteine causes allergic reactions (rash, itching, angioedema, bronchospasm, hypotension), most often in response to the first dose. Fortunately, these reactions tend to be mild and self-limiting, and can be minimized by infusing the initial dose slowly (over a 1-hour interval).

841

842

71.5.7 Preparations, Dosage, and Administration

71.5.7.1 Preparations.

Numerous acetaminophen-containing products are on the market, including a wide assortment of fixed-dose combinations. The drug is available in rectal suppositories and multiple oral formulations (standard tablets, chewable tablets, effervescent granules, capsules, liquids, elixirs, and solutions). Many products are available over the counter, and many others require a prescription. Why do I mention this plethora of products? Because it creates a significant risk of overdose: *Patients who don't carefully read the labels may well take two or more products that contain acetaminophen, thereby exceeding the safe dosage.* You should alert patients to this danger.

71.5.7.2 Dosage and Administration.

The recommended dosage for adults and children over 12 years is 325 to 650 mg every 4 to 6 hours, up to a maximum of 4 gm/day. *Single* doses for younger children vary with age as follows:

- Up to 3 months—40 mg
- 4 to 11 months—80 mg
- 12 to 23 months—120 mg
- 2 to 3 years—160 mg

- 4 to 5 years—240 mg
- 6 to 8 years—320 mg
- 9 to 10 years—400 mg
- 11 years—480 mg
- 12 years—640 mg

These doses can be given every 4 to 6 hours as needed, up to a maximum of five doses a day. For round-the-clock dosing, a 6-hour dosing interval should be used.

^{71.6} AHA Statement on COX Inhibitors in Chronic Pain

Because most COX inhibitors—and especially COX-2 inhibitors—increase the risk of MI and stroke, the American Heart Association recommends a stepped-care approach to their use, as discussed in a 2007 article titled *Use of Nonsteroidal Anti-inflammatory Drugs: An Update for Clinicians: A Scientific Statement from the American Heart Association*. Recommendations in the article apply specifically to managing musculoskeletal pain in patients with or at high risk of cardiovascular disease. However, the recommendations may also apply to patients who lack documented cardiovascular risk. The approach has four basic steps:

Step 1. Begin with nondrug measures. Options include physical therapy, exercise, weight loss, orthotics, and application of heat or cold.

Step 2. If nondrug measures don't work, initiate drug therapy using *acetaminophen* or *aspirin*, which do not increase cardiovascular risk. If these drugs can't control pain, an opioid or tramadol can be tried, but only short term.

Step 3. If step 2 drugs are ineffective or intolerable, try other nonselective NSAIDs, such as naproxen, ibuprofen, or a nonacetylated salicylate (eg, magnesium salicylate).

Step 4. As a *last resort*, try a selective COX-2 inhibitor (eg, celecoxib). Of all the NSAIDs, COX-2 inhibitors pose the greatest risk of cardiovascular harm, and hence are last-choice drugs for chronic pain.

Whenever drugs are employed, patients should use the lowest effective dosage for the shortest time required. During steps 2, 3, and 4, if the patient is considered at high risk of a thrombotic event, low-dose aspirin (81 mg/day) plus a PPI should be *added* to the regimen (except, of course, if high-dose aspirin is already in use).

71.6.1

KEY POINTS

- All of the drugs discussed in this chapter inhibit cyclooxygenase (COX), an enzyme that converts arachidonic acid into prostanoids (prostaglandins and related compounds).
- Cyclooxygenase has two forms, named COX-1 and COX-2.
- The cyclooxygenase inhibitors fall into two major groups: nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen (in a group by itself).
- The NSAIDs can be subdivided into two groups: (1) first-generation NSAIDs, which inhibit COX-1 *and* COX-2, and (2) second-generation NSAIDs, which selectively inhibit COX-2.
- Inhibition of COX-1 can cause gastric ulceration, renal impairment, and bleeding.
- Inhibition of COX-2 suppresses inflammation, pain, and fever, and can also cause renal impairment.
- Aspirin is the prototype of the first-generation NSAIDs.
- Aspirin has four major beneficial actions: suppression of inflammation, relief of mild to moderate pain, reduction of fever, and prevention of MI and stroke (secondary to suppressing platelet aggregation). All of these benefits result from inhibiting COX-2.
- Because aspirin inhibits COX-1 as well as COX-2, it cannot cause beneficial effects without posing a risk of gastric ulceration, bleeding, and renal impairment.
- Aspirin causes *irreversible* inhibition of cyclooxygenase. As a result, the effects of aspirin persist until cells can make more cyclooxygenase.
- Because platelets are unable to synthesize new cyclooxygenase, the antiplatelet effects of a single dose of aspirin persist for the life of the platelet (about 8 days).

- Anti-inflammatory doses of aspirin are much higher than analgesic or antipyretic doses.
- Aspirin is a useful drug for rheumatoid arthritis and other chronic inflammatory conditions.
- Aspirin is a very effective analgesic. It can be as effective as opioids for some types of postoperative pain.
- The risk of aspirin-induced gastric ulcers can be reduced by (1) testing for and eliminating *H. pylori* prior to starting therapy, and by (2) giving a proton pump inhibitor.
- Because of its antiplatelet actions, aspirin can protect against MI, stroke, and other thrombotic events. However, protection against MI in particular is limited to men and to women older than 65.

842

843

- Ibuprofen can antagonize the antiplatelet actions of aspirin, and can thereby decrease protection against MI and stroke.
- Because of its antiplatelet actions, *high-dose* aspirin should be discontinued 1 week prior to elective surgery or parturition. In most cases, *low-dose* aspirin taken to protect against thrombosis can be continued.
- Because of its antiplatelet actions, aspirin intensifies the anticoagulant response to warfarin and heparin.
- By impairing renal function, aspirin can cause sodium and water retention, edema, and elevation of blood pressure. However, adverse outcomes are likely only in patients with additional risk factors: advanced age, pre-existing renal dysfunction, hypovolemia, hypertension, hepatic cirrhosis, or heart failure. Long-term aspirin use may lead to renal papillary necrosis and other forms of renal injury.
- Because of the risk of Reye's syndrome, aspirin should be avoided by children with influenza or chickenpox.
- Use of aspirin during labor and delivery can suppress spontaneous uterine contractions, induce premature closure of the ductus arteriosus, and intensify uterine bleeding.
- Although rarely fatal in adults, aspirin poisoning may prove lethal in children.

- Aspirin can cause hypersensitivity reactions, especially in adults with asthma, rhinitis, and nasal polyps. Severe reactions (anaphylaxis) can be treated with epinephrine.
- All of the nonaspirin first-generation NSAIDs are much like aspirin itself. All of these drugs inhibit COX-1 and COX-2; they all can suppress inflammation, pain, and fever; and they all can cause gastric ulceration, renal impairment, and bleeding.
- The nonaspirin NSAIDs differ from aspirin in three important ways. First, nonaspirin NSAIDs cause *reversible* inhibition of COX, and hence their effects decline as soon as their blood levels decline. Second, although they can suppress platelet aggregation, these drugs are not used to prevent MI and stroke. Third, these drugs actually *increase* the risk of MI and stroke, and hence should be used in the lowest effective dosage for the shortest possible time.
- By inhibiting COX-2, the second-generation NSAIDs (coxibs) can suppress inflammation, pain, and fever.
- By sparing COX-1, the coxibs *may* cause less gastric ulceration than the first-generation NSAIDs.
- Coxibs do not inhibit platelet aggregation, and hence do not pose a risk of bleeding.
- Like all first-generation NSAIDs except aspirin, coxibs pose a risk of MI and stroke.
- Currently, celecoxib [Celebrex] is the only coxib on the market.
- Acetaminophen reduces pain and fever, but not inflammation.
- Acetaminophen inhibits prostaglandin synthesis in the CNS, but not in the periphery. As a result, acetaminophen differs from the NSAIDs in four ways: (1) it lacks anti-inflammatory actions, (2) does not cause gastric ulceration, (3) does not suppress platelet aggregation, and (4) does not impair renal function.
- Hepatic necrosis from acetaminophen overdose results from accumulation of a toxic metabolite.
- Chronic alcohol consumption increases the risk of liver damage from acetaminophen *overdose* (but not from therapeutic doses). Two major mechanisms are involved: induction of cytochrome P450 (which increases production of the toxic metabolite of

acetaminophen) and depletion of glutathione stores (which reduces detoxification of the metabolite).

- Acetaminophen may increase the risk of warfarin-induced bleeding by inhibiting the metabolism of warfarin.
- Acetaminophen poisoning is treated with PO or IV acetylcysteine, a drug that substitutes for depleted glutathione in the reaction that removes the toxic metabolite of acetaminophen.

71.6.2 Summary of Major Nursing Implications*

71.6... NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

71.6... First-Generation NSAIDs

Aspirin

Diclofenac

Diflunisal

Etodolac

Fenoprofen

Flurbiprofen

Ibuprofen

Indomethacin

Ketoprofen

Ketorolac

Magnesium salicylate

Meclofenamate

Mefenamic acid

Meloxicam

Nabumetone

Naproxen

Oxaprozin

Piroxicam

Salsalate

Sodium salicylate

Sulindac

Tolmetin

Second-Generation NSAIDs (Coxibs)

Celecoxib

Except where noted, the nursing implications summarized below apply to aspirin and all other NSAIDs.

843

Preadministration Assessment

Therapeutic Goal

Major indications for the NSAIDs are inflammatory disorders (eg, rheumatoid arthritis, osteoarthritis), mild to moderate pain, fever, and primary dysmenorrhea. In addition, *aspirin* is used to prevent MI and stroke. Applications of individual NSAIDs are summarized in [Table 70-5](#).

Identifying High-Risk Patients

NSAIDs are *contraindicated* for patients with a history of severe NSAID hypersensitivity and, except for aspirin, they are contraindicated for perioperative use in patients undergoing CABG surgery.

NSAIDs should be used with *extreme caution* by pregnant women and patients with peptic ulcer disease and bleeding disorders (eg, hemophilia, vitamin K deficiency, hypoprothrombinemia) and patients taking warfarin, heparin, glucocorticoids, ACE inhibitors, or ARBs. *Caution* is also needed when treating elderly patients and patients with heart failure, angina pectoris, history of MI, hypertension, hypovolemia, hepatic cirrhosis, renal dysfunction, asthma, hay fever, chronic urticaria, nasal polyps, or a history of alcoholism or heavy smoking.

NSAIDs (especially aspirin) are *contraindicated* for children with chickenpox or influenza.

Aspirin should be discontinued 1 week prior to elective surgery or the anticipated date of parturition, and should not be used in the days before or after CABG surgery. *Nonaspirin* NSAIDs should be discontinued five half-lives before elective surgery or parturition.

Celecoxib is contraindicated for patients with sulfa allergy.

71.6... Implementation: Administration

71.6... Routes

71.6... Oral.

All NSAIDs.

71.6... Intramuscular.

Ketorolac.

71.6... Rectal Suppository.

Aspirin and indomethacin.

71.6... Topical.

Diclofenac (patch and gel).

71.6... Administration

Advise patients to take NSAIDs with food, milk, or a glass of water to reduce gastric upset.

Warn patients not to crush or chew enteric-coated or sustained-release formulations.

Advise patients to discard aspirin preparations that smell of vinegar.

Advise patients using topical diclofenac to apply the gel 4 times a day and to apply a new patch twice a day.

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Gastrointestinal Effects

NSAIDs frequently cause mild GI reactions (dyspepsia, abdominal pain, nausea). **To minimize GI effects, advise patients to take NSAIDs with food, milk, or a glass of water.**

Long-term therapy, even at moderate doses, can cause gastric ulceration, perforation, and hemorrhage. Several measures can reduce risk:

- Avoid NSAIDs in patients with a recent history of peptic ulcer disease and use NSAIDs with caution in patients with other risk factors (advanced age, previous intolerance to NSAIDs, heavy cigarette smoking, history of alcoholism).
- Test for and eliminate *H. pylori* prior to starting long-term therapy.
- Give a proton pump inhibitor for prophylaxis in high-risk patients.
- Use celecoxib instead of a traditional NSAID in high-risk patients.
- **Warn patients not to consume alcohol.**
- **Instruct patients to notify the prescriber if gastric irritation is severe or persistent.**

Manage ulcers by giving an antiulcer medication (eg, H₂-receptor antagonist, proton pump inhibitor).

Bleeding

Aspirin promotes bleeding by causing irreversible suppression of platelet aggregation. *High-dose* aspirin should be discontinued 1 week prior to elective surgery or anticipated date of parturition, but need not be stopped prior to dental, dermatologic, or cataract surgery. In most cases, *low-dose* aspirin should *not* be stopped for surgical procedures; intracranial surgery is the principal exception. Exercise caution when using aspirin in

conjunction with warfarin. Avoid aspirin in patients with bleeding disorders (eg, hemophilia, vitamin K deficiency, hypoprothrombinemia).

Discontinue *ibuprofen and other nonaspirin NSAIDs* five half-lives prior to elective surgery and parturition.

The *nonacetylated salicylates*—sodium salicylate, magnesium salicylate, and salsalate—have minimal effects on platelet aggregation. Accordingly, these drugs are preferred for use in surgical patients and patients with bleeding disorders.

The risk of bleeding can be minimized by using celecoxib instead of a traditional NSAID.

71.6....

Renal Impairment

NSAIDs can cause acute renal insufficiency in elderly patients and in patients with heart failure, hypovolemia, hepatic cirrhosis, or pre-existing renal dysfunction. Keep NSAID dosages as low as possible in these patients. Monitor high-risk patients for indications of renal impairment (reduced urine output, weight gain despite diuretic therapy, rapid elevation of serum creatinine and blood urea nitrogen). Discontinue NSAIDs if these signs occur.

Prolonged NSAID therapy can cause renal papillary necrosis. Avoid prolonged NSAID use whenever possible.

71.6....

Myocardial Infarction and Stroke

Nonaspirin NSAIDs—but not aspirin itself—increase the risk of myocardial infarction and stroke. To minimize cardiovascular risk, nonaspirin NSAIDs should be used in the lowest effective dosage for the shortest time needed, and they should not be used before CABG surgery or for 14 days after. In patients with cardiovascular risk factors, use all NSAIDs (except aspirin) with caution, and use COX-2 inhibitors only as a last resort.

844

845

71.6....

Hypersensitivity Reactions

Hypersensitivity reactions are most likely in adults with a history of asthma, rhinitis, and nasal polyps. Use NSAIDs with caution in these patients. If a severe hypersensitivity reaction occurs, parenteral epinephrine is the treatment of choice. Avoid NSAIDs in patients with a history of NSAID hypersensitivity.

71.6....

Salicylism

Aspirin and other salicylates can cause salicylism. **Educate patients about manifestations of salicylism (tinnitus, sweating, headache, dizziness), and advise them to notify the prescriber if these occur.** Aspirin should be withheld until symptoms subside, after which therapy can resume but at a slightly reduced dosage.

71.6....

Reye's Syndrome

Use of NSAIDs (especially aspirin) by children with chickenpox or influenza may precipitate Reye's syndrome. **Advise parents to avoid aspirin in these children and use acetaminophen instead.**

71.6....

Use in Pregnancy

NSAIDs can cause maternal anemia and can prolong labor. In addition, they can promote premature closure of the ductus arteriosus. NSAIDs should be avoided by expectant mothers unless the potential benefits outweigh the risks. If NSAIDs are employed during pregnancy, they should be discontinued at least five half-lives before the anticipated day of delivery.

71.6....

Sulfonamide Allergy

Celecoxib can cause severe allergic reactions in patients with sulfa allergy, and hence must not be given to these people.

71.6....

Minimizing Adverse Interactions

71.6....

Anticoagulants

NSAIDs can increase the risk of spontaneous bleeding in patients taking warfarin or heparin. Monitor patients for signs of bleeding.

71.6....

Glucocorticoids

Glucocorticoids increase the risk of gastric ulceration in patients taking NSAIDs. Prophylactic therapy with a proton pump inhibitor can decrease the risk.

71.6....

Alcohol

Alcohol increases the risk of gastric ulceration from NSAIDs. Exercise caution.

71.6....

Aspirin-Ibuprofen Interaction

Ibuprofen can block the antiplatelet effects of aspirin. Patients taking low-dose aspirin to protect against thrombosis should avoid ibuprofen.

71.6....

ACE Inhibitors and ARBs

These drugs increase the risk of acute renal failure in patients taking NSAIDs. If possible, avoid all NSAIDs—*except low-dose aspirin*—in patients taking ACE inhibitors or ARBs.

71.6....

Managing Aspirin Toxicity

Aspirin poisoning is an acute medical emergency that requires hospitalization. Treatment is largely supportive and consists of external cooling (eg, sponging with tepid water), infusion of fluids (to correct dehydration and electrolyte loss), infusion of bicarbonate (to reverse acidosis and promote renal excretion of salicylates), and mechanical ventilation (if respiration is severely depressed). Absorption of aspirin can be reduced by gastric lavage and by giving activated charcoal. If necessary, hemodialysis or peritoneal dialysis can accelerate salicylate removal.

71.6....

ACETAMINOPHEN

71.6....

Preadministration Assessment

71.6....

Therapeutic Goal

Acetaminophen is indicated for relief of pain and suppression of fever. The drug is preferred to NSAIDs for use in children with chickenpox or influenza, and for all patients with peptic ulcer disease.

71.6....

Identifying High-Risk Patients

Use with *caution* in chronic alcohol abusers, patients who consume moderate amounts of alcohol daily, and patients taking warfarin.

71.6... Implementation: Administration

71.6... Routes

Oral, rectal.

71.6... Administration

Do not exceed recommended doses.

71.6... Ongoing Evaluation and Interventions

71.6... Minimizing Adverse Effects

Acetaminophen is largely devoid of significant adverse effects at usual therapeutic doses, except possibly in people who routinely consume alcohol. Overdose can cause liver damage (see below).

71.6... Hypertension

Taking at least 500 mg of acetaminophen per day is associated with an increased risk of hypertension in *women*, although a direct causal relationship has not been established. Nonetheless, prudence dictates monitoring blood pressure in women who take acetaminophen each day.

71.6... Minimizing Adverse Interactions

71.6... Alcohol

Chronic alcohol consumption increases the risk of liver injury from *excessive* doses of acetaminophen, but probably not from *therapeutic* doses.

71.6... Warfarin

Taking acetaminophen for several days may increase the risk of bleeding in patients on warfarin. Monitor warfarin effects closely.

71.6....

Managing Toxicity

Overdose can cause hepatic necrosis. Acetylcysteine, given PO or IV, is a specific antidote. Oral acetylcysteine has an extremely unpleasant odor and may induce vomiting. If vomiting interferes with oral administration, there are two options: give acetylcysteine intravenously or through an oroduodenal tube.

* Patient education information is highlighted as **blue text**.

⁷²CHAPTER 71 Glucocorticoids in Nonendocrine Diseases

The glucocorticoid drugs (eg, cortisone, prednisone), also known as *corticosteroids*, are nearly identical to the glucose-regulating steroids produced by the adrenal cortex. Accordingly, we can look on the glucocorticoids as having two kinds of effects: physiologic and pharmacologic. *Physiologic* effects, such as modulation of glucose metabolism, are elicited by *low* doses of glucocorticoids. In contrast, *pharmacologic* effects (eg, suppression of inflammation) require *high* doses.

As implied by the chapter title, glucocorticoids have both endocrine and nonendocrine applications. In low (physiologic) doses, glucocorticoids are used to treat adrenocortical insufficiency. In high (pharmacologic) doses, glucocorticoids are used to treat inflammatory disorders (eg, asthma, rheumatoid arthritis) and certain cancers and to suppress immune responses in organ transplant recipients. The endocrine applications of the glucocorticoids are discussed in [Chapter 59](#). Nonendocrine uses are discussed here.

Toxicity of the glucocorticoids can be severe and is determined by the pattern of drug use. Glucocorticoids are devoid of toxicity when used in physiologic doses. However, when taken in pharmacologic doses, especially for extended periods, glucocorticoids can cause an array of serious adverse effects.

All of the glucocorticoid drugs can elicit the same spectrum of therapeutic effects. Differences among individual agents pertain to time course and side effects. Because the similarities among these drugs are much more striking than the differences, we will forego our practice of focusing on a prototypic agent. Instead, we will discuss the glucocorticoids as a group.

^{72.1} REVIEW OF GLUCOCORTICOID PHYSIOLOGY

^{72.1.1} Physiologic Effects

Physiologic responses can be elicited with low doses of glucocorticoids. At higher doses, these effects are simply more intense. When glucocorticoids are used to treat nonendocrine disorders, physiologic responses occur as side effects. Physiologic effects are discussed at length in [Chapter 59](#), and hence discussion here is brief.

^{72.1.1.1} Metabolic Effects.

Glucocorticoids influence the metabolism of carbohydrates, proteins, and fats. The principal effect on carbohydrate metabolism is elevation of blood glucose. This is accomplished by promoting synthesis of glucose from amino acids, reducing peripheral glucose utilization, and

reducing glucose uptake by muscle and adipose tissue. Glucocorticoids also promote storage of glucose in the form of glycogen.

Glucocorticoids have an unfavorable impact on protein metabolism. These agents suppress synthesis of proteins from amino acids and divert amino acids for production of glucose. These actions can reduce muscle mass, decrease the protein matrix of bone, and cause thinning of the skin. Nitrogen balance becomes negative.

The most consistent effect of glucocorticoids on fat metabolism is stimulation of lipolysis (fat breakdown). Long-term, high-dose therapy can cause fat redistribution, resulting in the potbelly, “moon face,” and “buffalo hump” that characterize Cushing's syndrome.

72.1.1.2 Cardiovascular Effects.

Glucocorticoids are required to maintain the functional integrity of the vascular system. When levels of endogenous glucocorticoids are low, capillaries become more permeable, vasoconstriction is suppressed, and blood pressure falls. Glucocorticoids *increase* the number of circulating red blood cells and polymorphonuclear leukocytes, and *decrease* counts of lymphocytes, eosinophils, basophils, and monocytes.

72.1.1.3 Effects During Stress.

At times of physiologic stress (eg, pain, surgery, infection, trauma, hypovolemia), the adrenals secrete large quantities of glucocorticoids and epinephrine. Working together, these hormones help maintain blood pressure and blood glucose levels. If glucocorticoid release is insufficient, hypotension and hypoglycemia will occur. If the stress is especially severe, glucocorticoid insufficiency can result in circulatory failure and death.

846

TABLE 71-1 Systemic Glucocorticoids: Half-Lives, Relative Potencies, and Equivalent Doses

Drug	Biologic Half-Life (hr)	Relative Mineralocorticoid Potency [*]	Relative Glucocorticoid (Anti-inflammatory) Potency [†]	Equivalent Anti-inflammatory Dose (mg) [‡]
Short Acting				
Cortisone	8–12	2	0.8	25
Hydrocortisone	8–12	2	1	20
Intermediate Acting				
Prednisone	18–36	1	4	5
Prednisolone	18–36	1	4	5
Methylprednisolone	18–36	0	5	4
Triamcinolone	18–36	0	5	4
Long Acting				
Betamethasone	36–54	0	20–30	0.75
Dexamethasone	36–54	0	20–30	0.75

* Relative mineralocorticoid activity (sodium and water retention; potassium depletion): 0 = very low, 1 = moderate, 2 = high.

† Glucocorticoid potency values are relative to the potency of hydrocortisone.

‡ Approximate *oral* or *intravenous* dose needed to produce equivalent anti-inflammatory effects.

72.1.1.4 Effects on Water and Electrolytes.

To varying degrees, individual glucocorticoids can exert actions like those of aldosterone, the major mineralocorticoid released by the adrenals. Accordingly, glucocorticoids can act on the kidney to promote retention of sodium and water while increasing urinary excretion of potassium. The net result is hypernatremia, hypokalemia, and edema. Fortunately, most of the glucocorticoids employed as drugs have very low mineralocorticoid activity ([Table 71-1](#)).

72.1.1.5 Respiratory System in Neonates.

During labor and delivery, the adrenals of the full-term infant release a burst of glucocorticoids, which act to hasten maturation of the lungs. In the premature infant, production of glucocorticoids is low, resulting in a high incidence of respiratory distress syndrome.

72.1.2 Control of Synthesis and Secretion

Synthesis and release of glucocorticoids are regulated by a negative feedback loop. The principal components of the loop are the hypothalamus, anterior pituitary, and adrenal cortex ([Fig. 71-1](#)). The loop is turned on when stress or some other stimulus from the central nervous system acts on the hypothalamus to cause release of corticotropin-releasing hormone (CRH). CRH then stimulates the pituitary to release adrenocorticotrophic hormone (ACTH), which in turn acts on the adrenal cortex to promote synthesis and release of cortisol (the principal endogenous glucocorticoid). Cortisol has two basic effects: first, it stimulates physiologic responses; second, it acts on the hypothalamus and pituitary to suppress further release of CRH and ACTH. By inhibiting release of CRH and ACTH, cortisol suppresses its own production. As a result, this negative feedback loop keeps glucocorticoid levels within an appropriate range. When glucocorticoids are administered chronically in large doses, the feedback loop remains continuously suppressed. As discussed later, persistent suppression can be dangerous.

72.2 PHARMACOLOGY OF THE GLUCOCORTICOIDS

72.2.1 Molecular Mechanism of Action

Mechanistically, glucocorticoids differ from most drugs in two ways: (1) glucocorticoid receptors are located *inside* the cell, rather than on the cell surface; and (2) glucocorticoids modulate the production of regulatory proteins, rather than the activity of signaling pathways.

Here's how they do it. First, glucocorticoids penetrate the cell membrane, and then bind with receptors in the *cytoplasm*, thereby converting the receptor from an inactive form to an active form. Next, the receptor-steroid complex migrates to the cell *nucleus*, where it binds to chromatin in DNA, thereby altering the activity of target genes. In most cases, activity of the target gene is increased, causing increased transcription of messenger RNA molecules that code for specific regulatory proteins. However, in some cases, activity of the target gene is suppressed, and hence synthesis of certain regulatory proteins declines.

72.2.2 Pharmacologic Effects

When administered in the high doses employed to treat nonendocrine disorders, glucocorticoids produce anti-inflammatory and immunosuppressive effects—effects not seen at physiologic doses. Of course, these high doses also produce the physiologic effects seen at low doses.

72.2.2.1 Effects on Metabolism and Electrolytes

The effects of high-dose therapy on metabolism and electrolytes are like those seen with physiologic doses—but are more intense. Hence, with high doses, glucose levels rise, protein synthesis is suppressed, and fat deposits are mobilized. As noted, most glucocorticoids have very little mineralocorticoid activity. Accordingly, these drugs do not usually induce sig

847

848

Figure 71-1 Feedback regulation of glucocorticoid synthesis and secretion.(ACTH = adrenocorticotrophic hormone, CNS = central nervous system, CRH = corticotropin-releasing hormone.)

nificant sodium retention or potassium loss. However, these effects do occur in some patients and can be hazardous. In all patients, high-dose therapy can inhibit intestinal absorption of calcium, an effect not seen at physiologic doses.

72.2.2.2 Anti-inflammatory and Immunosuppressant Effects

The major clinical applications of the glucocorticoids stem from their ability to suppress immune responses and inflammation. Effects on the immune system and inflammation are interrelated, and hence we consider them together.

Before discussing the actions of glucocorticoids, we need to review the process of inflammation. Characteristic symptoms of inflammation are pain, swelling, redness, and warmth. These are initiated by chemical mediators (prostaglandins, histamine, leukotrienes) and are amplified by the actions of lymphocytes and phagocytic cells (neutrophils and macrophages). Prostaglandins and histamine promote several symptoms of inflammation—swelling, redness, and warmth—by causing vasodilation and increasing capillary permeability. Prostaglandins and histamine contribute to pain: histamine stimulates pain receptors directly; prostaglandins sensitize pain receptors to stimulation by histamine and other mediators. Neutrophils and macrophages heighten inflammation by releasing lysosomal enzymes (which cause tissue injury). Lymphocytes, which are important elements of the immune system, intensify inflammation by (1) causing direct cell injury and (2) promoting formation of antibodies that help perpetuate the inflammatory response.

Glucocorticoids act through several mechanisms to interrupt the inflammatory processes. These drugs can inhibit synthesis of chemical mediators (prostaglandins, leukotrienes, histamine) and thereby reduce swelling, warmth, redness, and pain. In addition, they suppress infiltration of phagocytes. Hence, damage from lysosomal enzymes is averted. Lastly, glucocorticoids suppress proliferation of lymphocytes, and thereby reduce the immune component of inflammation.

It is important to appreciate that the mechanisms by which glucocorticoids suppress inflammation are more diverse than the mechanisms by which nonsteroidal anti-inflammatory drugs (NSAIDs) act. As discussed in [Chapter 70](#), NSAIDs suppress inflammation primarily by inhibiting prostaglandin production. The glucocorticoids share this mechanism and act in other ways too. Because they act by multiple mechanisms, glucocorticoids have greater anti-inflammatory effects than do NSAIDs.

72.2.3 Pharmacokinetics

72.2.3.1 Absorption.

The rate of glucocorticoid absorption depends on the route of administration and the specific glucocorticoid. With oral administration, absorption of all glucocorticoids is rapid and nearly complete. Following IM injection, absorption is rapid with two types of glucocorticoid esters (sodium phosphates and sodium succinates) and relatively slow with other derivatives (eg, acetates, acetonides). Absorption from local sites of injection (eg, intra-articular, intrasynovial) is slower than from IM sites.

72.2.3.2 Duration of Action.

Duration depends on dosage, route, and drug solubility. For glucocorticoids administered orally or IV, duration is determined largely by biologic half-life (see [Table 71-1](#)). With IM administration, duration is a function of water solubility: Highly soluble preparations have a shorter duration than less soluble preparations. For locally administered glucocorticoids, duration is determined by solubility and by the specific site of administration.

72.2.3.3 Metabolism and Excretion.

Glucocorticoids are metabolized primarily by the liver. As a rule, the resulting metabolites are inactive. Metabolite excretion is renal.

72.2.4 Therapeutic Uses in Nonendocrine Disorders

Glucocorticoids are used to treat endocrine disorders and nonendocrine disorders. Endocrine disorders (eg, Addison's disease, acute adrenal insufficiency) can be managed with low-dose therapy and are considered in [Chapter 59](#). Nonendocrine applications, which require much higher doses, are discussed here. Because prolonged, high-dose therapy can produce serious adverse effects, the potential benefits of treatment must be weighed carefully against the very real risks.

72.2.4.1 Rheumatoid Arthritis.

Glucocorticoids are indicated for adjunctive treatment of acute exacerbations of rheumatoid arthritis. These drugs can reduce inflammation and pain, but do not alter the course of the disease. Because of the risk of serious complications, prolonged systemic use should be avoided.

When arthritis is limited to just a few joints, intra-articular injections should be employed. Local injections can be highly effective and cause less toxicity than systemic therapy. Frequently, reductions in pain and inflammation may be so dramatic as to prompt vigorous use of joints that were previously immobile. Since excessive use of diseased joints can cause injury, patients should be warned against overactivity, even though symptoms have eased.

848

849

The use of glucocorticoids in rheumatoid arthritis is discussed further in [Chapter 72](#).

72.2.4.2 Systemic Lupus Erythematosus.

Systemic lupus erythematosus (SLE) is a chronic disease similar in many ways to rheumatoid arthritis. However, in SLE, inflammation is not limited to joints. Rather, it occurs throughout the body. Symptoms frequently include pleuritis, pericarditis, and nephritis. A severe episode can be fatal. Fortunately, manifestations of SLE can usually be controlled with prompt and aggressive glucocorticoid therapy.

72.2.4.3 Inflammatory Bowel Disease.

Glucocorticoids are used to treat severe cases of ulcerative colitis and Crohn's disease, the two most common forms of inflammatory bowel disease. Administration may be oral or intravenous. Glucocorticoid therapy of these disorders is considered further in [Chapter 79](#).

72.2.4.4 Miscellaneous Inflammatory Disorders.

Glucocorticoids are useful in a variety of inflammatory disorders in addition to those discussed above. Conditions that respond include *bursitis*, *tendinitis*, *synovitis*, *osteoarthritis*, *gouty arthritis*, and *inflammatory disorders of the eye*.

72.2.4.5 Allergic Conditions.

Glucocorticoids can control symptoms of allergic reactions. Responsive conditions include allergic rhinitis (see [Chapter 76](#)), bee stings, and drug-induced allergies. Because glucocorticoid responses are delayed, these drugs have little value as acute therapy for severe allergic reactions (eg, anaphylaxis). For life-threatening allergic reactions, epinephrine is the treatment of choice.

72.2.4.6 Asthma.

Glucocorticoids are the most effective antiasthma agents available. For treatment of asthma, they may be administered orally or by inhalation. Because oral therapy can be associated with

serious toxicity, it should be reserved for patients who have failed to respond to safer medications (eg, beta₂-adrenergic agonists, cromolyn sodium). Fortunately, adverse effects are minimal when glucocorticoids are inhaled. The use of glucocorticoids in asthma is discussed at length in [Chapter 75](#).

72.2.4.7 Dermatologic Disorders.

Glucocorticoids are beneficial in a wide variety of skin diseases, including pemphigus, psoriasis, mycosis fungoides, seborrheic dermatitis, contact dermatitis, and exfoliative dermatitis. For mild disease, topical administration is usually adequate. For severe disorders, systemic therapy may be needed. It should be noted that topical glucocorticoids can be absorbed in amounts sufficient to produce systemic toxicity. Topical therapy is discussed further in [Chapter 104](#).

72.2.4.8 Neoplasms.

Glucocorticoids are used in conjunction with other anticancer agents to treat acute lymphocytic leukemia, Hodgkin's disease, and non-Hodgkin's lymphomas. Benefits derive from the direct toxicity of glucocorticoids to malignant lymphocytes. Treatment kills lymphoid cells and causes regression of lymphatic tissue. The use of glucocorticoids to treat cancers is discussed further in [Chapter 102](#).

72.2.4.9 Suppression of Allograft Rejection.

Glucocorticoids, together with other immunosuppressant agents, are used to prevent rejection of organ transplants. Glucocorticoids are initiated at the time of surgery and continued indefinitely. The use of glucocorticoids for immunosuppression is discussed further in [Chapter 68](#).

72.2.4.10 Prevention of Respiratory Distress Syndrome in Preterm Infants.

Preterm infants are at high risk of respiratory distress syndrome, because their adrenals cannot produce the glucocorticoids needed for lung maturation. When preterm delivery is imminent, injecting the mother with glucocorticoids (usually dexamethasone or betamethasone) reduces the risk of respiratory distress. Steroids may also reduce the incidence of intraventricular hemorrhage and necrotizing enterocolitis (inflammation of the small intestine and colon). Antenatal use of glucocorticoids is discussed further in [Chapter 106](#).

72.2.5 Adverse Effects

The adverse effects discussed below occur in response to *pharmacologic* doses of glucocorticoids. The intensity of these effects increases with dosage size and treatment duration. These toxicities are not seen when dosage is physiologic. Furthermore, most are not seen when treatment is brief (a few days or less), even when doses are high.

72.2.5.1 Adrenal Insufficiency.

Pharmacologic doses of glucocorticoids can suppress production of glucocorticoids by the adrenals, resulting in adrenal insufficiency. The mechanism, consequences, and management of adrenal insufficiency are discussed later.

72.2.5.2 Osteoporosis.

72.2.5.2.1 Development.

Osteoporosis with resultant fractures is a frequent and serious complication of glucocorticoid therapy. In most patients receiving glucocorticoids long term, bone mineral density declines substantially, and over 25% sustain osteoporotic fractures. The ribs and vertebrae are affected most. In some patients, vertebral compression fractures occur within weeks of beginning glucocorticoid use. Osteoporosis is most likely with systemic therapy. In contrast, osteoporosis is uncommon when glucocorticoids are inhaled or administered topically. Patients should be observed for signs of compression fractures (back and neck pain) and for indications of fractures in other bones.

How do glucocorticoids cause bone loss? The most important mechanism is suppression of bone formation by osteoblasts. In addition, glucocorticoids accelerate bone resorption by osteoclasts. Also, these drugs reduce intestinal absorption of calcium, causing hypocalcemia. In response to hypocalcemia, release of parathyroid hormone increases, which increases mobilization of calcium from bone.

72.2.5.2.2 Management.

Several measures can greatly reduce development of osteoporosis and subsequent fractures. Prior to glucocorticoid treatment, bone mineral density of the lumbar spine should be measured. This will identify patients at highest risk and provide a baseline for evaluating bone loss during treatment. When appropriate, glucocorticoids should be administered topically or by inhalation (because less bone loss occurs with these routes than with systemic therapy).

Drugs can help reduce bone loss. All patients should receive *calcium* and *vitamin D* supplements. Sodium restriction combined with a thiazide diuretic can enhance intestinal absorption of calcium and can decrease urinary excretion of calcium. There is solid evidence that a *bisphosphonate* (eg, alendronate, etidronate) can prevent glucocorticoid-induced bone loss. How? By inhibiting osteoclastic bone resorption. *Calcitonin*, which also inhibits osteoclasts, is another option. For patients with significant bone loss, *teriparatide* may be preferred the preferred treatment. Why? Because, unlike bisphosphonates and calcitonin, which only prevent bone *resorption*, teriparatide actively promotes new bone *formation*. In postmenopausal women, *estrogen* therapy is an effective way to reduce bone loss. However, as discussed in [Chapter 60](#), the risks of estrogen therapy generally outweigh the benefits. The roles of calcium, vitamin D, bisphosphonates, calcitonin, teriparatide, and estrogen in the prophylaxis and treatment of osteoporosis are discussed fully in [Chapter 74](#).

849

850

72.2.5.3 Infection.

By suppressing host defenses (immune responses and phagocytic activity of neutrophils and macrophages), glucocorticoids can increase susceptibility to infection. The risk of acquiring a new infection is increased, as is the risk of reactivating a latent infection (eg, tuberculosis). In addition, since suppression of both the immune system and neutrophils reduces inflammation and other manifestations of infection, a fulminant infection may develop without detection. Hence, not only do glucocorticoids increase susceptibility to infection, they can mask the presence of an infection as it progresses. To minimize acquisition of infection, patients should avoid close contact with people who have a communicable disease. If a significant infection occurs, glucocorticoids should be continued only if absolutely necessary, and then only in combination with appropriate antimicrobial or antifungal therapy.

One infection—known as PCP (for *Pneumocystis pneumonia*)—deserves special mention. The causative organism is *Pneumocystis jiroveci* (formerly thought to be *Pneumocystis carinii*). PCP occurs with alarming frequency in people receiving high doses of glucocorticoids (not just in people with AIDS, among whom PCP is the most common opportunistic infection). Accordingly, it has been suggested that PCP prophylaxis be considered for all people taking glucocorticoids in high doses.

72.2.5.4 Glucose Intolerance.

Because of their effects on glucose production and utilization, glucocorticoids can increase plasma glucose levels, thereby causing hyperglycemia and glycosuria. Patients with diabetes

may need to reduce caloric intake or increase the dosage of hypoglycemic medication (insulin or an oral agent). For patients with normal pancreatic function, significant elevation of blood glucose is unlikely. However, since glucocorticoids can unmask latent diabetes, nondiabetics should undergo periodic evaluation of blood glucose levels.

72.2.5.5 Myopathy.

High-dose glucocorticoid therapy can cause myopathy, manifesting as muscle weakness. The proximal muscles of the arms and legs are affected most. Damage to muscle may be sufficient to prevent ambulation. If myopathy develops, glucocorticoid dosage should be reduced. Myopathy then gradually resolves over several months.

72.2.5.6 Fluid and Electrolyte Disturbance.

Because of their mineralocorticoid activity, glucocorticoids can cause sodium and water retention and potassium loss. Retention of water and sodium can cause hypertension and edema. Hypokalemia can predispose to dysrhythmias and toxicity from digitalis. Fortunately, most of the glucocorticoids in current use have minimal mineralocorticoid activity (see [Table 71-1](#)). Hence, serious fluid and electrolyte disturbance is rare. The risk of fluid and electrolyte disturbance can be reduced by (1) using glucocorticoids that have low mineralocorticoid activity, (2) restricting sodium intake, and (3) taking potassium supplements or consuming potassium-rich foods (eg, potatoes, bananas, citrus fruits). Patients should be informed about signs of fluid retention (eg, weight gain, swelling of the lower extremities) and advised to contact the prescriber if these develop. Patients should also be alert for signs of hypokalemia (eg, muscle weakness or fatigue, irregular pulse).

72.2.5.7 Growth Retardation.

Glucocorticoids can suppress growth in children. Growth retardation is probably the result of reduced DNA synthesis and decreased cell division. To assess effects on growth, height and weight should be measured at regular intervals. Growth suppression can be minimized with alternate-day therapy. This dosing schedule is discussed below.

72.2.5.8 Psychologic Disturbances.

Rarely, glucocorticoids have caused hallucinations, mood changes (depression, euphoria, mania), and other psychologic disturbances. These effects are related more to dosage size than to duration of treatment, and can occur within the first few days of treatment. Previous psychiatric illness does not seem to predispose patients to adverse psychologic reactions.

Conversely, a history of good mental health does confer protection from psychologic disturbance.

72.2.5.9 Cataracts and Glaucoma.

Cataracts are a common complication of long-term glucocorticoid therapy. Risk factors are in dispute; cataract development may be related to age, dosage, or individual susceptibility. To facilitate early detection, patients should undergo an eye exam every 6 months. Also, patients should be advised to contact the prescriber if vision becomes cloudy or blurred.

Oral glucocorticoids can cause open-angle glaucoma. Onset of ocular hypertension develops rapidly and reverses within 2 weeks of glucocorticoid cessation.

72.2.5.10 Peptic Ulcer Disease.

Although glucocorticoids have actions that could lead to peptic ulcer disease, whether they actually cause GI ulceration is controversial. By inhibiting prostaglandin synthesis, glucocorticoids can augment secretion of gastric acid and pepsin, inhibit production of cytoprotective mucus, and reduce gastric mucosal blood flow. These actions predispose to GI ulceration. Making matters worse, glucocorticoids can decrease gastric pain, thereby masking ulcer development. As a result, perforation and hemorrhage can occur without warning. The risk of ulceration is increased by concurrent use of other ulcerogenic drugs, such as aspirin and other NSAIDs. To provide early detection of ulcer formation, stools should be periodically checked for occult blood. Patients should be instructed to notify the prescriber if feces become black and tarry. If GI ulceration occurs, glucocorticoids should be slowly withdrawn (unless their continued use is considered essential to support life). Treatment with antiulcer medication is indicated.

72.2.5.11 Iatrogenic Cushing's Syndrome.

Long-term glucocorticoid therapy can induce a cushingoid syndrome with symptoms identical to those of naturally occurring Cushing's syndrome. Prominent symptoms are hyperglycemia, glycosuria, fluid and electrolyte disturbances, osteoporosis, muscle weakness, cutaneous striae, and lowered resistance to infection. Redistribution of fat produces a potbelly, “moon face,” and “buffalo hump.”

72.2.6 Use in Pregnancy and Lactation

72.2.6.1 Pregnancy.

Glucocorticoids can cross the placenta and affect the developing fetus. Animal studies indicate an increased incidence of cleft palate, spontaneous abortion, and low birth weight. No adequate studies of these effects have been done in humans. Prolonged therapy with very large doses can cause fetal adrenal hypoplasia. Therefore, when large doses have been employed, the infant should be assessed for adrenal sufficiency and given replacement therapy if indicated.

850

Whenever glucocorticoids are to be used during pregnancy, the benefits must be carefully weighed against the potential fetal risk.

851

72.2.6.2 Lactation.

Glucocorticoids enter breast milk. When physiologic doses or low pharmacologic doses are used, the concentration achieved in milk is probably too low to affect the nursing infant. However, when large pharmacologic doses are employed (eg, doses greater than 5 mg/day of prednisone or its equivalent), the amount ingested by the infant may be sufficient to cause growth retardation and other adverse effects. Consequently, women receiving high-dose glucocorticoid therapy should be warned against breast-feeding.

72.2.7 Drug Interactions

72.2.7.1 Interactions Related to Potassium Loss.

As noted, glucocorticoids can increase urinary loss of potassium, and can thereby induce hypokalemia. Consequently, glucocorticoids must be used with caution when combined with *digoxin* (because hypokalemia increases the risk of digoxin-induced dysrhythmias) and when combined with *thiazide* or *loop diuretics* (because these potassium-depleting diuretics will increase the risk of hypokalemia). When glucocorticoids are given together with any of the above drugs, it is advisable to monitor plasma potassium levels and be alert for signs of cardiotoxicity.

72.2.7.2 Nonsteroidal Anti-inflammatory Drugs.

NSAIDs have the same effects on the gastrointestinal tract as do glucocorticoids. Accordingly, concurrent use of these agents increases the risk of ulceration.

72.2.7.3 Insulin and Oral Hypoglycemics.

As noted, glucocorticoids promote hyperglycemia. To maintain glycemic control, diabetic patients may require increased doses of a glucose-lowering drug (insulin or an oral hypoglycemic agent).

72.2.7.4 Vaccines.

Because of their immunosuppressant actions, glucocorticoids can decrease antibody responses to vaccines. Furthermore, if a live virus vaccine is employed, there is an increased risk of developing viral disease. Accordingly, attempts at immunization should not be made while glucocorticoids are being used.

72.2.8 Summary of Precautions and Contraindications

72.2.8.1 Contraindications.

Glucocorticoids are contraindicated for patients with *systemic fungal infections* and for those receiving *live virus vaccines*.

72.2.8.2 Precautions.

Glucocorticoids must be used with caution in *pediatric patients* and in *women who are pregnant or breast-feeding*. Caution is also required in patients with *hypertension, heart failure, renal impairment, esophagitis, gastritis, peptic ulcer disease, myasthenia gravis, diabetes mellitus, osteoporosis, and infections that are resistant to treatment*. In addition, caution is required during concurrent therapy with *potassium-depleting diuretics, digoxin, insulin, oral hypoglycemics, and NSAIDs*.

72.2.9 Adrenal Suppression

72.2.9.1 Development of Adrenal Suppression.

Like the naturally occurring glucocorticoids (eg, cortisol), the glucocorticoids that we administer as drugs suppress release of CRH from the hypothalamus and ACTH from the anterior pituitary. By doing so, exogenous glucocorticoids inhibit the synthesis and release of endogenous glucocorticoids by the adrenals. During long-term therapy, the pituitary loses much of its ability to manufacture ACTH and, in response to the prolonged absence of ACTH, the adrenals atrophy and lose their ability to synthesize cortisol and other glucocorticoids. As a

result, when prolonged glucocorticoid therapy is discontinued, there is a period during which the adrenals are unable to produce glucocorticoids. The time needed for adrenal recovery is highly variable: It may be as short as 5 days or as long as a year. The extent of adrenal suppression and the time required for recovery are determined primarily by the duration of glucocorticoid use; dosage size is less important. Development of adrenal suppression can be minimized through alternate-day dosing (see below).

72.2.9.2 Adrenal Suppression and Physiologic Stress.

Because of adrenal suppression, patients taking glucocorticoids long term require increased doses at times of stress. Recall that, when stress occurs, the adrenals normally secrete large amounts of glucocorticoids. If the stress is sufficiently severe (eg, trauma, surgery), these glucocorticoids are essential for supporting life. Accordingly, *it is imperative that patients receiving long-term glucocorticoid therapy be given increased doses at times of stress* (unless the dosage is already very high). Furthermore, *once glucocorticoid use has ceased, supplemental doses are required whenever stress occurs until recovery of adrenal function is complete*. To ensure appropriate care in emergencies, patients should carry an identification card or bracelet to inform emergency personnel of their glucocorticoid needs. In addition, patients should always have an emergency supply of glucocorticoids on hand.

72.2.9.3 Glucocorticoid Withdrawal.

Withdrawal of glucocorticoids should be done slowly. The withdrawal schedule is determined by the degree of adrenal suppression. A representative schedule is as follows: (1) taper the dosage to a physiologic range over 7 days; (2) switch from multiple daily doses to single doses administered each morning; (3) taper the dosage to 50% of physiologic values over the next month; and (4) monitor for production of endogenous cortisol and, when basal levels have returned to normal, cease routine steroid administration (but be prepared to give supplemental glucocorticoids at times of stress).

In addition to unmasking adrenal insufficiency, stopping glucocorticoids may produce a withdrawal syndrome. Symptoms include hypotension, hypoglycemia, myalgia, arthralgia, and fatigue. In patients being treated for arthritis and certain other disorders, these symptoms may be confused with return of the underlying disease. Discomfort of withdrawal can be minimized by gradual dosage reduction and by concurrent treatment with NSAIDs.

72.2.10 Preparations and Routes of Administration

72.2.10.1 Preparations

The glucocorticoids employed clinically include hydrocortisone (cortisol) and synthetic derivatives of hydrocortisone. Individual glucocorticoids differ with respect to (1) biologic half-life, (2) mineralocorticoid potency, and (3) glucocorticoid (anti-inflammatory) potency (see [Table 71-1](#)).

851

852

TABLE 71-2 Glucocorticoid Routes of Administration*

* Glucocorticoids for topical, inhalational, and intranasal use are listed in [Tables 104-1, 75-3, and 76-3](#), respectively.

† IA = intra-articular, IB = intrabursal, IL = intralesional, IM = intramuscular, IS = intrasynovial, IV = intravenous, PO = oral, ST = soft tissue, SubQ = subcutaneous.

The term *biologic half-life* refers to the time required for glucocorticoids to leave body tissues. In most cases, these drugs are cleared from tissues more slowly than from the blood. Hence, the biologic half-life is usually longer than the plasma half-life. When glucocorticoids are administered by mouth or by IV injection, it is the biologic half-life, and not the plasma half-life, that determines duration of action. Because of differences in their biologic half-lives, individual glucocorticoids can be classified as short acting, intermediate acting, or long acting (see [Table 71-1](#)).

Glucocorticoids with high *mineralocorticoid potency* (cortisone, hydrocortisone) can cause significant retention of sodium and water, coupled with depletion of potassium. These effects can be especially hazardous for patients with hypertension or heart failure and for those taking digoxin. Because of the potential dangers of sodium retention and potassium loss, glucocorticoids with high mineralocorticoid activity should not be administered systemically for long periods.

The differences in *glucocorticoid potency* summarized in [Table 71-1](#) are reflected in the doses required to produce anti-inflammatory effects—not mineralocorticoid effects. As with other drugs, potency is relatively unimportant. However, it is important to appreciate that, in order to produce equivalent therapeutic effects, dosages for some glucocorticoids must be much larger than for others.

72.2.10.2 Routes of Administration

Glucocorticoids can be administered *orally*, *parenterally* (IV, IM, subQ), *topically*, and *intranasally* and by *local injection* (eg, intra-articular, intralesional) or *inhalation*. Topical application is used for dermatologic disorders (see [Chapter 104](#)), inhalation therapy is used for asthma (see [Chapter 75](#)), and intranasal therapy is used for allergic rhinitis (see [Chapter 76](#)). Since local therapy (topical, intranasal, inhalation, local injection) minimizes systemic toxicity, this form of treatment is preferred to systemic therapy (oral, parenteral). When systemic effects are needed, oral administration is preferred to parenteral. It is important to note that, even when glucocorticoids are administered for local effects, absorption can be sufficient to produce systemic effects. That is, local administration does not eliminate the risk of toxicity.

Individual glucocorticoids are available as various esters (eg, acetate, sodium phosphate). When glucocorticoids are administered by routes other than oral or IV, the particular ester employed is

a major determinant of duration of action. As indicated in [Table 71-2](#), not all esters can be administered by all routes. Hence, when preparing to give a glucocorticoid, you should verify that the particular ester ordered is appropriate for the intended route.

852

853

72.2.11 Dosage

72.2.11.1 General Guidelines for Dosing

For most patients, the therapeutic objective is to reduce symptoms to an acceptable level. Complete relief is usually not an appropriate goal.

Dosages are highly individualized and, for any patient with any disease, dosage must be determined empirically (by trial and error). For patients whose disease is not an immediate threat to life, the dosage should be low initially and then increased gradually until symptoms are under control. In the event of life-threatening disease, a large initial dose should be used, and, if a response does not occur rapidly, the dose should be doubled or even tripled. When glucocorticoids are used for a long time, the dosage should be reduced until the smallest effective amount has been established. Prolonged treatment with high doses should be done only if the disorder (1) is life threatening or (2) has the potential to cause permanent disability. During long-term treatment, an increase in dosage will be needed at times of stress (unless the dosage is very high to begin with). If disease status changes, appropriate adjustment of dosage must be made.

As noted, abrupt termination of long-term therapy may unmask adrenal insufficiency. To minimize the impact of adrenal insufficiency, glucocorticoid withdrawal should be gradual. Patients must be warned against abrupt discontinuation.

72.2.11.2 Alternate-Day Therapy

In alternate-day therapy, a large dose (of an intermediate-acting glucocorticoid) is given every other morning. This dosing schedule contrasts with traditional therapy, in which multiple smaller doses are administered daily. Benefits of alternate-day therapy are (1) reduced adrenal suppression, (2) reduced risk of growth retardation, and (3) reduced toxicity overall. Adrenal insufficiency is decreased because, over the extended interval between doses, plasma glucocorticoids decline to a level that is low enough to permit some production of ACTH, thereby promoting some synthesis of cortisol by the adrenals. To allow maximal recovery of endocrine function, doses should be administered prior to 9:00 in the morning, and long-acting agents should be avoided. Early-morning administration is also helpful in that it mimics (sort of) the burst of glucocorticoids normally released by the adrenals at dawn.

Unfortunately, alternate-day therapy does have one drawback: In the long interval between doses, drug levels may fall to a subtherapeutic value, thus permitting flare-up of symptoms. Symptoms are likely to be most intense late on the second day after a dose is given. If symptoms become intolerable, switching to a single daily dose may be sufficient to provide control. As with alternate-day treatment, patients taking single daily doses should administer their medicine before 9:00 AM.

72.2.11.2.1

KEY POINTS

- Glucocorticoids are used in low (physiologic) doses to treat endocrine disorders (see [Chapter 59](#)) and in high (pharmacologic) doses to treat nonendocrine disorders (eg, arthritis, asthma).
- Glucocorticoids are beneficial in nonendocrine disorders primarily because they suppress inflammatory and immune responses.
- Glucocorticoids produce their effects by penetrating the cell membrane and activating cytoplasmic receptors, which then travel to the cell nucleus where they modulate the activity of genes that code for specific regulatory proteins.
- Glucocorticoids reduce inflammation by multiple mechanisms, including suppressing the (1) synthesis of inflammatory mediators (prostaglandins, leukotrienes, histamine), (2) infiltration of phagocytes, (3) release of lysosomal enzymes, and (4) proliferation of lymphocytes.
- Important nonendocrine indications for glucocorticoids include arthritis, allergic disorders, asthma, cancer, and suppression of allograft rejection.
- When used in pharmacologic doses, especially for prolonged times, glucocorticoids can cause severe adverse effects. These are not seen at physiologic doses.
- Adverse effects of the glucocorticoids include adrenal insufficiency, osteoporosis, increased vulnerability to infection, muscle wasting, thinning of the skin, fluid and electrolyte imbalance, glucose intolerance, and, possibly, peptic ulcer disease.
- By causing potassium loss, glucocorticoids can increase the risk of toxicity from digoxin, and they can exacerbate hypokalemia caused by thiazide and loop diuretics.

- Concurrent use of NSAIDs with glucocorticoids increases the risk of peptic ulcer disease.
- Prolonged glucocorticoid use causes adrenal insufficiency.
- Patients with adrenal insufficiency must be given supplemental doses of glucocorticoids at times of stress (eg, surgery, trauma). Failure to do so may be fatal!
- To minimize expression of adrenal insufficiency when glucocorticoids are discontinued, doses should be tapered very gradually.
- Following glucocorticoid withdrawal, supplemental glucocorticoids are needed at times of stress until adrenal function has fully recovered.
- Alternate-day dosing can help minimize development of adrenal insufficiency.
- Glucocorticoids should be administered before 9:00 AM. Why? Because this helps minimize adrenal insufficiency and mimics (sort of) the burst of glucocorticoids released naturally by the adrenals each morning.

853

72.2.11.2.2

Summary of Major Nursing Implications*

72.2.11.2.2.1

GLUCOCORTICOIDS

Betamethasone

Cortisone

Dexamethasone

Hydrocortisone

Methylprednisolone

Prednisolone

Prednisone

854

Triamcinolone

The nursing implications summarized here apply to all glucocorticoids, but only to their use for *nonendocrine diseases*. Implications that apply specifically to their use for *replacement therapy* are summarized in [Chapters 59](#). Implications specific to *asthma therapy* are summarized in [Chapter 75](#).

72.2.11.2....

Preadministration Assessment

72.2.11.2....

Therapeutic Goal

Glucocorticoids are used to suppress rejection of organ transplants, and to treat a variety of inflammatory, allergic, and neoplastic disorders. When treating inflammatory and allergic disorders, the goal is to suppress signs and symptoms to an acceptable level, not to eliminate them.

72.2.11.2....

Baseline Data

Make a full assessment of the specific disorder (eg, rheumatoid arthritis, asthma, psoriasis) being treated. These data are used to determine the initial dosage and to guide dosage adjustments as treatment proceeds. Determine bone mineral density of the lumbar spine.

72.2.11.2....

Identifying High-Risk Patients

Glucocorticoids are *contraindicated* for patients with systemic fungal infections and for individuals receiving live virus vaccines.

Use glucocorticoids with *caution* in pediatric patients and in women who are pregnant or breast-feeding. In addition, exercise *caution* in patients with hypertension, open-angle glaucoma, heart failure, renal impairment, esophagitis, gastritis, peptic ulcer disease, myasthenia gravis, diabetes mellitus, osteoporosis, and infections that are resistant to treatment, and in patients receiving potassium-depleting diuretics, digoxin, insulin, oral hypoglycemics, or NSAIDs.

72.2.11.2....

Implementation: Administration and Dosage

72.2.11.2....

Routes and Administration

Glucocorticoids are administered orally, parenterally (IV, IM, subQ), topically (to skin and mucous membranes), intranasally, by inhalation, and by local injection (eg, intra-articular, intralesional). Routes for specific preparations are summarized in [Table 71-2](#). (Glucocorticoids administered topically, intranasally, and by inhalation are presented in [Chapters 104](#), [76](#), and [75](#), respectively.) When getting ready to administer a glucocorticoid, verify that the preparation is appropriate for the intended route.

72.2.11.2....

Dosage

Dosage is determined empirically. For patients whose disease does not threaten life, dosage should be low initially and then gradually increased, until the desired response is achieved. For life-threatening disease, initial doses should be as large as needed to control symptoms. During prolonged therapy, the dosage should be reduced to the smallest effective amount. Supplemental doses are needed at times of stress, unless the dosage is very high to begin with.

72.2.11.2....

Alternate-Day Therapy

Alternate-day dosing reduces adrenal suppression and other toxicities. **Instruct patients to take their medicine before 9:00 AM every other day.**

72.2.11.2....

Drug Withdrawal

Glucocorticoids must be withdrawn gradually. **Warn the patient against abrupt discontinuation of treatment.** Following termination, supplemental doses are needed during times of stress until adrenal function has recovered fully.

72.2.11.2....

Ongoing Evaluation and Interventions

72.2.11.2....

Evaluating Therapeutic Effects

Evaluate therapy by making periodic comparisons of current signs and symptoms with the pretreatment assessment. Dosage adjustment is based on these evaluations.

72.2.11.2....	Minimizing Adverse Effects	
72.2.11.2....	General Measures. (1) Keep the dosage as low as possible and the duration of treatment as short as possible. (2) Use alternate-day therapy if possible. (3) When appropriate, administer glucocorticoids topically, intranasally, by inhalation, or by local injection, rather than systemically.	
72.2.11.2....	Adrenal Insufficiency. Long-term therapy suppresses the ability of the adrenal glands to make glucocorticoids. Increase the dosage when stress occurs (eg, surgery, trauma, infection) unless the dosage is very high to begin with. Following termination of therapy, supplemental doses are required at times of stress until adrenal recovery is complete. Advise the patient to carry identification (eg, Medic Alert bracelet) to ensure proper dosing in emergencies. Advise the patient to always have an emergency supply of glucocorticoids on hand. Expression of adrenal insufficiency can be reduced by withdrawing glucocorticoids gradually. Adrenal insufficiency can be minimized through alternate-day dosing and use of glucocorticoids that have an intermediate duration of action.	
72.2.11.2....	Osteoporosis. Glucocorticoid-induced osteoporosis predisposes the patient to fractures, especially of the ribs and vertebrae. Monitor patients for signs of compression fractures (neck or back pain) and for indications of other fractures. Evaluate status with bone densitometry. Several drugs can help prevent osteoporosis. Important among these are calcium supplements, vitamin D supplements, thiazide diuretics (combined with salt restriction), bisphosphonates (eg, etidronate), teriparatide, and calcitonin. Estrogen replacement therapy can reduce bone loss in postmenopausal women, but the benefits are not likely to outweigh the risks.	854 855
72.2.11.2....	Infection. Glucocorticoids increase the risk of morbidity from infection. Warn patients to avoid close contact with persons with communicable diseases. Inform patients about early signs of infection (eg, fever, sore throat), and instruct them to	

notify the prescriber if these occur. Treat established infections with appropriate antimicrobial drugs, and withdraw glucocorticoids unless they are absolutely required.

72.2.11.2....

Glucose Intolerance.

Glucocorticoids can cause hyperglycemia and glycosuria. Diabetic patients may need to decrease their caloric intake and use higher doses of hypoglycemic medication (insulin or an oral hypoglycemic).

72.2.11.2....

Fluid and Electrolyte Disturbance.

Glucocorticoids can cause sodium and water retention and loss of potassium. These effects can be minimized by (1) using glucocorticoids that have low mineralocorticoid activity, (2) restricting sodium intake, and (3) taking potassium supplements or consuming potassium-rich foods (eg, bananas, citrus fruits).

Educate patients about signs and symptoms of fluid retention (eg, weight gain, swelling of the lower extremities) and hypokalemia (eg, muscle weakness, irregular pulses, cramping), and instruct them to notify the prescriber if these develop.

72.2.11.2....

Growth Retardation.

Glucocorticoids can suppress growth in children. Evaluate growth by making periodic measurements of height and weight. Alternate-day therapy minimizes growth suppression.

72.2.11.2....

Cataracts and Glaucoma.

Cataracts are a common complication of long-term therapy. Open-angle glaucoma may also develop. The patient should be given an eye exam every 6 months. Instruct the patient to notify the prescriber if vision becomes cloudy or blurred.

72.2.11.2....

Peptic Ulcer Disease.

Glucocorticoids may increase the risk of ulcer formation and can mask ulcer symptoms. **Instruct the patient to notify the prescriber if feces become black and tarry.** Have stools checked periodically for occult blood. If ulcers develop, glucocorticoids should be slowly withdrawn—unless their continued use is considered essential for life—and antiulcer therapy should be instituted.

72.2.11.2....

Use in Pregnancy and Lactation.

Glucocorticoids can induce adrenal hypoplasia in the developing fetus. When large doses have been employed, the newborn should be assessed for adrenal insufficiency, and given replacement therapy if indicated.

During high-dose therapy, the glucocorticoid content of breast milk may become high enough to affect the nursing infant. **Warn women who are receiving high-dose therapy not to breast-feed.**

72.2.11.2....

Other Adverse Effects.

Psychologic disturbances, myopathy, and Cushing's syndrome can be minimized by implementing the general measures noted at the beginning of this section. There are no specific measures to prevent these complications.

72.2.11.2....

Minimizing Adverse Interactions

72.2.11.2....

Interactions Related to Potassium Loss.

Glucocorticoid-induced potassium loss can be augmented by *potassium-depleting diuretics* (thiazides, loop diuretics) and can increase the risk of toxicity from *digoxin*. If digoxin and glucocorticoids are used concurrently, potassium levels should be monitored. Also, be alert for indications of cardiotoxicity.

72.2.11.2....

Nonsteroidal Anti-inflammatory Drugs.

NSAIDs can increase the risk of gastric ulceration during glucocorticoid therapy. Exercise caution when this combination is employed.

72.2.11.2....

Insulin and Oral Hypoglycemics.

Glucocorticoids can elevate blood levels of glucose. Diabetic patients may need to increase their dosage of insulin or oral hypoglycemic drug.

72.2.11.2....

Vaccines.

Glucocorticoids can decrease antibody responses to vaccines and can increase the risk of infection from live virus vaccines. Immunization should not be done while glucocorticoids are in use.

* Patient education information is highlighted as **blue text**.

⁷³CHAPTER 72 Drug Therapy of Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an autoimmune, inflammatory disorder that affects about 1% of the American population. Each year, the disease results in more than 9 million physician visits and over 250,000 hospitalizations. Although RA can develop at any age, initial symptoms usually appear during the third and fourth decades. Among younger patients, the incidence of RA is 3 times greater in females than in males. However, among patients over the age of 60, the incidence in men and women is equal. Rheumatoid arthritis follows a progressive course and can eventually cripple its victim. In some cases, drug therapy can halt the advance of the disease. In others, benefits are limited to symptomatic relief. Some of the drugs used for RA have been introduced in preceding chapters. Additional drugs are introduced here.

^{73.1} PATHOPHYSIOLOGY OF RHEUMATOID ARTHRITIS

Onset of RA is heralded by symmetric joint stiffness and pain. Symptoms are most intense in the morning and abate as the day advances. Joints become swollen, tender, and warm. For some patients, periods of spontaneous remission occur. For others, injury progresses steadily. In addition to joint injury, RA has systemic manifestations, including fever, weakness, fatigue, weight loss, thinning of the skin, scleritis (inflammation of the sclera), corneal ulcers, vasculitis (which can be severe), and nodules under the skin and periosteum (connective tissue that surrounds all bones).

The progression of joint deterioration is depicted in [Figure 72-1](#). Inflammation begins in the synovium—the membrane that encloses the joint cavity. As inflammation intensifies, the synovial membrane thickens and begins to envelop the articular cartilage. This overgrowth is referred to as pannus. Damage to the cartilage is caused by enzymes released from the pannus and by chemicals and enzymes produced by the inflammatory process raging within the synovial space. Ultimately, the articular cartilage undergoes total destruction, resulting in direct contact between bones of the joint, followed by eventual bone fusion. After this, inflammation subsides.

Joint destruction is caused by an autoimmune process in which the immune system mounts an attack against synovial tissue. During the attack, mast cells, macrophages, and T lymphocytes produce cytokines and cytotoxins—compounds that promote inflammation and joint destruction. The cytokines of greatest importance are tumor necrosis factor, interleukin-1, interleukin-6, interferon gamma, platelet-derived growth factor, and granulocyte-macrophage colony-stimulating factor. Why the immune system attacks joints is unclear.

73.2 OVERVIEW OF THERAPY

Treatment is directed at (1) relieving symptoms (pain, inflammation, and stiffness), (2) maintaining joint function and range of motion, (3) minimizing systemic involvement, and (4) delaying disease progression. To achieve these goals, a combination of pharmacologic and nonpharmacologic measures is employed.

73.2.1 Nondrug Measures

Nondrug measures for managing RA include physical therapy, exercise, and surgery. Physical therapy may consist of massage, warm baths, and application of heat to the affected regions. These procedures can enhance mobility and reduce inflammation. A balanced program of rest and exercise can decrease joint stiffness and improve function. However, excessive rest and excessive exercise should be avoided: too much rest will foster stiffness, and too much activity can intensify inflammation.

Orthopedic surgery has made marked advances. For patients with severe disease of the hip or knee, total joint replacement can be performed. When joints of the hands or wrists have been damaged severely, function can be improved through removal of the diseased synovium and repair of ruptured tendons. Plastic implants can help correct deformities.

A complete program of treatment should include patient education and counseling. The patient should be informed about the nature of RA, the possible consequences of joint degeneration, management measures, and the benefits and limitations of drug therapy. If loss of mobility limits function

856

at home, on the job, or in school, consultation with a social worker, occupational therapist, or specialist in vocational rehabilitation may be appropriate.

73.2.2 Drug Therapy

Antiarthritic drugs can produce symptomatic relief, and some drugs can induce protracted remission. However, remission is rarely complete, and the disease typically advances steadily. As a result, drug therapy is chronic, and hence success requires motivation and cooperation by the patient.

73.2.2.1 Classes of Antiarthritic Drugs

The antirheumatic drugs fall into three major groups:

- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Glucocorticoids (adrenal corticosteroids)
- Disease-modifying antirheumatic drugs (DMARDs)

The three major groups differ with respect to time course of effects, toxicity, and ability to slow RA progression.

The NSAIDs provide rapid relief of symptoms but do not prevent joint damage and do not slow disease progression. The NSAIDs are safer than DMARDs and glucocorticoids, and hence treatment requires less vigorous monitoring.

Like the NSAIDs, glucocorticoids provide rapid relief of symptoms. In addition, they can slow disease progression. Unfortunately, although glucocorticoids are effective, with long-term use they can cause serious toxicity. As a result, treatment is usually limited to short courses.

By definition, DMARDs are drugs that reduce joint destruction and retard disease progression. However, benefits develop more slowly than with the NSAIDs. The DMARDs are more toxic than NSAIDs, and therefore close monitoring is required. In the discussion below, DMARDs are subdivided into two basic groups—*nonbiologic DMARDs* and *biologic DMARDs*—based on their molecular size and method of production. The nonbiologic DMARDs are small molecules that are synthesized using traditional chemical techniques. In contrast, the biologic DMARDs are large molecules that are produced through recombinant DNA technology.

73.2.2.2 Drug Selection

Drug therapy of RA is evolving. In the past, treatment followed a simple protocol: (1) Start with an NSAID (eg, aspirin, ibuprofen, celecoxib). (2) If symptoms can't be controlled with an NSAID, add a DMARD (eg, methotrexate), and continue the NSAID until the DMARD takes effect. And (3) if necessary, provide a short course of glucocorticoid therapy while responses to the DMARD are developing, and to supplement treatment any time that symptoms “flare.” Note that, in this protocol, DMARDs are used only if NSAIDs are insufficient.

Today, treatment is more aggressive. Current guidelines recommend starting a DMARD *early*—within 3 months of RA diagnosis for most patients. The aim is to delay joint degeneration. Recall that NSAIDs only provide symptomatic relief; they do not retard disease progression. In contrast, DMARDs may be able to arrest the disease process. Hence, by instituting DMARD therapy early (rather than waiting until joint degeneration has advanced to the point where NSAIDs can no longer control symptoms), it is possible to delay or even prevent serious joint injury. Because the effects of DMARDs take weeks or months to develop, whereas the effects of NSAIDs are immediate, an NSAID is given until the DMARD has had time to act, after which the NSAID can be withdrawn. As in the past, glucocorticoids are generally reserved for short-course management of symptom flare-ups and for control of symptoms until DMARDs take effect. If joint injury progresses despite treatment with an initial DMARD (typically methotrexate), another DMARD can be added or substituted.

You can find detailed information on the diagnosis and management of RA in two documents sponsored by the American College of Rheumatology (ACR): (1) *Guidelines for the Management of Rheumatoid Arthritis: 2002 Update*, available online at www3.interscience.wiley.com/cgi-bin/fulltext/90510617/PDFSTART and (2) *American College of Rheumatology 2008 Recommendations for the Use of Nonbiologic and Biologic Disease-Modifying Antirheumatic Drugs in Rheumatoid Arthritis*, available online at www.rheumatology.org/publications/guidelines/.

857

73.3 NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

858

The basic pharmacology of the NSAIDs is discussed in [Chapter 70](#). Consideration here is limited to their role in RA.

73.3.1 Therapeutic Role.

NSAIDs are drugs of first choice for RA, thanks to their efficacy and rapid onset. Benefits derive primarily from anti-inflammatory actions, although analgesic actions help too. Both actions result from inhibiting cyclooxygenase (COX). NSAIDs only provide symptomatic relief; they do not slow disease progression.

73.3.2 NSAID Classification.

As discussed in [Chapter 70](#), there are two main classes of NSAIDs: (1) *first-generation NSAIDs*, which inhibit COX-1 and COX-2; and (2) *second-generation NSAIDs (coxibs)*, which selectively inhibit COX-2. Antiinflammatory and analgesic effects result from inhibiting COX-2, whereas major adverse effects—especially gastroduodenal ulceration—result from inhibiting COX-1. Because of their selectivity, the coxibs may cause less GI ulceration than the first-generation NSAIDs, while producing equal therapeutic effects.

73.3.3 Drug Selection.

Selection of an NSAID is based largely on efficacy, safety, and cost.

73.3.3.1 Efficacy.

All of the NSAIDs have essentially equal antirheumatic effects. However, individual patients may respond better to one NSAID than to another. Accordingly, it may be necessary to try more than one agent to achieve an optimal response.

73.3.3.2 Safety and Cost.

The COX-2 inhibitors (eg, celecoxib [Celebrex]) appear somewhat safer than the first-generation NSAIDs, but are also more expensive. Hence, selection must balance these factors. If symptoms are controlled with a first-generation NSAID, and the drug is well tolerated, cost considerations would dictate using that drug. However, if a first-generation NSAID produces serious gastric ulceration, then switching to a COX-2 inhibitor might be appropriate—despite the increased cost.

73.3.4 Dosage.

Dosages employed for anti-inflammatory effects are considerably higher than those required for analgesia or fever reduction. For example, treatment of RA may require 5.2 gm (16 standard

tablets) of aspirin a day, compared with only 2.6 gm for aches, pain, and fever. Dosages for RA are summarized in [Table 72-1](#).

73.4 GLUCOCORTICOIDS

The glucocorticoids are powerful anti-inflammatory drugs that can relieve symptoms of severe RA, and may also retard disease progression. For patients with generalized symptoms, *oral* glucocorticoids are indicated. However, if only one or two joints are affected, *intra-articular injections* may be employed. Because long-term oral therapy can cause serious toxicity (eg, osteoporosis, gastric ulceration, adrenal suppression), short-term therapy should be used whenever possible. Most often, glucocorticoids are used for temporary relief until drugs with more slowly developing effects (eg, methotrexate) can provide control. Long-term therapy should be limited to patients who have failed to respond adequately to all other options. The most commonly employed oral glucocorticoids are *prednisone* and *prednisolone*. When symptoms flare, patients may be given 10 to 20 mg/day until symptoms are controlled, followed by gradual drug withdrawal over 5 to 7 days. The pharmacology of the glucocorticoids is discussed at length in [Chapter 71](#) (Glucocorticoids in Nonendocrine Diseases).

858

859

TABLE 72-1 Nonsteroidal Anti-inflammatory Drugs: Oral Dosage for Rheumatoid Arthritis

Generic Name	Trade Name	Daily Dosage
First-Generation NSAIDs		
Salicylates		
Aspirin (extended release)		800 mg 4 times/day
Choline magnesium trisalicylate	Trilisate, Tricosal	3 gm/day (in 1–3 doses)
Magnesium salicylate	Magan, Mobidin	1090 mg 3 times/day
Salsalate	Disalcid, others	3–4 gm/day (in 2 or 3 doses)
Sodium salicylate		3.6–5.4 gm/day (in divided doses)
Nonsalicylates		
Diclofenac	Voltaren, Cataflam	150–200 mg/day (in 3 or 4 doses)
Diclofenac/misoprostol	Arthrotec	50 mg diclofenac/200 mcg misoprostol 3 or 4 times daily
Diffunisal		250–500 mg twice daily
Etodolac		600–1200 mg/day (in 2–4 doses)
Fenoprofen	Nalfon	300–600 mg 3 or 4 times/day
Flurbiprofen	Ansaid	200–300 mg/day (in 2–4 doses)
Ibuprofen	Motrin, Advil, others	600–800 mg 3 or 4 times/day
Indomethacin	Indocin	25–50 mg 3 times/day
Ketoprofen		150–300 mg/day (in 3 or 4 doses)
Meclofenamate		200–400 mg/day (in 3 or 4 doses)
Meloxicam	Mobic	7.5 mg once a day
Nabumetone		1.5–2 gm/day (in 1 or 2 doses)
Naproxen	Naprosyn	250–500 mg twice daily
Naproxen sodium	Anaprox, Aleve	250–500 mg twice daily
Oxaprozin	Daypro	1.2 gm a day
Piroxicam	Feldene	20 mg once a day
Sulindac	Clinoril	150–200 mg twice daily
Tolmetin		200–400 mg 3 times/day
Second-Generation NSAIDs (COX-2 Inhibitors)		
Celecoxib	Celebrex	100–200 mg twice daily

73.5 DMARDs I: MAJOR NONBIOLOGIC DMARDs

As noted above, the nonbiologic DMARDs are small molecules produced using traditional synthetic procedures. With several of these drugs, benefits result from immunosuppression. Unlike the NSAIDs, whose benefits are limited to symptomatic relief, the nonbiologic DMARDs can retard or even stop disease progression. These drugs are much more toxic than the NSAIDs, and clinical responses develop more slowly. The nonbiologic DMARDs cost much less than the biologic DMARDs, largely because the nonbiologic agents are easier to manufacture.

73.5.1 Methotrexate

Methotrexate [Rheumatrex, Trexall] acts faster than all other DMARDs. Therapeutic effects may develop in 3 to 6 weeks. At least 80% of patients improve with this drug. Benefits are the result of immunosuppression secondary to reducing the activity of B and T lymphocytes. Many rheumatologists consider methotrexate the DMARD of first choice, owing to its efficacy, relative safety, low cost, and extensive use in RA. Major toxicities are hepatic fibrosis, bone marrow suppression, GI ulceration, and pneumonitis. Periodic tests of liver and kidney function are mandatory, as are complete blood cell and platelet counts. Methotrexate can cause fetal death and congenital abnormalities, and therefore is contraindicated during pregnancy. Recent data suggest that patients using methotrexate for RA may have a reduced life expectancy, owing to increased deaths from cardiovascular disease, infection, and certain cancers (melanoma, lung cancer, and non-Hodgkin's lymphoma). For treatment of RA, methotrexate is administered once a *week*, either orally or by injection. The usual maintenance dosage range is 10 to 20 mg/wk. Dosing with folic acid (at least 5 mg/wk) is recommended to reduce toxicity. Methotrexate is discussed at length in [Chapter 101](#) (Anticancer Drugs I: Cytotoxic Agents).

73.5.2 Sulfasalazine

Sulfasalazine [Azulfidine] has been used for decades to treat inflammatory bowel disease (see [Chapter 79](#)) and is now used for RA as well. Benefits may result from anti-inflammatory and immunomodulatory actions. In patients with RA, sulfasalazine can slow the progression of joint deterioration, sometimes with just 1 month of treatment. Gastrointestinal reactions (nausea, vomiting, diarrhea, anorexia, abdominal pain) are the most common reasons for stopping treatment. These reactions can be minimized by using an enteric-coated formulation and by dividing the daily dosage. Dermatologic reactions (pruritus, rash, urticaria) are also common. Fortunately, serious adverse effects—hepatitis and bone marrow suppression—are rare. To ensure early detection, periodic monitoring for hepatitis and bone marrow function (complete blood

counts, platelet counts) should be performed. Because of its structure, sulfasalazine should not be given to patients with sulfa allergy. The initial dosage for RA is 1000 mg/day. The usual maintenance dosage is 1000 mg 2 or 3 times a day. Sulfasalazine is discussed further in [Chapter 79](#).

73.5.3 Leflunomide

73.5.3.1 Actions and Uses.

Leflunomide [Arava] is a powerful immunosuppressant indicated for adults with active RA. In clinical trials, the drug decreased signs and symptoms and slowed disease progression. Compared with methotrexate, leflunomide is about equally effective, but more dangerous and more expensive. Accordingly, the drug is often reserved for second-line use.

Leflunomide is a prodrug that undergoes conversion to its active form—metabolite 1 (M1)—in the body. Metabolite 1 inhibits dihydroorotate dehydrogenase, a mitochondrial enzyme needed for *de novo* synthesis of pyrimidines, which in turn are needed for T-cell proliferation and antibody production. *In vitro*, leflunomide inhibits T-cell proliferation. In animals, it suppresses inflammation.

73.5.3.2 Pharmacokinetics.

Following oral dosing, leflunomide is converted to M1 by enzymes in the intestine and liver. Levels of M1 peak in 6 to 12 hours. The active form undergoes further metabolism followed by excretion in the urine and bile. The half-life is prolonged: 16.5 days. As a result, a series of loading doses is needed to achieve steady state quickly.

73.5.3.3 Adverse Effects.

The most common adverse effects are diarrhea (17%), respiratory infection (15%), reversible alopecia (10%), rash (10%), and nausea (9%). The drug has also been associated with much more serious reactions: pancytopenia, Stevens-Johnson syndrome, and severe hypertension.

Leflunomide is *hepatotoxic*. Elevation of liver enzymes occurs in about 10% of patients. In postmarketing reports, the drug has been associated with over 130 cases of severe liver injury, including 12 that were fatal. Liver function should be assessed at baseline, every month for the first 6 months of treatment, and every 6 to 8 weeks thereafter. Leflunomide should be avoided in patients with liver impairment, hepatitis B, or hepatitis C. Patients should be informed about

signs of liver injury—abdominal pain, fatigue, dark urine, and jaundice—and advised to report them immediately.

Leflunomide may increase the risk of *serious infection*. The drug is immunosuppressive and can suppress the bone marrow. Rarely, patients experience sepsis and other severe infections. Deaths have occurred. If an infection develops, it may be necessary to interrupt leflunomide use. To reduce risk, counts of platelets and blood cells should be conducted at baseline, monthly for the first 6 months of treatment, and every 6 to 8 weeks thereafter. If evidence of bone marrow suppression is detected, leflunomide should be discontinued.

Leflunomide is carcinogenic in animals, but has not been associated with cancer in humans.

73.5.3.4 Leflunomide and Pregnancy.

Leflunomide is contraindicated during pregnancy. The drug is teratogenic and embryotoxic in animals and has been classified in Food and Drug Administration (FDA) Pregnancy Risk Category X. Women of child-bearing age must use a reliable form of contraception.

Patients who wish to become pregnant must first clear leflunomide from the body. A three-step protocol is followed:

Step 1: Discontinue leflunomide.

Step 2: Take cholestyramine (8 gm 3 times a day) for 11 days. (Cholestyramine binds leflunomide and its metabolites in the intestine, and thereby accelerates their excretion. Without cholestyramine, safe levels might not be achieved for 2 years.)

Step 3: Verify that plasma drug levels are below 20 mcg/L.

To minimize any risk of fetal injury, men using leflunomide who wish to father a child should undergo the same clearance procedure.

73.5.3.5 Drug Interactions.

Leflunomide can inhibit the metabolism of certain NSAIDs (eg, ibuprofen, diclofenac), causing their levels to rise. In addition, leflunomide can intensify liver damage from other hepatotoxic drugs (eg, methotrexate), and hence should not be combined with such agents. Rifampin (a drug for tuberculosis) can raise leflunomide levels by 40%. Conversely, leflunomide levels can be rapidly decreased with cholestyramine or activated charcoal.

73.5.3.6 Preparations, Dosage, and Administration.

Leflunomide [Arava] is available in tablets (10, 20, and 100 mg) for oral dosing. Treatment begins with a series of loading doses (100 mg once a day for 3 days) followed by daily maintenance doses of 10 or 20 mg.

859

73.5.4 Minocycline

860

Minocycline [Minocin], an antibiotic in the tetracycline family, can improve symptoms in patients with RA. The drug was originally tried because of suspicions that RA may have an infectious basis in some patients. However, it now appears that the most likely mechanism underlying benefits is inhibition of collagenase, an enzyme that promotes joint destruction. Other potential mechanisms include inhibition of phospholipase A₂, interleukins, leukocyte infiltration, and lymphocyte proliferation.

In patients with RA, minocycline can improve morning stiffness, joint pain and tenderness, and activities of daily living. In addition, it may delay disease progression in some patients. The usual dosage is 100 mg twice daily. Increasing the dosage increases adverse effects but does not increase benefits. Symptoms begin improving within 12 weeks, but may not be maximal until 12 months. Adverse effects include dizziness and skin rash. Minocycline is an experimental therapy, and hence should be reserved for patients who have not responded to other DMARDs.

73.5.5 Hydroxychloroquine

Hydroxychloroquine [Plaquenil], a drug with antimalarial actions, is considered a preferred DMARD in the 2008 ACR treatment guidelines. As a rule, the drug is usually combined with methotrexate. By itself, hydroxychloroquine does not slow disease progression, but early use *can* improve long-term outcomes. Like other DMARDs, hydroxychloroquine has a delayed onset; full therapeutic effects take 3 to 6 months to develop. Concurrent therapy with anti-inflammatory agents (NSAIDs or glucocorticoids) is indicated during the latency period. How hydroxychloroquine works in RA is unknown.

Retinal damage, which is rare, is the most serious toxicity. Retinopathy may be irreversible and can produce blindness. Visual loss is directly related to dosage. Low doses may be used in long-term treatment with little risk. When dosage has been excessive, retinal damage may appear after treatment has ceased and may progress in the absence of continued drug use. Patients should undergo a thorough ophthalmologic exam prior to treatment and every 6 months thereafter.

Hydroxychloroquine should be discontinued at the first sign of retinal injury. Patients should be advised to contact the prescriber if any visual disturbance is noted.

^{73.6} DMARDs II: MAJOR BIOLOGIC DMARDs

The biologic DMARDs are immunosuppressive drugs that target specific components of the inflammatory process. These drugs are often combined with methotrexate. Of the biologic agents available, only five are used routinely ([Table 72-2](#)). Three of these—etanercept, infliximab, and adalimumab—interfere with tumor necrosis factor (TNF). One agent—rituximab—promotes destruction of B lymphocytes. And one agent—abatacept—inhibits activation of T lymphocytes. Since these drugs suppress immune function, they all pose a risk of serious infections. As noted, the biologic DMARDs are so named because they are manufactured using recombinant DNA technology, an expensive process that is reflected in the cost of these drugs, which can range from \$14,000 to more than \$35,000 a year.

^{73.6.1} Tumor Necrosis Factor Antagonists

The drugs discussed in this section work by neutralizing TNF, an important immune mediator of joint injury in RA. At this time three TNF antagonists are available: etanercept, infliximab, and adalimumab. In patients with RA, all three drugs are highly effective. Unfortunately, all three pose a risk of serious infections, including bacterial sepsis, invasive fungal infections, and tuberculosis (TB). Rarely, patients develop severe skin reactions. In addition to their use in RA, these drugs are approved for several other inflammatory disorders, including psoriatic arthritis, ankylosing spondylitis, and Crohn's disease ([Table 72-3](#)).

TABLE 72-2 Disease-Modifying Antirheumatic Drugs (DMARDs)

Major Nonbiologic DMARDs
Methotrexate [Rheumatrex, Trexall]
Sulfasalazine [Azulfidine]
Leflunomide [Arava]
Minocycline [Minocin]
Hydroxychloroquine [Plaquenil]
Major Biologic DMARDs
Tumor Necrosis Factor Antagonists
Etanercept [Enbrel]
Infliximab [Remicade]
Adalimumab [Humira]
B-Lymphocyte–Depleting Agents
Rituximab [Rituxan]
T-Cell Activation Inhibitors
Abatacept [Orencia]
Minor Biologic and Nonbiologic DMARDs
Anakinra [Kineret]
Azathioprine [Imuran]
Cyclosporine
Gold salts
Penicillamine [Cuprimine, Depen]
Protein A [Prosorba]

73.6.1.1 Etanercept

Etanercept [Enbrel], approved in 1998, was the first TNF antagonist available for general use. Like all TNF antagonists, etanercept is highly effective at reducing RA symptoms and disease progression, but may also promote serious infections and severe skin reactions.

73.6.1.1.1 Mechanism of Action.

Etanercept suppresses inflammation by neutralizing TNF. As noted above, TNF is an important contributor to RA pathophysiology. In patients with RA, TNF binds with receptors on cells in the synovium, and thereby stimulates production of chemotactic factors and endothelial adhesion molecules, which in turn promote infiltration of neutrophils and macrophages. The result is inflammation and joint destruction.

How does etanercept neutralize TNF? Etanercept is a large molecule composed of two receptors for TNF linked to the Fc component of immunoglobulin G (IgG). The TNF receptors, which are produced through recombinant DNA technology, are identical to the TNF receptors found on human cells. Like the TNF receptors on our cells, etanercept binds tightly with TNF, and thereby prevents TNF from interacting with its natural receptors on cells.

73.6.1.1.2 Therapeutic Uses.

Etanercept is indicated for patients with moderately to severely active RA. In clinical trials, the drug was slightly superior to methotrexate at delaying progression of joint damage, and it suppressed signs and symptoms of RA more rapidly. Among patients who had failed to respond to methotrexate, addition of etanercept for 6 months reduced symptoms in 61%, compared with 27% who continued taking methotrexate alone.

In addition to RA, etanercept is approved for ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, and juvenile idiopathic arthritis.

860

TABLE 72-3 Approved Indications for TNF Antagonists

Approved Indications	Etanercept [Enbrel]	Infliximab [Remicade]	Adalimumab [Humira]
Rheumatoid arthritis	✓	✓	✓
Ankylosing spondylitis	✓		✓
Juvenile idiopathic arthritis	✓		✓
Psoriatic arthritis	✓	✓	✓
Plaque psoriasis	✓	✓	✓
Crohn's disease		✓	✓
Ulcerative colitis		✓	

73.6.1.1.3 Pharmacokinetics.

Etanercept is administered by subQ injection. Plasma levels peak about 3 days after dosing. The drug is cleared from the plasma with a half-life of 115 hours (about 5 days). The mode of elimination is unknown.

73.6.1.1.4 Adverse Effects.

Injection-site reactions—itching, erythema, swelling, pain—occur in 37% of patients. Other mild but less common reactions include headache, rhinitis, dizziness, cough, and abdominal pain.

73.6.1.1.4.1 Serious Infections.

Etanercept increases vulnerability to serious infections. Why? Because TNF helps protect against infection, and hence when we neutralize TNF with etanercept, the risk of infection goes up. Although serious infections were not seen during clinical trials, severe infections, including some that were fatal, were reported during postmarketing surveillance. To reduce risk, etanercept should not be given to patients with active infection, including infections that are chronic or localized. Patients who develop a new infection should be monitored closely. Etanercept should be used with caution in patients with a history of recurrent infection or any condition that predisposes them to acquiring infection (eg, advanced or poorly controlled diabetes). If a severe infection develops, etanercept should be discontinued.

Tuberculosis is a special concern. When TB develops in patients taking etanercept, the disease is often extrapulmonary and disseminated. To reduce risk, candidates should be tested for latent TB and, if the test is positive, should undergo TB treatment before etanercept is used. During etanercept treatment, patients should be monitored closely for TB development.

73.6.1.1.4.2 Severe Skin Reactions.

Rarely, etanercept has been associated with severe skin reactions, including Stevens-Johnson syndrome (SJS), erythema multiforme (EM), and toxic epidermal necrolysis (TEN). As of 2006, 22 such cases had been reported. The median onset was 28 days after starting etanercept. Patients and providers should monitor for adverse skin reactions.

73.6.1.1.4.3 Heart Failure.

Etanercept may pose a risk of heart failure. In patients using the drug, existing cases of heart failure have gotten worse, and new cases have developed. Exercise caution when patients with existing heart failure are given this agent.

73.6.1.1.4.4 Cancer.

There is concern that etanercept and other TNF blockers may increase the risk of lymphoma and other malignancies. However, a causal relationship has not been established.

73.6.1.1.4.5 Other Adverse Effects.

Etanercept has been associated with rare cases of *central nervous system (CNS) demyelinating disorders* (eg, multiple sclerosis, myelitis, optic neuritis) and *hematologic disorders*, including fatal cases of aplastic anemia. However, a causal relationship has not been established. Nonetheless, caution is advised, especially in patients with (1) pre-existing or recent-onset CNS demyelinating disorders or (2) a history of significant hematologic abnormalities. Advise patients who develop signs or symptoms that suggest a blood disorder (persistent fever, bruising, bleeding, pallor) to seek immediate medical attention. If a significant hematologic abnormality is diagnosed, discontinuing etanercept should be considered.

73.6.1.1.5 Drug Interactions.

By neutralizing TNF, etanercept may increase the risk of acquiring or transmitting infection following immunization with a live vaccine. Accordingly, live vaccines should be avoided. In pediatric patients, vaccinations should be up to date before starting the drug.

Etanercept should not be combined with anakinra, another biologic agent for RA. Combining these drugs does not increase therapeutic responses, but does increase the risk of infection.

73.6.1.1.6 Preparations, Dosage, and Administration.

Etanercept [Enbrel] is available in two formulations: (1) a 50-mg/mL solution and (2) a 25-mg powder to be reconstituted in 1 mL of sterile bacteriostatic water (supplied by the manufacturer). Administration is by subQ injection. Solutions that are discolored or cloudy or contain particles should not be used. The adult dosage is 25 mg subQ twice a week. The dosage for children 4 to 17 years old is 0.4 mg/kg (up to a maximum of 25 mg) twice a week. For both adults and children, injections are made 3 to 4 days apart. Etanercept is expensive: The cost for a 12-month course of treatment is about \$16,000.

73.6.1.2 Infliximab

Infliximab [Remicade] was the second TNF blocker approved for RA. Like etanercept, infliximab binds to and thereby neutralizes TNF. However, the two drugs are structurally different: whereas etanercept is composed of two TNF *receptors*, infliximab is a TNF *antibody*.

Infliximab has several approved uses. In patients with RA, the drug is approved for combined use with methotrexate to reduce symptoms and delay disease progression. Infliximab is also approved for psoriasis (see [Chapter 104](#)) and two intestinal disorders: Crohn's disease and ulcerative colitis (see [Chapter 79](#)).

Common adverse effects include headache and infusion reactions (eg, fever, chills, pruritus, urticaria, chest pain). In patients with heart failure, infliximab may increase the risk of hospitalization and mortality, and hence is inappropriate for these patients. The drug may also cause new-onset heart failure. There is some evidence that infliximab may increase the risk of hepatosplenic T-cell lymphoma.

Like etanercept, infliximab has immunosuppressant actions, and hence can increase the risk of serious infection, including bacterial sepsis, invasive fungal infections, and TB. Accordingly, the drug should not be given to patients with chronic infections, and should be temporarily

withdrawn if an acute infection develops. Patients should receive a TB test and chest x-ray to rule out latent tuberculosis prior to treatment.

Infliximab may cause liver injury. There have been postmarketing reports of severe reactions, including jaundice, hepatitis, cholestasis, and acute liver failure. Autoimmune hepatitis has been diagnosed in some of these cases. Some patients with liver injury required a liver transplant, and some patients have died.

Infliximab is administered by slow IV infusion (over 2 hours or more). The dosage is 3 mg/kg at 0, 2, and 6 weeks, and every 8 weeks thereafter. Patients should also receive methotrexate (oral or subQ). Infliximab is expensive: Depending on dosage and dosing schedule, treatment costs between \$14,000 and \$37,000 a year.

861

73.6.1.3

Adalimumab

862

Adalimumab [Humira] was the third TNF blocker approved for RA. Like infliximab, adalimumab is a monoclonal antibody that binds to and thereby neutralizes TNF. The drug is indicated for adults with moderately to severely active RA who have not responded adequately to one or more DMARDs. In these patients, adalimumab can reduce symptoms and slow progression of joint damage. The drug may be used alone or in combination with methotrexate or other DMARDs. In addition to RA, adalimumab is approved for ankylosing spondylitis, juvenile idiopathic arthritis, plaque psoriasis, psoriatic arthritis, and Crohn's disease.

Adalimumab is generally well tolerated. The most common side effects are injection-site reactions (rash, erythema, itching, pain, swelling), which develop in about 20% of patients. Headache is also common (12%). Allergic reactions develop in about 1% of patients. If a serious allergic reaction develops (eg, anaphylaxis), the drug should be discontinued. Very rarely, adalimumab has been associated with neurologic injury; signs include numbness, tingling, dizziness, disturbed vision, and weakness in the legs. Testing in pregnant monkeys showed no evidence of fetal harm, but we have no data on safety in pregnant women. Like other TNF antagonists, adalimumab may increase the risk of malignancy, and has been associated with rare cases of severe skin reactions, including SJS, EM, and TEN.

Like other TNF antagonists, adalimumab can increase the risk of serious infection, including bacterial sepsis, invasive fungal infection, and TB. Accordingly, the drug should not be given to patients with active infection. Patients who develop a new infection during treatment should be monitored closely and, if the infection becomes serious, adalimumab should be discontinued. Patients should be tested for latent TB prior to treatment.

Adalimumab [Humira] is supplied in single-use, prefilled syringes (40 and 80 mg) and single-use, prefilled “pens” (80 mg). Administration is by subQ injection in the anterior thigh or abdomen. The injection giver—physician, nurse, patient, or caregiver—should rotate the injection site and avoid areas where the skin is tender, bruised, red, or hard. The recommended dosage for RA in adults is 40 mg every 2 weeks. If adalimumab is being used without methotrexate, giving it more frequently (40 mg once a week) may improve results. The drug should be stored cold—2°C to 8°C (36°F to 46°F)—and protected from light. Like etanercept and infliximab, adalimumab is expensive: For patients taking 40 mg every 2 weeks, the annual cost is about \$18,000.

73.6.2 B-Lymphocyte–Depleting Agents

In patients with RA, B lymphocytes play an important role in the autoimmune attack on joints. Accordingly, drugs that decrease the number of circulating B cells can reduce symptoms of RA and disease progression. At this time, only one drug—rituximab—works by this mechanism.

73.6.2.1 Rituximab

73.6.2.1.1 Actions and Uses.

Rituximab [Rituxan] is a monoclonal antibody directed against CD20, an antigen found exclusively on the surface of B lymphocytes. When rituximab binds with CD20, the immune system attacks the rituximab–B-cell complex, causing B-cell lysis and death. Rituximab, in combination with methotrexate, is indicated for IV therapy of adults with moderate to severe RA who have not responded to one or more TNF antagonists. As discussed in [Chapter 102](#), rituximab is also used for B-cell non-Hodgkin's lymphoma.

73.6.2.1.2 Adverse Effects.

73.6.2.1.2.1 Infusion Reactions.

Rituximab can cause severe infusion-related hypersensitivity reactions, beginning within 30 to 120 minutes. The immediate reaction and its sequelae include hypotension, bronchospasm, angioedema, hypoxia, pulmonary infiltrates, myocardial infarction, and cardiogenic shock. Deaths have occurred within 24 hours. To reduce the risk of these events, patients should be premedicated with an antihistamine and acetaminophen. If a severe infusion reaction occurs, management includes giving glucocorticoids, epinephrine, bronchodilators, and oxygen.

73.6.2.1.2.2 Mucocutaneous Reactions.

Rituximab has been associated with severe mucocutaneous reactions, including SJS, lichenoid dermatitis, vesiculobullous dermatitis, and TEN. Deaths have occurred. Reaction onset is typically 1 to 3 weeks after rituximab exposure. Patients who experience these reactions should seek immediate medical attention, and should not receive rituximab again.

73.6.2.1.2.3 Hepatitis B Reactivation.

There have been reports of hepatitis B virus (HBV) reactivation, leading to fulminant hepatitis, hepatic failure, and death. Patients at high risk of HBV should be screened before getting rituximab. Asymptomatic carriers should be closely monitored for clinical and laboratory signs of active HBV infection while taking rituximab, and for several months after stopping.

73.6.2.1.2.4 Progressive Multifocal Leukoencephalopathy (PML).

Rituximab has been associated with rare cases of PML, a severe infection of the CNS caused by reactivation of the JC virus, an opportunistic pathogen resistant to all available drugs. As of December 2006, the FDA had received 24 reports of PML in patients taking this drug. Most cases occurred in patients being treated for non-Hodgkin's lymphoma. Patients and prescribers should be alert for any new neurologic signs and symptoms. If PML is diagnosed, rituximab should be discontinued immediately.

73.6.2.1.2.5 Other Adverse Effects.

Like other monoclonal antibodies, rituximab can cause a flu-like syndrome, especially during the initial infusion. Symptoms include fever, chills, nausea, vomiting, and myalgia. Rituximab causes transient neutropenia, but this does not appear to increase the risk of infection.

73.6.2.1.3 Preparations, Dosage, and Administration.

Rituximab [Rituxan] is supplied in solution (10 mg/mL) in 10- and 50-mL vials. The concentrated solution should be diluted in 0.9% sodium chloride or 5% dextrose in water to a final concentration of 1 to 4 mg/mL, and then administered by IV infusion. To reduce the risk of infusion reactions, patients should be premedicated with an antihistamine and acetaminophen. For RA, dosing consists of two 1000-mg infusions given 2 weeks apart. The first infusion should start at 50 mg/hr; if no infusion reaction occurs, the rate may be slowly

increased to a maximum of 400 mg/hr. If the first infusion was well tolerated, the second can be started at 100 mg/hr, and then, if well tolerated, gradually increased to 400 mg/hr.

73.6.3 T-Cell Activation Inhibitors

In patients with RA, activated T lymphocytes play a key role in the autoimmune attack on joints. Accordingly, drugs that prevent T-cell activation can reduce symptoms of RA and disease progression. Currently, only one drug—abatacept—works by this mechanism.

73.6.3.1 Abatacept

Abatacept [Orencia] is the first representative of a new class of antiarthritic drugs: the T-cell activation inhibitors. Patients who have not responded adequately to methotrexate or TNF antagonists have experienced significant improvement with this new drug. Like other biologic DMARDs, abatacept poses a risk of serious infections, and may also pose a small risk of cancer.

73.6.3.1.1 Therapeutic Uses.

Abatacept has two approved indications. In 2006, the drug was approved for reducing symptoms and delaying disease progression in *adults with moderately to severely active RA*. For these patients, abatacept may be used alone or in combination with most other DMARDs, but *not* with TNF antagonists or anakinra. In 2007, abatacept was approved for decreasing symptoms of moderately to severely active *polyarticular juvenile idiopathic arthritis* in children 6 years and older. For these patients, the drug may be used alone or in combination with methotrexate.

73.6.3.1.2 Mechanism of Action.

For T cells to achieve full activity, they must be stimulated by antigen-presenting cells (APCs). Abatacept—a complex molecule composed of a ligand (cytotoxic T-lymphocyte–associated antigen 4) linked to immunoglobulin G1—binds with receptors on APCs, and thereby prevents the APCs from stimulating T cells. The result is reduced T-cell proliferation, and reduced production of interferon gamma, interleukins, and TNF.

73.6.3.1.3 Adverse Effects.

The most common adverse effects are headache, upper respiratory infection, nasopharyngitis, and nausea.

Because abatacept suppresses immune function, the drug can increase the risk of *serious infections*. Infections seen most often are pneumonia, cellulitis, bronchitis, diverticulitis, pyelonephritis, and urinary tract infections. Patients should be told about infection risk and advised to report suspected infection immediately. If a serious infection develops, abatacept should be discontinued.

Abatacept may blunt the effect of all *vaccines*, and may increase the risk of infection from live vaccines. Before abatacept is given to children, all vaccinations should be up to date. Live vaccines should not be used in adults or children during abatacept use and for 3 months after stopping.

73.6.3.1.4 Drug Interactions.

Abatacept should not be used in conjunction with *TNF antagonists*. Why? Because the combination increases the risk of serious infection, and offers no benefit over abatacept alone.

73.6.3.1.5 Preparations, Dosage, and Administration.

Abatacept [Orencia] is supplied as a 250-mg powder to be reconstituted with sterile water, using the disposable *silicon-free* syringe provided. To minimize foam formation, the vial should be rotated with gentle swirling until the contents are completely dissolved. Following reconstitution, the solution should be diluted to a final volume of 100 mL. Solutions that are discolored or contain particles should be discarded.

Administration is by IV infusion, using an infusion set with a sterile, nonpyrogenic, low-protein-binding filter (pore size 0.2 to 1.2 micrometer). Each dose should be infused over a 30-minute span. No other agents should be given through the same line.

862

The dosage for *RA in adults* is based on body weight as follows: less than 60 kg, give 500 mg; 60 to 100 kg, give 750 mg; and over 100 kg, give 1000 mg. This dosage is given on days 0, 14, and 28, and every 4 weeks thereafter.

863

The dosage for *polyarticular juvenile idiopathic arthritis* is based on body weight as follows: less than 75 kg, give 10 mg/kg; 75 kg or more, use the corresponding adult dosage. As in adults, dosing is done on days 0, 14, and 28, and every 4 weeks thereafter.

73.7 DMARDs III: MINOR NONBIOLOGIC AND BIOLOGIC DMARDs

Several drugs that are FDA-approved for RA are used infrequently, largely because of adverse effects. These drugs are discussed briefly below. For more information, refer to the 6th edition of this book.

73.7.1 Gold Salts

Gold salts—*aurothioglucose* [Solganal], *gold sodium thiomalate* [Aurolate, Myochrysine], and *auranofin* [Ridaura]—have been used in RA for decades. Treatment can relieve pain and stiffness, and may also retard disease progression. The mechanism underlying these benefits is unknown. Unfortunately, adverse effects are common. Potential reactions include intense pruritus, rashes, stomatitis, kidney damage, severe blood dyscrasias, encephalitis, hepatitis, peripheral neuritis, pulmonary infiltrates, and profound hypotension.

73.7.2 Penicillamine

Penicillamine [Cuprimine, Depen] can relieve symptoms of RA and can retard disease progression. Unfortunately, treatment may be associated with serious toxicity, especially bone marrow suppression and autoimmune disorders. Therapeutic effects take 3 to 6 months to develop. The pharmacology of penicillamine is discussed further in [Chapter 108](#) (Management of Poisoning).

73.7.3 Azathioprine

Azathioprine [Imuran] is an older DMARD with immunosuppressive and anti-inflammatory actions. Serious toxicities include hepatitis and blood dyscrasias (leukopenia, thrombocytopenia, anemia). Also, azathioprine is teratogenic in animals and should not be used during pregnancy. The drug may also pose a small risk of malignancy. As discussed in [Chapter 68](#) (Immunosuppressants), azathioprine is also used to prevent rejection of kidney transplants.

73.7.4 Cyclosporine

Cyclosporine, an immunosuppressive drug used to prevent rejection of transplanted organs, can reduce symptoms of RA. Because it can cause kidney damage and other serious adverse effects, cyclosporine should be reserved for severe, progressive RA that has not responded to safer DMARDs. In patients with an inadequate response to methotrexate, adding cyclosporine may produce significant improvement. Cyclosporine is discussed at length in [Chapter 68](#) (Immunosuppressants).

73.7.5 Anakinra

Anakinra [Kineret], approved in 2001, reduces symptoms of RA by blocking receptors for interleukin-1, a proinflammatory cytokine that plays a central role in synovial inflammation and joint destruction. The drug is indicated for patients with moderate to severe RA that has not responded to one or more older DMARDs (eg, methotrexate). Like the TNF antagonists, anakinra poses a risk of serious infections. Accordingly, the drug should not be given to patients with active infection, and should be stopped if a serious infection develops. Because both anakinra and the TNF blockers increase infection risk, these drugs should not be combined.

73.7.6 Protein A Column [Prosorba]

The *Prosorba* column, used in combination with plasmapheresis, decreases the titer of circulating immune complexes that promote symptoms of RA. The column contains an adsorbent compound—*protein A*—that binds to antibodies of the IgG class and to IgG-antigen complexes. When the patient's plasma is passed through the column, these antibodies and immune complexes are removed. Treatment should be reserved for patients with moderate to severe RA who have been refractory to or intolerant of methotrexate and other DMARDs. The most common adverse effects are transient increases in joint swelling, joint pain, and fatigue.

73.7.6.1

KEY POINTS

- The objectives of RA therapy are to (1) reduce symptoms (pain, inflammation, stiffness), (2) maintain joint function and range of motion, (3) minimize systemic involvement, and (4) delay disease progression.
- RA is treated with three classes of drugs: (1) nonsteroidal anti-inflammatory drugs (NSAIDs), (2) glucocorticoids, and (3) disease-modifying antirheumatic drugs (DMARDs).
- DMARDs can be divided into two groups: (1) nonbiologic DMARDs, which are small molecules produced by conventional chemical techniques; and (2) biologic DMARDs, which are large molecules produced by recombinant DNA technology.
- NSAIDs act quickly to relieve symptoms, but do not prevent joint injury and do not delay disease progression.
- Glucocorticoids act quickly and may delay disease progression.

- DMARDs delay disease progression and reduce joint injury, but onset of effects is delayed.
- In the past, treatment of RA was initiated with NSAIDs alone; DMARDs were added only after NSAIDs could no longer control symptoms. Today, guidelines recommend initiating DMARDs within 3 months of RA diagnosis; the rationale is to delay joint degeneration and retard disease progression. During the DMARD latency period, NSAIDs (and sometimes glucocorticoids) are used to control symptoms.
- NSAIDs are much safer than glucocorticoids and DMARDs.
- Because glucocorticoids cause serious toxicity when used long term, they are generally reserved for short-term use to (1) control symptoms while responses to DMARDs are developing or (2) supplement other drugs when symptoms flare.
- Second-generation NSAIDs (COX-2 inhibitors, coxibs) may cause less GI ulceration than first-generation NSAIDs, but are more expensive.
- The doses of NSAIDs used for RA are much higher than the doses used to relieve pain or fever.
- Methotrexate, a nonbiologic DMARD, acts relatively quickly and is considered the DMARD of first choice by most rheumatologists.
- Etanercept, a biologic DMARD, neutralizes TNF, and thereby suppresses the autoimmune attack on joints.
- Etanercept and other TNF antagonists pose a risk of serious infections (eg, bacterial sepsis, invasive fungal infections, TB), and are associated with rare cases of severe skin reactions.

⁷⁴CHAPTER 73 Drug Therapy of Gout

Our topic for the chapter is gout, a painful inflammatory disorder seen mainly in men. Symptoms result from deposition of uric acid crystals in joints. We begin by discussing the pathophysiology of gout, after which we discuss the drugs used for treatment.

^{74.1} PATHOPHYSIOLOGY OF GOUT

Gout is a recurrent inflammatory disorder characterized by *hyperuricemia* (high blood levels of uric acid) and episodes of *severe joint pain*, typically in the large toe. Hyperuricemia—defined as blood uric acid above 7 mg/dL in men, or 6 mg/dL in women—can occur through two mechanisms: (1) excessive production of uric acid and (2) impaired renal excretion of uric acid. Acute attacks are precipitated by crystallization of sodium urate (the sodium salt of uric acid) in the synovial space. Deposition of urate crystals promotes inflammation by triggering a complex series of events. A key feature of the inflammatory process is infiltration of leukocytes; once inside the synovial cavity, these cells phagocytize urate crystals and then break down, causing release of destructive lysosomal enzymes. When hyperuricemia is chronic, large and gritty deposits, known as *tophi*, may form in the affected joint. Also, deposition of urate crystals in the kidney may cause renal damage. Fortunately, when gout is detected and treated early, the disease can be arrested and these chronic sequelae avoided.

^{74.2} OVERVIEW OF DRUG THERAPY

In patients with gout, drugs are used in two ways. First, they are given short term to relieve symptoms of an acute gouty attack. Second, they are given long term to lower blood levels of uric acid.

In patients with infrequent flare-ups (less than 3 per year), treatment of symptoms may be all that is needed. Nonsteroidal anti-inflammatory drugs (NSAIDs) are considered first-line agents for relieving pain of an acute gouty attack. Glucocorticoids are an acceptable option. In the past, colchicine was considered a drug of choice for acute gout—even though it has a poor risk/benefit ratio. Today, colchicine is generally reserved for patients who are unresponsive to or intolerant of safer agents.

In patients with chronic gout, tophaceous gout, or frequent gouty attacks (3 or more per year), drugs for hyperuricemia are indicated. Two types of drugs may be employed: agents that decrease uric acid production and agents that increase uric acid excretion. Agents that increase urate excretion are known as *uricosuric* drugs.

74.3 DRUGS FOR ACUTE GOUTY ARTHRITIS

74.3.1 Nonsteroidal Anti-inflammatory Drugs

For acute gouty arthritis, NSAIDs are considered agents of first choice. Compared with colchicine, NSAIDs are better tolerated and their effects are more predictable. Benefits derive from suppressing inflammation. Treatment should start as soon as possible after symptom onset. Most patients experience marked relief within 24 hours; swelling subsides over the next few days. Adverse effects of NSAIDs include GI ulceration, impaired renal function, fluid retention, and increased risk of cardiovascular events. However, since the duration of treatment is brief, the risk of these complications is low. Which NSAID should be used? There is no good evidence that any NSAID is superior to the others for treatment of gout. Commonly used drugs and dosages are as follows:

- Indomethacin [Indocin]—50 mg 4 times daily for 3 to 6 days
- Naproxen [Naprosyn]—500 mg 2 or 3 times daily for 3 to 6 days
- Diclofenac sodium [Voltaren]—50 mg 3 times daily for 3 to 6 days

NSAIDs are discussed at length in [Chapter 70](#).

74.3.2 Glucocorticoids

Glucocorticoids (eg, prednisone), given PO or IM, are highly effective for relieving an acute gouty attack—although NSAIDs are generally preferred. Candidates for glucocorticoid therapy include patients who are hypersensitive to NSAIDs, patients who have medical conditions that contraindicate use of NSAIDs, and patients with severe gout that is unresponsive to NSAIDs. Because of their effects on carbohydrate metabolism, glucocorticoids should be avoided in patients prone to hyperglycemia. For oral therapy, prednisone can be used. The dosage is 20 to 40 mg on day 1, followed by progressively smaller doses over the next 8 days. For IM therapy, triamcinolone acetonide can be used. The dosage is 60 mg every 1 to 4 days as needed. Glucocorticoids are discussed at length in [Chapter 71](#).

864

865

74.3.3 Colchicine

Colchicine is an anti-inflammatory agent whose effects are specific for gout. The drug is not active against other inflammatory disorders. Colchicine is not an analgesic and does not relieve pain in conditions other than gout. The drug's principal adverse effect is GI toxicity. In the past,

Pharmacology for Nursing Care, 7th Edition

colchicine was considered a first-line drug for gout. However, owing to the availability of safe and effective alternatives, its use has declined.

74.3.3.1 Therapeutic Use

Colchicine has two distinct applications in gout. First, it can be used to treat an acute gouty attack. Second, it can help prevent attacks in chronic gout.

74.3.3.1.1 Acute Gouty Arthritis.

When taken in large doses, colchicine produces dramatic relief of acute gouty attacks. Within hours, patients whose pain had made movement impossible are able to walk. Inflammation disappears completely within 2 to 3 days. Administration may be IV or PO. With IV administration, symptoms resolve sooner than with oral administration, and GI reactions are minimal. However, if extravasation occurs, IV colchicine can cause severe local necrosis.

74.3.3.1.2 Prophylaxis of Gouty Attacks.

When taken during asymptomatic periods, low doses of colchicine (eg, 0.6 mg/day) can decrease the frequency and intensity of acute flare-ups. Colchicine is also given for prophylaxis when therapy with antihyperuricemic agents is initiated. Why? Because there is a tendency for gouty episodes to increase at this time.

74.3.3.2 Mechanism of Action

We do not fully understand the mechanisms by which colchicine relieves or prevents episodes of gout. It is clear that the drug does not influence either the production or excretion of uric acid. An important contributory action is inhibition of leukocyte infiltration; in the absence of leukocytes, there is no phagocytosis of uric acid and no subsequent release of lysosomal enzymes. Leukocyte migration is inhibited by disruption of microtubules, the structures required for cellular motility. Because microtubules are also required for cell division, colchicine is toxic to any tissue that has a large percentage of proliferating cells. Disruption of cell division underlies the GI toxicity of the drug.

74.3.3.3 Pharmacokinetics

Colchicine is readily absorbed following oral administration. At therapeutic doses, large amounts re-enter the intestine via the bile and intestinal secretions. The drug is excreted primarily in the feces.

74.3.3.4 Adverse Effects

The most characteristic side effects—*nausea, vomiting, diarrhea, and abdominal pain*—are seen in up to 80% of patients. These responses, which occur during treatment of acute gouty attacks, result from injury to the rapidly proliferating cells of the GI epithelium. If GI symptoms develop, colchicine should be discontinued immediately, regardless of the status of joint pain.

Intravenous colchicine can be especially hazardous. Risks include bone marrow suppression, renal failure, hepatic necrosis, seizures, and death. Because of these risks, many clinicians feel IV colchicine should not be used.

74.3.3.5 Precautions

Colchicine should be used with care in elderly and debilitated patients, and in patients with cardiac, renal, and GI diseases. Colchicine is classified in Food and Drug Administration Pregnancy Risk Category C (for oral use) and Category D (for IV use). Because the drug can cause fetal harm, it should be avoided during pregnancy, unless the perceived benefits outweigh the potential risk.

74.3.3.6 Preparations, Dosage, and Administration

Colchicine is available in 0.6-mg oral tablets and in solution (0.5 mg/mL in 2-mL ampules) for IV use.

74.3.3.6.1 Oral.

For an acute gouty attack, the dosage is 1.2 mg initially followed by 1.2 mg every 1 to 2 hours. Administration is repeated until pain is relieved or until signs of GI toxicity appear. The total dose should not exceed 8 mg. The usual dosage for prophylaxis is 0.6 mg/day. The dosage for aborting an impending attack is 0.6 mg every 2 hours.

74.3.3.6.2 Intravenous.

Intravenous administration can be used to abort an acute gouty attack. In many cases, relief can be achieved with a single 2-mg injection. To minimize vascular injury, the contents of 1 ampule (1 mg) should be diluted in 20 mL of sterile 0.9% sodium chloride injection and then injected slowly (over 5 minutes or more). Extravasation can cause local necrosis with sloughing of skin and subcutaneous tissue. Accordingly, care must be taken to ensure that the IV line remains in place.

74.4 DRUGS FOR HYPERURICEMIA

Four drugs—*allopurinol*, *febuxostat*, *probenecid*, and *sulfinpyrazone*—are used to reduce uric acid levels. Allopurinol and febuxostat inhibit uric acid formation, whereas probenecid and sulfinpyrazone increase uric acid excretion. With all four drugs, the goal is to lower plasma uric acid to 7 mg/dL or less in men and 6 mg/dL or less in women. Treatment is long term. These drugs lack anti-inflammatory and analgesic actions, and hence are not useful against an acute gouty attack.

74.4.1 Allopurinol

74.4.1.1 Therapeutic Uses

Allopurinol [Zyloprim] is the current drug of choice for *chronic tophaceous gout*. By reducing blood uric acid levels, the drug prevents tophus formation and causes regression of tophi that have already formed, thereby allowing joint function to improve. Reversal of hyperuricemia also decreases the risk of nephropathy from deposition of urate crystals in the kidney. During the initial months of treatment, allopurinol may *increase* the incidence of acute gouty arthritis. The risk of an attack can be reduced by concurrent treatment with low-dose colchicine.

Allopurinol can be used for hyperuricemia that develops secondary to cancer chemotherapy and to certain blood dyscrasias, such as polycythemia vera, myeloid metaplasia, and leukemia. Why does hyperuricemia develop during chemotherapy? Because, when cells die, breakdown of DNA releases uric acid. To minimize hyperuricemia, allopurinol should be administered before chemotherapy starts.

74.4.1.2 Mechanism of Action

Allopurinol and its major metabolite (alloxanthine) inhibit *xanthine oxidase* (XO), an enzyme required for uric acid formation. As indicated in [Figure 73-1](#), XO catalyzes the final two reactions that lead to formation of uric acid from breakdown products of DNA.

74.4.1.3 Pharmacokinetics

Allopurinol is well absorbed following oral dosing, and then undergoes rapid conversion to alloxanthine, an active metabolite. Alloxanthine is then eliminated slowly by renal excretion. Because alloxanthine has a prolonged half-life (about 25 hours), therapeutic effects are long lasting. Consequently, once-a-day dosing is adequate.

74.4.1.4 Adverse Effects

Allopurinol is generally well tolerated. The most serious toxicity is a rare but potentially fatal *hypersensitivity syndrome*, characterized by rash, fever, eosinophilia, and dysfunction of the liver and kidneys. If rash or fever develops, allopurinol should be discontinued immediately. Many patients recover spontaneously; others may require hemodialysis or glucocorticoid therapy.

Mild side effects seen occasionally include *GI reactions* (nausea, vomiting, diarrhea, abdominal discomfort) and *neurologic effects* (drowsiness, headache, metallic taste). Prolonged use (more than 3 years) may cause *cataracts*; periodic ophthalmic examinations are recommended.

74.4.1.5 Drug Interactions

Allopurinol can inhibit hepatic drug-metabolizing enzymes, thereby delaying the inactivation of other drugs. This interaction is of particular concern for patients taking *warfarin*, whose dosage should be reduced. If possible, com

865

866

Figure 73-1 Reduction of uric acid formation by allopurinol.

bined use with *mercaptopurine* or *azathioprine* should be avoided. Why? Because both of these anticancer drugs are substrates for XO, and hence could accumulate to toxic levels in the presence of allopurinol. If combined use can't be avoided, then dosages of mercaptopurine and azathioprine should be greatly reduced (by as much as 75%). Theophylline, a drug for asthma, is also a substrate for XO, and hence should not be combined with allopurinol. The combination of allopurinol plus *ampicillin* is associated with a high incidence of rash; if rash develops, allopurinol should be discontinued immediately.

74.4.1.6 Preparations, Dosage, and Administration

Allopurinol [Zyloprim] is supplied in 100- and 300-mg tablets.

For *chronic tophaceous gout*, the objective is to decrease plasma urate to 7 mg/dL or less in males and 6 mg/dL or less in females. Dosages should be individualized. In patients with normal renal function, the usual initial dosage is 100 mg once a day. Dosage is then increased by 50- to 100-mg increments every few weeks until the urate target level has been reached, usually at a dose of 300 mg/day. The maximum approved dosage is 800 mg/day. To prevent renal injury, fluid intake should be sufficient to maintain a urine flow of at least 2 L/day. Since allopurinol is eliminated by the kidneys, dosage should be reduced in patients with renal impairment.

For *secondary hyperuricemias in adults*, dosages range from 100 to 800 mg/day. For *children* ages 6 to 10 years who are undergoing cancer chemotherapy, the recommended dosage is 300 mg daily. The dosage for children under 6 years is 150 mg/day.

74.4.2 Febuxostat

Febuxostat [Uloric], approved in 2009, is the first new drug for gout in over 40 years. Like allopurinol, febuxostat lowers urate levels by inhibiting XO. In clinical trials febuxostat (40 or 80 mg/day) was at least as effective as allopurinol. As with allopurinol, symptoms of gout may flare during initial therapy. Accordingly, patients should receive prophylactic NSAIDs or colchicine for up to 6 months after starting treatment. Adverse effects of febuxostat, which are uncommon, include liver function abnormalities (4.6% to 6.6%), nausea (1.2%), arthralgia (0.7% to 1.1%), and rash (0.5% to 1.6%). High doses (80 mg/day) are associated with a small increase in cardiovascular events. Like allopurinol, febuxostat should not be combined with drugs that are substrates for XO, especially theophylline, mercaptopurine, and azathioprine. In contrast to allopurinol, which is eliminated entirely by the kidneys, febuxostat is eliminated by hepatic metabolism, followed by renal excretion. Febuxostat is supplied in 40- and 80-mg tablets. Dosage is 40 mg/day initially, and can be increased to 80 mg/day if needed. No dosage adjustment is needed for patients with mild to moderate renal or hepatic impairment.

74.4.3 Probenecid

74.4.3.1 Actions and Uses.

Probenecid (generic only) acts on renal tubules to inhibit reabsorption of uric acid. As a result, excretion of uric acid is increased and hyperuricemia is reduced. By lowering plasma urate levels, probenecid prevents formation of new tophi and facilitates regression of existing tophi.

The drug may exacerbate acute episodes of gout, and hence treatment should be delayed until the acute attack has been controlled. During the initial months of therapy, probenecid may induce acute attacks of gout. If an attack occurs, colchicine or indomethacin can be added for relief. In addition to its use in gout, probenecid may be employed to prolong the effects of penicillins and cephalosporins (by delaying their excretion by the kidneys).

74.4.3.2 Adverse Effects.

Probenecid is well tolerated by most patients. Mild *GI effects* (nausea, vomiting, anorexia) occur occasionally. These can be reduced by taking the drug with food. *Hypersensitivity reactions*, usually manifesting as rash, develop in about 4% of patients. *Renal injury* may occur from deposition of urate in the kidney. The risk of kidney damage can be minimized by alkalinizing the urine and consuming 2.5 to 3 L of fluid daily during the first few days of treatment.

74.4.3.3 Drug Interactions.

Aspirin and other *salicylates* interfere with the uricosuric action of probenecid. Accordingly, probenecid should not be used concurrently with these drugs. Probenecid inhibits the renal excretion of several drugs, including *indomethacin* and *sulfonamides*; dosages of these agents may require reduction.

74.4.3.4 Preparations, Dosage, and Administration.

Probenecid is supplied in 500-mg tablets. The initial dosage for adults is 250 mg twice daily for 1 week. The maintenance dosage is 500 mg twice daily. Administration with food decreases GI upset. Therapy should not be initiated during an acute gouty attack.

74.4.4 Sulfinpyrazone

74.4.4.1 Actions and Uses.

Like probenecid, sulfinpyrazone [Anturane] acts in renal tubules to inhibit reabsorption of uric acid, and thereby enhances uric acid excretion. The drug is used to reduce hyperuricemia in patients with *chronic* gout. Sulfinpyrazone lacks anti-inflammatory and analgesic actions and is of no benefit during an acute gouty attack. During the first few months of therapy, the drug may precipitate an acute gouty attack. Concurrent use of low-dose colchicine can reduce this risk.

866

867

74.4.4.2 Adverse Effects.

Gastrointestinal effects (nausea, abdominal pain) are common but rarely necessitate stopping treatment. These reactions can be reduced by administering sulfinpyrazone with meals.

Sulfinpyrazone can *exacerbate GI ulcers*, and hence is contraindicated in patients with active ulcers and should be used with caution in patients with a history of ulcer disease. As with probenecid, there is a risk of *uric acid deposition in the kidney*, which can be reduced by alkalinizing the urine and having the patient ingest large volumes of fluids.

74.4.4.3 Drug Interactions.

Salicylates will counteract the uricosuric action of sulfinpyrazone, and hence should not be taken concurrently. Sulfinpyrazone can inhibit hepatic metabolism of *tolbutamide* (causing hypoglycemia) and *warfarin* (causing bleeding tendencies). If combined with sulfinpyrazone, these drugs may require a reduction in dosage.

74.4.4.4 Preparations, Dosage, and Administration.

Sulfinpyrazone [Anturane] is supplied in 100-mg tablets and 200-mg capsules. Administration with meals decreases GI side effects. The initial adult dosage is 100 to 200 mg twice daily. Maintenance dosages range from 200 to 800 mg/day, given in divided doses.

74.4.4.4.1

KEY POINTS

- Gout is an inflammatory disorder characterized by hyperuricemia and episodic joint pain, typically in the big toe.
- NSAIDs and glucocorticoids are preferred drugs for treating acute gouty attacks. Benefits derive mainly from anti-inflammatory actions.
- Four drugs—allopurinol, febuxostat, probenecid, and sulfinpyrazone—are used long term to prevent gouty attacks. Benefits derive from lowering plasma uric acid levels. These drugs lack anti-inflammatory and analgesic actions, and hence are not effective against acute gouty attacks.
- Allopurinol and febuxostat lower plasma urate by decreasing urate production. How? By inhibiting xanthine oxidase, an enzyme that forms uric acid from breakdown products of DNA.
- Probenecid and sulfinpyrazone lower plasma urate by promoting renal urate excretion. How? By inhibiting tubular reabsorption of urate.

⁷⁵CHAPTER 74 Drugs Affecting Calcium Levels and Bone Mineralization

It is difficult to exaggerate the biologic importance of calcium, an element critical to blood coagulation and to the functional integrity of bone, nerve, muscle, and the heart. Because these calcium-dependent processes can be seriously disrupted by alterations in calcium availability, calcium levels must stay within narrow limits. To regulate calcium, the body employs three factors: parathyroid hormone, vitamin D, and calcitonin. When these regulatory mechanisms fail, hypercalcemia or hypocalcemia results.

Our discussion of calcium and related drugs has four parts. First, we review calcium physiology. Second, we discuss the syndromes produced by disruption of calcium metabolism. Third, we discuss the pharmacologic agents used to treat calcium-related disorders. And fourth, we consider osteoporosis, the most common calcium-related disorder.

^{75.1}CALCIUM PHYSIOLOGY

^{75.1.1} Functions and Daily Requirements

Calcium is critical to the function of the skeletal system, nervous system, muscular system, and cardiovascular system. In the skeletal system, calcium is required for the structural integrity of bone. In the nervous system, calcium helps regulate axonal excitability and transmitter release. In the muscular system, calcium participates in excitation-contraction coupling and contraction itself. In the cardiovascular system, calcium plays a role in myocardial contraction, vascular contraction, and coagulation of blood.

TABLE 74-1 Daily Calcium Intake by Life-Stage Group

Life-Stage Group [*]	Calcium Intake (mg/day)	
	Adequate Level [†]	Tolerable Upper Level [‡]
0–6 months	210	ND [§]
6–12 months	270	ND
1–3 years	500	2500
4–8 years	800	2500
9–18 years	1300	2500
19–50 years	1000	2500
51 years and older	1200	2500

Adapted from Food and Nutrition Board: Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D and Fluoride. Washington, DC: National Academy Press, 1997.

* Values apply to males and females. For females, there is no change during pregnancy or lactation.

† Values for Adequate Intake (AI) are derived through experimental or observational data that show a mean calcium intake that appears to sustain a desired indicator of health, such as calcium retention in bone, for most members of the population group. AI values are employed for calcium because there are insufficient data to derive an Estimated Average Requirement (EAR). AI values are *not* equivalent to Recommended Dietary Allowances (RDAs).

‡ The Tolerable Upper Intake Level (UI) is defined as the maximum intake that is not likely to pose a risk of adverse health effects in almost all healthy individuals in a specified group. The UI is not intended to be a recommended level of intake. There is no established benefit to consuming calcium above the AI.

§ ND = upper limit not determined owing to lack of data on adverse effects in this age group and concern regarding inability to handle excess calcium. To prevent excessive levels, calcium intake should be from food only.

Given the widespread functions of calcium, adequate calcium intake is essential. [Table 74-1](#) summarizes recommendations for calcium intake issued by the Food and Nutrition Board of the Institute of Medicine of the National Academy of Sciences in 1997. With the exception of children less than 4 years old, no one should consume less than 800 mg of calcium each day, and

most people need 1000 mg/day or more. However, according to the Continuing Survey of Food Intakes of Individuals, the majority of Americans are not meeting this goal. Therefore, to minimize the risk of osteoporosis and other calcium-deficiency disorders, we need to increase our dietary calcium or take calcium supplements.

868

75.1.2 Body Stores

869

75.1.2.1 Calcium in Bone.

The vast majority of calcium in the body (more than 98%) is present in bone. Calcium is deposited in bone in the form of hydroxyapatite crystals. It is important to appreciate that bone—and the calcium it contains—is not static. Rather, bone undergoes continuous remodeling, a process in which old bone is resorbed, after which new bone is laid down ([Fig. 74-1](#)). The cells that resorb old bone are called *osteoclasts* and the cells that deposit new bone are called *osteoblasts*. Both cell types originate in the bone marrow. In adults, about 25% of trabecular bone (the honeycomb-like material in the center of bones) is replaced each year. In contrast, only 3% of cortical bone (the dense material that surrounds trabecular bone) is replaced annually.

75.1.2.2 Calcium in Blood.

The normal value for total serum calcium is 10 mg/dL (2.5 mmol/L, 5 mEq/L). Of this total, about 50% is bound to proteins and other substances, and hence is unavailable for use. The remaining 50% is present as free, ionized calcium. This free calcium is the form that participates in physiologic processes.

75.1.3 Absorption and Excretion

75.1.3.1 Absorption.

Absorption of calcium takes place in the small intestine. Under normal conditions, about one-third of ingested calcium is absorbed. Absorption is increased by parathyroid hormone (PTH) and vitamin D (see below). In contrast, glucocorticoids decrease calcium absorption. Also, a variety of foods (eg, spinach, whole-grain cereals, bran) contain compounds that can interfere with calcium absorption.

75.1.3.2 Excretion.

Calcium excretion is primarily renal. The amount lost is determined by glomerular filtration and by the extent of tubular reabsorption. Excretion can be reduced by PTH and vitamin D (see below). Conversely, excretion can be increased with loop diuretics (eg, furosemide) and by loading with sodium. Calcitonin also augments calcium elimination (see below). In addition to renal excretion, substantial amounts of calcium can be lost through lactation.

75.1.4 Physiologic Regulation of Calcium Levels

Blood levels of calcium are tightly controlled. The body maintains calcium levels by adjusting the rates of three processes: (1) absorption of calcium from the intestine, (2) excretion of calcium by the kidney, and (3) resorption or deposition of calcium in bone. Regulation of these processes is under the control of three factors: *parathyroid hormone*, *vitamin D*, and *calcitonin*. It should be noted that preservation of plasma calcium levels takes priority over the calcium requirements of bone. Hence, if serum calcium is low, calcium will be resorbed from bone and transferred to the blood—even if resorption compromises the structural integrity of bone.

75.1.4.1 Parathyroid Hormone.

Release of PTH is regulated primarily by calcium, acting through calcium-sensing receptors on cells of the parathyroid gland. When calcium levels are *high*, activation of the calcium-sensing receptors is *increased*, causing secretion of PTH to be *suppressed*. Conversely, when calcium levels are low, receptor activation is reduced, causing PTH release to rise. PTH then restores calcium to normal levels by three mechanisms: it (1) promotes calcium resorption from bone; (2) promotes reabsorption of calcium that had

Figure 74-1 **Bone remodeling cycle.** **A**, Quiescent bone with lining cells covering the surface. **B**, Resorption of old bone by multinucleated osteoclasts. **C**, Osteoblasts migrate to the absorption site. **D**, Osteoblasts deposit osteoid, a matrix of collagen and other proteins. **E**, Osteoid undergoes calcification.

869

been filtered by the glomerulus; and (3) activates vitamin D, and thereby promotes absorption of calcium from the intestine. In addition to its effects on calcium, PTH reduces plasma levels of phosphate.

870

75.1.4.2 Vitamin D.

Vitamin D is similar to PTH in two ways. First, both agents increase plasma calcium levels. Second, they increase calcium levels by the same mechanisms: (1) increasing calcium resorption from bone, (2) decreasing calcium excretion by the kidney, and (3) increasing calcium absorption from the intestine. Vitamin D differs from PTH in that vitamin D elevates

plasma levels of phosphate, whereas PTH reduces levels of phosphate. The actions of vitamin D are discussed further below.

75.1.4.3 Calcitonin.

Calcitonin, a hormone produced by the thyroid gland, decreases plasma levels of calcium. Hence, calcitonin acts in opposition to PTH and vitamin D. Calcitonin is released from the thyroid gland when calcium levels in blood rise too high. Calcitonin lowers calcium levels by inhibiting the resorption of calcium from bone and increasing calcium excretion by the kidney. Unlike PTH and vitamin D, calcitonin does not influence calcium absorption.

75.2 CALCIUM-RELATED PATHOPHYSIOLOGY

75.2.1 Hypercalcemia

75.2.1.1 Clinical Presentation.

Hypercalcemia is usually asymptomatic. When symptoms *are* present, they often involve the kidney (damage to tubules and collecting ducts, resulting in polyuria, nocturia, and polydipsia), GI tract (nausea, vomiting, and constipation), and central nervous system (lethargy and depression). Hypercalcemia may also result in dysrhythmias and deposition of calcium in soft tissues.

75.2.1.2 Causes.

Hypercalcemia may arise from a variety of causes. Life-threatening elevations in calcium are most often the result of cancer. Hyperparathyroidism is another common cause of severe hypercalcemia (see below). Additional causes include vitamin D intoxication, sarcoidosis, and use of thiazide diuretics.

75.2.1.3 Treatment.

Calcium levels can be lowered with drugs that (1) promote urinary excretion of calcium, (2) decrease mobilization of calcium from bone, (3) decrease intestinal absorption of calcium, and (4) form complexes with free calcium in blood. For severe hypercalcemia, initial therapy consists of replacing lost fluid with IV saline, followed by diuresis using IV saline and a loop diuretic (eg, furosemide). Other agents for lowering calcium include inorganic phosphates (which promote calcium deposition in bone and reduce calcium absorption); edetate disodium (EDTA, which binds calcium and promotes its excretion); glucocorticoids (which reduce

intestinal absorption of calcium); and a group of drugs—calcitonin, bisphosphonates (eg, pamidronate), inorganic phosphates, and gallium nitrate—that inhibit resorption of calcium from bone. A relatively new drug—cinacalcet—can be used for hypercalcemia associated with hyperparathyroidism.

75.2.2 Hypocalcemia

75.2.2.1 Clinical Presentation and Cause.

Hypocalcemia increases neuromuscular excitability. As a result, tetany, convulsions, and spasm of the pharynx and other muscles may occur. Hypocalcemia is caused most often by a deficiency of either PTH, vitamin D, or dietary calcium.

75.2.2.2 Treatment.

Severe hypocalcemia is corrected by infusing an IV calcium preparation, usually calcium gluconate. Once calcium levels have been restored, an oral calcium salt (eg, calcium citrate) can be given for maintenance. Vitamin D should be included in the regimen if there is a coexisting deficiency.

75.2.3 Rickets

Rickets is a disease of childhood brought on by either insufficient dietary vitamin D or limited exposure to sunlight. The disease is extremely rare in the United States. Rickets is characterized by defective bone growth and skeletal deformities. Bone abnormalities are caused as follows: (1) vitamin D deficiency results in reduced calcium absorption; (2) in response to hypocalcemia, PTH is released; (3) PTH restores serum calcium by promoting calcium resorption from bone, thereby causing bones to soften; and (4) stress on the softened bones caused by bearing weight results in deformity. Treatment consists of vitamin D replacement therapy.

75.2.4 Osteomalacia

Osteomalacia is the adult counterpart of rickets. Like rickets, this condition results from insufficient vitamin D. In the absence of vitamin D, mineralization of bone is impaired, resulting in bowing of the legs, fractures of the long bones, and kyphosis (“hunchback” curvature of the spine). In addition, patients may experience diffuse, dull, aching bone pain. Treatment consists of vitamin D replacement therapy.

75.2.5 Osteoporosis

Osteoporosis, the most common disorder of calcium metabolism, is characterized by low bone mass and increased bone fragility. Osteoporosis is discussed at length in a later section.

75.2.6 Paget's Disease of Bone

75.2.6.1 Clinical Presentation.

Paget's disease of bone is a chronic condition seen most frequently in adults over 40. After osteoporosis, Paget's disease is the most common disorder of bone in the United States. The disease is characterized by increased bone resorption and replacement of the resorbed bone with abnormal bone. Increased bone turnover causes elevation in serum alkaline phosphatase (reflecting increased bone deposition) and increased urinary hydroxyproline (reflecting increased bone resorption). It is important to note that alterations in bone homeostasis do not occur evenly throughout the skeleton. Rather, alterations occur locally, most often in the pelvis, femur, spine, skull, and tibia. Although most people with Paget's disease are asymptomatic, about 10% experience bone pain and osteoarthritis. Skeletal deformity may also occur. Bone weakness may lead to fractures. Neurologic complications may occur secondary to compression of the spinal cord, spinal nerves, and cranial nerves. If bone associated with hearing is affected, deafness may result.

75.2.6.2 Treatment.

Asymptomatic patients are usually not treated. Mild pain can be managed with analgesics and anti-inflammatory agents. When the disease is more severe, a bisphosphonate (eg, alendronate) is the treatment of choice. Calcitonin is an alternative. Both agents suppress bone resorption.

75.2.7 Hypoparathyroidism

Reductions in PTH usually result from inadvertent removal of the parathyroid glands during surgery on the thyroid gland. Lack of PTH causes hypocalcemia, which in turn may produce paresthesias, tetany, skeletal muscle spasm, laryngospasm, and convulsions. Symptoms can be relieved with calcium supplements (see *Hypocalcemia* above) and vitamin D.

75.2.8 Hyperparathyroidism

75.2.8.1 Primary Hyperparathyroidism.

Primary hyperparathyroidism usually results from a parathyroid adenoma. The resulting increase in PTH secretion causes hypercalcemia and lowers serum phosphate. Hypercalcemia can cause skeletal muscle weakness, constipation (from decreased smooth muscle tone), and central nervous system (CNS) symptoms (lethargy, depression). Hypercalciuria and hyperphosphaturia are also present and may cause renal calculi. Mobilization of calcium and phosphate from bone may produce bone abnormalities. The only definitive treatment for primary hyperparathyroidism is surgical resection of the parathyroid glands. Hypercalcemia can be managed with calcium-lowering drugs, including cinacalcet [Sensipar], a drug that suppresses PTH secretion.

75.2.8.2 Secondary Hyperparathyroidism.

Secondary hyperparathyroidism is a common complication of chronic kidney disease (CKD), occurring in nearly all patients undergoing dialysis. The disorder is characterized by high levels of PTH and disturbances of calcium and phosphorus homeostasis. Traditionally, the disorder has been managed with vitamin D sterols (eg, ergocalciferol) and calcium-containing phosphate-binding agents. However, these treatments frequently make mineral homeostasis worse. A relatively new drug—cinacalcet [Sensipar]—can reduce PTH levels while having a positive impact on calcium and phosphorus, and hence may become a treatment of choice.

75.3 DRUGS FOR DISORDERS INVOLVING CALCIUM

75.3.1 Calcium Salts

Calcium salts are available in oral and parenteral formulations for treating hypocalcemic states. The various calcium salts differ in their percentage of elemental calcium. These differences must be accounted for when determining dosage.

870

75.3.1.1 Oral Calcium Salts

871

75.3.1.1.1 Therapeutic Uses.

Oral calcium preparations are used to treat *mild hypocalcemia*. In addition, calcium salts are taken as *dietary supplements*. People who may need supplementary calcium include children, adolescents, the elderly, postmenopausal women, and women who are pregnant or breast-

feeding. As discussed in [Chapter 60](#) (see [Box 60-1](#)), calcium supplements may have the added benefit of reducing symptoms of *premenstrual syndrome*. Also, recent data indicate that calcium supplements can produce a significant, albeit modest, reduction in recurrence of *colorectal adenomas*.

75.3.1.1.2 Adverse Effects.

When calcium is taken chronically in high doses (3 to 4 gm/day), *hypercalcemia* can result. Hypercalcemia is most likely in patients who are also receiving large doses of vitamin D. Signs and symptoms include GI disturbances (nausea, vomiting, constipation), renal dysfunction (polyuria, nephrolithiasis), and CNS effects (lethargy, depression). In addition, hypercalcemia may cause cardiac dysrhythmias and deposition of calcium in soft tissue. Hypercalcemia can be minimized with frequent monitoring of plasma calcium content.

75.3.1.1.3 Drug Interactions.

Glucocorticoids (eg, prednisone) reduce absorption of oral calcium. Calcium reduces absorption of *tetracyclines*, and hence these agents should be administered at least 1 hour apart. Similarly, calcium reduces absorption of *thyroid hormone*; to ensure adequate thyroid hormone absorption, these agents should be administered several hours apart. *Thiazide diuretics* decrease renal calcium excretion and may thereby cause hypercalcemia.

75.3.1.1.4 Food Interactions.

Certain foods contain substances that can suppress calcium absorption. One such substance—oxalic acid—is found in spinach, rhubarb, Swiss chard, and beets. Phytic acid, another depressant of calcium absorption, is present in bran and whole-grain cereals. Oral calcium should not be administered with these foods.

75.3.1.1.5 Preparations and Dosage.

The calcium salts available for oral administration are listed in [Table 74-2](#). Note that the dosage required to provide a particular amount of elemental calcium differs among preparations. Calcium carbonate, for example, has the highest percentage of calcium. Chewable tablets are preferred to standard tablets because of more consistent bioavailability. Bioavailability of *calcium citrate* appears especially good, owing to high solubility. When calcium supplements are taken, total daily calcium intake (dietary plus supplemental) should equal the values in [Table 74-1](#). To help ensure adequate absorption, no more than 600 mg should be consumed at one time.

75.3.1.2 Parenteral Calcium Salts

75.3.1.2.1 Therapeutic Use.

Parenteral calcium salts are given to raise calcium levels rapidly in patients with symptoms of severe hypocalcemia (ie, hypocalcemic tetany). Only two parenteral preparations are available: *calcium chloride* and *calcium gluconate*. A third product—*calcium gluceptate*—has been withdrawn. Intravenous calcium gluconate is preferred to calcium chloride.

75.3.1.2.2 Adverse Effects.

Calcium chloride is highly irritating. Intramuscular injection may cause necrosis and sloughing, and hence this route must never be used. When the drug is administered IV, care must be taken to avoid extravasation, because local infiltration can produce severe injury. Although less irritating than calcium chloride, *calcium gluconate* can produce pain, sloughing, and abscess formation if administered IM. Overdose with either calcium salt can produce signs and symptoms of hypercalcemia (weakness, lethargy, nausea, vomiting, coma, and possibly death).

75.3.1.2.3 Drug Interactions.

Parenteral calcium may cause severe bradycardia in patients taking *digoxin*. Accordingly, calcium infusions should be done slowly and cautiously in these patients. Several classes of compounds—*phosphates*, *carbonates*, *sulfates*, and *tartrates*—may cause calcium to precipitate, and hence should not be added to parenteral calcium solutions.

75.3.1.2.4 Dosage and Administration.

Both parenteral calcium salts are given IV. Solutions of these salts should be warmed to body temperature prior to administration. Intravenous injections should be done slowly (0.5 to 2 mL/min). Dosage forms and dosages are summarized in [Table 74-3](#).

75.3.2 Vitamin D

The term *vitamin D* refers to two compounds: *ergocalciferol* (vitamin D₂) and *cholecalciferol* (vitamin D₃). Vitamin D₃ is the form of vitamin D produced naturally in humans when our skin is exposed to sunlight. Vitamin D₂ is a form of vitamin D that occurs in plants. Vitamin D₂ is used as a prescription drug and to fortify foods. Both forms are used in over-the-counter supplements.

871

872

Pharmacology for Nursing Care, 7th Edition

It is important to note that both forms of vitamin D produce nearly identical biologic effects. Therefore, rather than distinguishing between them, we will use the term *vitamin D* to refer to vitamins D₂ and D₃ collectively.

TABLE 74-2 Oral Calcium Salts

Generic Name	Trade Name	Calcium Content	Dose Providing 1000 mg Calcium
Calcium acetate	PhosLo	25%	4 gm
Calcium carbonate	Tums, Rolaids, others	40%	2.6 gm
Calcium citrate	Citracal	21%	4.8 gm
Calcium glubionate	Calcionate, Calciquid	6.6%	15.2 gm
Calcium gluconate*	—	9%	11 gm
Calcium lactate	Cal-lac	13%	7.6 gm
Tricalcium phosphate	Posture	39%	2.6 gm

* Also available in parenteral form (see [Table 74-3](#)).

TABLE 74-3 Parenteral Calcium Salts

Generic Name	Dosage Form	Calcium per mL of Solution	Route	Usual Adult Dosage Range
Calcium chloride	10% solution	27 mg	IV	5–10 mL (135–270 mg Ca)
Calcium gluconate*	10% solution	9 mg	IV	5–20 mL (45–180 mg Ca)
Calcium gluceptate†	22% solution	18 mg	IV	5–20 mL (90–360 mg Ca)
			IM	2–5 mL (36–90 mg Ca)

* Also available in an oral formulation (see [Table 74-2](#)).

† No longer available in the United States.

75.3.2.1 Physiologic Actions

Vitamin D is an important regulator of calcium and phosphorus homeostasis. Vitamin D increases blood levels of both elements, primarily by increasing their absorption from the intestine and promoting their mobilization from bone. In addition, vitamin D reduces renal

excretion of calcium and phosphate (although the quantitative significance of this effect is not clear). With usual doses of vitamin D, there is no net loss of calcium from bone. However, vitamin D *can* promote bone decalcification if serum calcium concentrations cannot be maintained by increasing intestinal calcium absorption.

75.3.2.2 Sources and Daily Requirements

75.3.2.2.1 Sources.

Vitamin D is obtained through the diet and by exposure to sunlight. With the exception of shiitake mushrooms and oily fish (eg, salmon, tuna), natural foods have very little vitamin D. Accordingly, dietary vitamin D is obtained mainly through vitamin D–fortified foods, especially cereals, milk, yogurt, margarine, cheese, and orange juice.

75.3.2.2.2 Adult Requirements.

In 1997, the Institute of Medicine of the National Academy of Sciences issued revised guidelines for vitamin D intake. They recommend 200 international units (IU)/day for adults age 50 and under, 400 IU/day for those 51 to 70, and 600 IU/day for those over 70. However, recent data suggest these recommendations are too low. Yes, the recommendations are adequate to prevent obvious problems (rickets and osteomalacia), but they are probably inadequate for optimum health. Hence, some experts recommend that intake be increased to 400 to 800 IU/day for adults under age 50, and 800 to 1000 IU/day for adults age 50 and up.

Most older adults don't get enough vitamin D. They don't get enough sun exposure to make vitamin D, and they don't drink enough milk (the major dietary source of vitamin D) to meet daily requirements. Accordingly, older adults should use vitamin D *supplements*: 400 IU/day for those under 70, and 600 IU/day for those over 70.

75.3.2.2.3 Pediatric Requirements.

Recommendations for pediatric vitamin D intake were recently increased. According to the old guidelines, issued by the Institute of Medicine in 1997, all children should get 200 IU of vitamin D/day. However, in 2008, the American Academy of Pediatrics (AAP) doubled that recommendation, saying that all children—from infants to teenagers—should get 400 IU/day. Furthermore, since many children cannot get this amount from sun exposure and dietary sources, the AAP recommends that children in the following groups take 400 IU/day as supplements:

- Infants who receive less than 1 L/day of vitamin D–fortified formula (breast milk alone cannot supply enough vitamin D)
- Children older than 1 year who drink less than 1 L/day of vitamin D–fortified milk
- Adolescents who receive less than 400 IU/day of vitamin D from dietary sources

When a supplement is used, a children's multivitamin should be chosen. Supplements that contain vitamin D only are too concentrated for children.

75.3.2.3 Vitamin D Deficiency

Vitamin D *deficiency* is defined as a serum concentration of 25-hydroxyvitamin D below 50 nmol/L (20 ng/mL), while a level between 50 and 80 nmol/mL (20 to 32 ng/mL) is considered *insufficient*, but not deficient. A level of 80 nmol/mL (32 ng/mL) or higher is recommended.

The classic manifestations of vitamin D deficiency are *rickets* (in children) and *osteomalacia* (in adults). Signs and symptoms are described above. Taking vitamin D can completely reverse the symptoms of both conditions, unless permanent deformity has already developed.

Recent evidence indicates that the consequences of vitamin D deficiency may go far beyond rickets and osteomalacia. Some studies suggest that deficiency may contribute to autoimmune diseases, including type 1 diabetes, rheumatoid arthritis, multiple sclerosis, and inflammatory bowel disease. Other studies indicate that vitamin D may protect against several cancers, including cancer of the breast, colon, prostate, and ovary—suggesting that the converse may also be true: vitamin D deficiency may predispose to these cancers. In addition, vitamin D may reduce the risk of heart attack, falls (in the elderly), and overall mortality.

75.3.2.4 Activation of Vitamin D

In order to affect calcium and phosphate metabolism, vitamin D must first undergo activation. The extent of activation is carefully regulated, and is determined by calcium availability: When plasma calcium falls, activation of vitamin D is increased. The pathways for activating vitamins D₂ and D₃ are shown in [Figure 74-2](#).

Let's begin by focusing on vitamin D₃, the natural human vitamin. As shown in [Figure 74-2](#), vitamin D₃ (cholecalciferol) is produced in the skin through the action of sunlight on provitamin D₃ (7-dehydrocholesterol). Neither provitamin D₃ nor vitamin D₃ itself possesses significant biologic activity. In the next reaction, enzymes in the liver convert cholecalciferol into

calcifediol; calcifediol serves as a transport form of vitamin D₃ and possesses only slight biologic activity. In the final step, calcifediol is converted into the highly active calcitriol. This reaction occurs in the kidney and can be stimulated by (1) PTH, (2) a drop in dietary vitamin D, and (3) a fall in plasma levels of calcium.

Vitamin D₂ is activated by the same enzymes that activate vitamin D₃. As we saw with vitamin D₃, only the last compound in the series (in this case 1,25-dihydroxyergocalciferol) has significant biologic activity.

75.3.2.5 Pharmacokinetics

As a rule, vitamin D is administered orally and then absorbed from the small intestine. Bile is essential for absorption. In the absence of sufficient bile, IM administration may be required. In the blood, vitamin D is transported complexed with vitamin D-binding protein. Storage of vitamin D occurs primarily in the liver. As discussed, vitamin D undergoes metabolic activation. Reactions that occur in the liver produce the major transport form of vitamin D. A later reaction (in the kidney) produces the fully active form. Excretion of vitamin D is via the bile. Very little leaves in the urine.

75.3.2.6 Viewing Vitamin D as a Hormone

Although referred to as a vitamin, vitamin D has all the characteristics of a hormone. With sufficient exposure to sunlight, the body can manufacture all the vitamin D it needs. Hence, under ideal conditions, external sources of vitamin D appear unnecessary. Following its production in the skin, vitamin D travels to other locations (liver, kidney) for activation. Like other hormones, activated vitamin D then travels to various sites in the body (bone, intestine, kidney) to exert regulatory actions. Also like other hormones, vitamin D undergoes feedback regulation: as plasma levels of calcium fall, activation of vitamin D increases; when plasma levels of calcium return to normal, activation of vitamin D declines.

75.3.2.7 Toxicity (Hypervitaminosis D)

Vitamin D toxicity (hypervitaminosis D) can be produced by doses of vitamin D in excess of 1000 IU/day (in infants) and 50,000 IU/day (in adults). Poisoning occurs most commonly in children; causes include accidental ingestion

872

Figure 74-2 **Vitamin D activation.** Ergosterol is found in yeasts and fungi. 7-Dehydrocholesterol is present in the skin. (Green boxes indicate forms of vitamin D used therapeutically.)

by the child and excessive administration of vitamin D by parents. Doses of potentially toxic magnitude are also encountered clinically. When huge therapeutic doses are used, the margin of safety is small, and patients should be monitored closely for signs of poisoning.

75.3.2.7.1 Clinical Presentation.

Most signs and symptoms of vitamin D toxicity occur secondary to hypercalcemia. Early responses include weakness, fatigue, nausea, vomiting, and constipation. With persistent

hypercalcemia, kidney function is affected, resulting in polyuria, nocturia, and proteinuria. Calcium deposition in soft tissues can damage the heart, blood vessels, and lungs; calcium deposition in the kidneys can cause nephrolithiasis. Very large doses of vitamin D can cause decalcification of bone, resulting in osteoporosis; mobilization of bone calcium can occur despite the presence of high calcium concentrations in blood. In children, vitamin D poisoning can suppress growth for 6 months or longer.

75.3.2.7.2 Treatment.

Treatment consists of immediate discontinuation of vitamin D, high fluid intake, and institution of a low-calcium diet. Glucocorticoids may be given to suppress calcium absorption. If hypercalcemia is severe, renal excretion of calcium can be accelerated using a combination of IV saline and furosemide (a diuretic).

75.3.2.8 Therapeutic Uses

The primary indications for vitamin D are nutritional rickets, osteomalacia, and hypoparathyroidism. Other applications include vitamin D-resistant rickets, vitamin D-dependent rickets, and renal osteodystrophy.

75.3.2.9 Preparations, Dosage, and Administration

There are seven preparations of vitamin D. Four of these—ergocalciferol, cholecalciferol, calcifediol, and calcitriol—are identical to forms of vitamin D that occur naturally. The other three—dihydrotachysterol, paricalcitol, and doxercalciferol—are synthetic derivatives of natural vitamin D. (The naturally occurring preparations are highlighted in green boxes in [Fig. 74-2](#).) Individual vitamin D preparations differ in their clinical applications. Indications for specific preparations are given below.

Vitamin D is almost always administered by mouth. One product—calcitriol—can also be given IV. Dosage is usually prescribed in international units. (One IU is equivalent to the biologic activity in 0.025 mcg of vitamin D₃.) Daily dosages of vitamin D range from 400 IU (for dietary supplementation) to as high as 500,000 IU (for vitamin D-resistant rickets).

75.3.2.9.1 Ergocalciferol (Vitamin D₂).

Ergocalciferol [Calciferol, Drisdol] is approved for hypoparathyroidism, vitamin D-resistant rickets, and familial hypophosphatemia. Ergocalciferol is supplied in capsules (50,000 IU) and an oral solution (8000 IU/mL). The dosage for vitamin D-resistant rickets ranges from

12,000 to 500,000 IU daily. The dosage for hypoparathyroidism ranges from 50,000 to 200,000 IU daily (together with 4 gm of calcium lactate 6 times/day).

75.3.2.9.2 Cholecalciferol (Vitamin D₃).

Vitamin D₃ [Delta-D] is given as a dietary supplement and for prophylaxis and treatment of vitamin D deficiency. Cholecalciferol is available in tablets containing 400 and 1000 IU.

75.3.2.9.3 Calcifediol (25-Hydroxy-D₃).

Calcifediol [Calderol] is indicated for the management of metabolic bone disease and hypocalcemia in patients undergoing chronic renal dialysis. Calcifediol is available in capsules (20 and 50 mcg) for oral use. The initial dosage is 300 to 350 mcg/wk (administered in divided doses on a daily or every-other-day schedule). For maintenance, daily doses of 50 to 100 mcg are usually adequate.

75.3.2.9.4 Calcitriol (1,25-Dihydroxy-D₃).

Calcitriol [Rocaltrol, Calcijex] is indicated for treatment of hypoparathyroidism and management of hypocalcemia in patients undergoing chronic renal dialysis. The drug is supplied in capsules (0.25 and 0.5 mcg), oral solution (1 mcg/mL), and solution for injection (1 and 2 mcg/mL). For dialysis patients, daily doses of 0.5 to 1 mcg are usually adequate. The initial dosage for hypoparathyroidism is 0.25 mcg/day.

75.3.2.9.5 Dihydrotachysterol.

Dihydrotachysterol [DHT] is a synthetic derivative of vitamin D₂. DHT is interesting in that, unlike vitamins D₂ and D₃, it doesn't require renal enzymes for activation; metabolic conversion by the liver is all that is needed for full activity. DHT is indicated for hypoparathyroidism, postoperative tetany, and tetany of unknown cause. DHT is supplied in tablets (0.125, 0.2, and 0.4 mg), capsules (0.125 mg), and an oral solution (0.2 mg/mL).

873

75.3.2.9.6 Doxercalciferol.

Doxercalciferol [Hectorol] is indicated for prevention and treatment of secondary hyperparathyroidism in patients undergoing chronic renal dialysis. The drug is available in capsules (2.5 and 5 mcg) for oral dosing, and solution (2 mcg/mL) for IV dosing. Dosage must be carefully tailored to the patient. With oral administration, treatment begins with 10 mcg 3 times weekly administered at dialysis; dosage may be gradually increased to a

874

maximum of 20 mcg 3 times a week. With IV administration, treatment begins with a 4-mcg IV bolus 3 times weekly at the end of each dialysis session.

75.3.2.9.7 Paricalcitol.

Like doxercalciferol, paricalcitol [Zemlar] is indicated for prevention and treatment of secondary hyperparathyroidism in patients undergoing chronic renal dialysis. The drug is available in capsules (1, 2, and 4 mcg) for oral dosing, and in solution (5 mcg/mL) for dosing by IV bolus. With oral administration, two schedules may be used: (1) once daily and (2) 3 times a week. Treatment begins at 1 to 2 mcg/dose (with the once-daily schedule) or 2 to 4 mcg/dose (with the 3-times-weekly schedule). With IV administration, treatment begins with 0.04 to 0.1 mcg/kg given any time during dialysis—but no more frequently than every other day. Dosage may be gradually increased every 2 to 4 weeks. Doses as high as 0.24 mcg/kg have been used safely.

75.3.3 Calcitonin-Salmon

Calcitonin-salmon [Calcimar, Miacalcin, Fortical], a form of calcitonin derived from salmon, is similar in structure to calcitonin synthesized by the human thyroid. Salmon calcitonin produces the same metabolic effects as human calcitonin but has a longer half-life and greater milligram potency. The drug is available for administration by injection and by nasal spray. Both forms are extremely safe.

75.3.3.1 Actions

Calcitonin has two principal actions: (1) it inhibits the activity of osteoclasts, and thereby decreases bone resorption; and (2) it inhibits tubular resorption of calcium, and thereby increases calcium excretion. As a result of decreasing bone turnover, calcitonin decreases alkaline phosphatase in blood and increases hydroxyproline in urine.

75.3.3.2 Therapeutic Uses

75.3.3.2.1 Osteoporosis.

Calcitonin-salmon, administered by nasal spray or injection, is indicated for *treatment* of established postmenopausal osteoporosis—but not for prevention. Benefits derive from suppressing bone resorption. The treatment program should include supplemental calcium and adequate intake of vitamin D. Use of calcitonin for osteoporosis is discussed further under *Osteoporosis*.

75.3.3.2.2 Paget's Disease of Bone.

Calcitonin is helpful in moderate to severe Paget's disease and is the drug of choice for rapid relief of pain associated with the disorder. Benefits occur secondary to inhibition of osteoclasts. Neurologic symptoms caused by spinal cord compression may be reduced.

75.3.3.2.3 Hypercalcemia.

Calcitonin can lower plasma calcium levels in patients with hypercalcemia secondary to hyperparathyroidism, vitamin D toxicity, and cancer. Levels of calcium (and phosphorus) are lowered owing to inhibition of bone resorption and increased excretion of calcium by the kidneys. Although calcitonin is effective against hypercalcemia, it is not a preferred treatment.

75.3.3.3 Adverse Effects

Calcitonin is very safe. With intranasal administration, nasal dryness and irritation are the most common complaints. Following parenteral (IM, subQ) administration, about 10% of patients experience nausea, which diminishes with time. An additional 10% have inflammatory reactions at the site of injection. Flushing of the face and hands may also occur. When salmon calcitonin is taken for a year or longer, neutralizing antibodies often develop. In some patients, these antibodies bind enough calcitonin to prevent therapeutic effects.

75.3.3.4 Preparations, Dosage, and Administration

75.3.3.4.1 Intranasal Spray.

Salmon calcitonin for intranasal use [Miacalcin, Fortical] is available in a metered-dose spray device that delivers 200 IU/activation. This formulation is approved only for *postmenopausal osteoporosis*. The dosage is 200 IU (1 spray) each day, alternating nostrils daily.

Figure 74-3 Structure of pyrophosphate and general structure of bisphosphonates.

75.3.3.4.2 Parenteral.

Salmon calcitonin for parenteral use [Calcimar, Miacalcin] is supplied in 2-mL vials containing 200 IU/mL. Administration is IM or subQ. Dosages are the same for both routes. Dosages for specific indications are

- *Postmenopausal osteoporosis*—100 IU/day
- *Paget's disease of bone*—the initial dosage is 100 IU/day; the maintenance dosage is 50 IU either daily or every other day
- *Hypercalcemia*—the initial dosage is 4 IU/kg every 12 hours; the maximal dosage is 8 IU/kg every 6 hours

75.3.4 Bisphosphonates

Bisphosphonates are structural analogs of pyrophosphate ([Fig. 74-3](#)), a normal constituent of bone. These drugs undergo incorporation into bone, and then inhibit bone resorption by decreasing the activity of osteoclasts. Principal indications are postmenopausal osteoporosis, osteoporosis in men, glucocorticoid-induced osteoporosis, Paget's disease of bone, and hypercalcemia of malignancy. Bisphosphonates may also help prevent and treat bone metastases in patients with breast cancer (see [Chapter 102](#)). Although these drugs are generally very safe, serious adverse effects can occur, including ocular inflammation, osteonecrosis of the jaw, and atrial fibrillation (primarily with IV zoledronate).

Bisphosphonates differ with respect to indications, routes, and dosing schedules. As indicated in [Table 74-4](#), four bisphosphonates are given PO, two are given IV, and one is given by both routes. With oral dosing, absorption from the GI tract is extremely poor. Dosing schedules vary from as often as once a day (with oral agents) to as seldom as once a year (with IV zoledronate).

75.3.4.1 Alendronate

Alendronate [Fosamax], the most commonly used bisphosphonate, will serve as our prototype for the family. The drug is approved for postmenopausal osteoporosis, male osteoporosis, glucocorticoid-induced osteoporosis, and Paget's disease of bone. Oral bioavailability is poor. Although alendronate is generally safe, esophageal ulceration has occurred in some patients.

75.3.4.1.1 Pharmacokinetics.

Alendronate is administered orally, but bioavailability is very low (only 0.7%). If the drug is taken with solid food, essentially none is absorbed. Even coffee or orange juice can decrease absorption by 60%. Of the small fraction that undergoes absorption, about 50% is taken up rapidly by bone. The remaining 50% is excreted unchanged in the urine. Once alendronate has become incorporated into bone, it remains there for decades.

TABLE 74-4 Bisphosphonates: Routes and Uses

Major Uses*					
Drug Name	Route	Postmenopausal Osteoporosis	Osteoporosis in Men	Paget's Disease of Bone	Hypercalcemia of Malignancy
Alendronate [Fosamax]	PO	A	A	A	
Risedronate [Actonel]	PO	A	A	A	
Tiludronate [Skelid]	PO			A	
Ibandronate [Boniva]	PO	A			
Etidronate [Didronel]	PO, IV			A	
Zoledronate [Reclast]	IV	A		A	
Zoledronate [Zometa]	IV				A
Pamidronate [Aredia]	IV	I		A	A

* A = FDA-approved indication, I = investigational use.

75.3.4.1.2 Mechanism of Action.

Alendronate suppresses resorption of bone by decreasing both the number and activity of osteoclasts. Several mechanisms are involved. As osteoclasts begin to resorb alendronate-containing bone, they ingest some of the drug, which then acts on the osteoclasts to inhibit

their activity. In addition, alendronate reduces the *number* of osteoclasts by (1) acting directly to decrease their recruitment and (2) acting on osteoblasts, which then produce an inhibitor of osteoclast formation.

75.3.4.1.3 Therapeutic Use.

75.3.4.1.3.1 Postmenopausal Osteoporosis.

Alendronate is approved for both the prevention and treatment of osteoporosis in postmenopausal women. Benefits derive from decreasing bone resorption by osteoclasts. The use of alendronate for osteoporosis is discussed further under *Osteoporosis*, later in the chapter.

75.3.4.1.3.2 Osteoporosis in Men.

Alendronate is now approved for treating osteoporosis in men. When tested in men with osteoporosis, the drug increased bone mineral density (BMD), reduced vertebral fractures, and decreased loss of height.

75.3.4.1.3.3 Glucocorticoid-Induced Osteoporosis.

Alendronate is considered a first-choice drug for the prevention and treatment of glucocorticoid-induced osteoporosis (GIOP), a common complication of glucocorticoid therapy that leads to fractures in at least 50% of patients. Studies indicate that alendronate helps restore lost bone and may reduce the risk of fractures.

75.3.4.1.3.4 Paget's Disease of Bone.

Alendronate is a first-line treatment for Paget's disease. Continuous daily therapy for 3 months produces a 50% decrease in serum alkaline phosphatase, indicating a substantial reduction in bone turnover. As in osteoporosis, benefits derive from inhibiting bone resorption by osteoclasts.

75.3.4.1.4 Adverse Effects.

Alendronate is generally well tolerated. Esophagitis is the principal concern. Rarely, the drug causes musculoskeletal pain, ocular inflammation, and osteonecrosis of the jaw.

Esophagitis, sometimes resulting in ulceration, is the most serious adverse effect. Fortunately, esophagitis is rare, occurring in only 1 of every 10,000 patients. The cause of injury is

prolonged contact with the esophageal mucosa, which can occur if alendronate fails to pass completely through the esophagus. Reasons for incomplete passage include taking the drug with insufficient water, taking the drug in a supine position, lying down after taking the drug, and having a pre-existing esophageal disorder that impedes drug passage. To promote complete passage, and thereby minimize risk of esophagitis, alendronate should be administered according to established guidelines (see below). Patients should be instructed to discontinue alendronate and contact the prescriber if they experience symptoms of esophageal injury (difficulty swallowing, pain upon swallowing, or new or worsening heartburn). Because of the risk of esophagitis, alendronate is contraindicated for patients with esophageal disorders that could prevent successful swallowing and for patients who are unable to sit or stand for at least 30 minutes.

Musculoskeletal pain, sometimes severe, has been reported during postmarketing surveillance. So far, a causal link with alendronate has not been established. Onset may occur shortly after the first dose or months later. Pain can be managed with analgesics, including opioids and ketorolac when pain is severe. In most cases, discomfort gradually resolves after stopping alendronate. Interestingly, among patients who resume alendronate use, only 11% experience a return of pain. If pain does return, patients taking the drug for osteoporosis can switch to a different agent, such as raloxifene, calcitonin-salmon, or teriparatide.

Ocular problems are rare, but can be serious. Possible effects include conjunctivitis, scleritis, blurred vision, and eye pain. Drug-induced release of inflammatory cytokines may be the cause. Advise patients to report any vision changes or eye pain.

Very rarely, patients have developed *bisphosphonate-related osteonecrosis of the jaw* (BRONJ), a potentially severe complication seen mostly with IV bisphosphonates (see discussion of zoledronate).

In patients with Paget's disease, alendronate can induce *hyperparathyroidism*. How? By inhibiting accelerated bone resorption, alendronate causes blood levels of calcium to fall; in response, secretion of PTH is increased. To prevent hyperparathyroidism, patients should receive calcium supplements.

Because an *intravenous* bisphosphonate (zoledronate) has been associated with rare cases of *atrial fibrillation* (AF), there is concern that oral alendronate may also cause the disorder. However, a Danish case-control study involving 13,586 patients found no evidence that either of two oral bisphosphonates—alendronate or etidronate—increased AF risk.

75.3.4.1.5 Administration.

Proper administration is necessary to maximize bioavailability and minimize the risk of esophagitis. To maximize bioavailability, alendronate should be taken in the morning before breakfast (ie, on an empty stomach). No food, including orange juice or coffee, should be consumed for at least 30 minutes. To minimize the risk of esophagitis, patients should be instructed to

875

876

- Take alendronate with a full glass of water
- Remain upright (sitting or standing) for at least 30 minutes
- Avoid chewing or sucking alendronate tablets

75.3.4.1.6 Preparations and Dosage.

Alendronate [Fosamax] is available in tablets (5, 10, 35, 40, and 70 mg) and an oral solution (70 mg in 75 mL). Dosing for *osteoporosis* in women or men may be done once daily (in the morning) or once weekly (on the same morning each week). Once-weekly dosing, which is just as effective as once-daily dosing, is possible because alendronate undergoes incorporation into bone, where it remains and acts for years. Calcium and antacids (containing calcium, aluminum, or magnesium) can decrease alendronate absorption, and hence should not be taken for at least 30 minutes after taking alendronate. Dosages are as follows:

- *Osteoporosis in postmenopausal women*—for *prevention*, 5-mg tablet daily or 35 mg once weekly; for *treatment*, 10 mg once daily or 70 mg once weekly
- *Osteoporosis in men*—10 mg once daily or 70 mg once weekly
- *Paget's disease*—40 mg once daily for 6 months for men or women
- *Glucocorticoid-induced osteoporosis*—5 mg once daily (for men, premenopausal women, and postmenopausal women taking estrogen) or 10 mg once daily (for postmenopausal women not taking estrogen)

75.3.4.2 Risedronate

75.3.4.2.1 Actions and Uses.

Risedronate [Actonel] is an oral bisphosphonate approved for *postmenopausal osteoporosis*, *male osteoporosis*, *glucocorticoid-induced osteoporosis*, and *Paget's disease of bone*. As with other bisphosphonates, benefits derive from inhibiting osteoclast-mediated resorption of bone. In postmenopausal women with osteoporosis, risedronate increases bone mineral density and reduces the risk of vertebral and nonvertebral fractures.

75.3.4.2.2 Pharmacokinetics.

Like other oral bisphosphonates, risedronate is poorly absorbed from the GI tract. Absorption is only 1% under fasting conditions, and even worse in the presence of food. Most of the absorbed drug becomes incorporated into bone. The rest is excreted unchanged in the urine. Risedronate in bone persists for years.

75.3.4.2.3 Adverse Effects.

The most common adverse effects are arthralgia (32%), diarrhea (20%), headache (18%), rash (12%), nausea (10%), and a flu-like syndrome (10%). Like alendronate, risedronate poses a significant risk of esophagitis. Ocular problems and musculoskeletal pain are rare. If risedronate poses a risk of BRONJ or AF, the risk is very small.

75.3.4.2.4 Preparations, Dosage, and Administration.

Risedronate [Actonel] is supplied in tablets (5, 30, 35, 75, and 100 mg). For prevention and treatment of osteoporosis, dosing may be done daily, weekly, one day a month, or on 2 consecutive days each month. Each dose should be taken in the morning with a full glass of water, and before ingesting the first food or fluids of the day (except for water). To minimize possible adverse GI effects, patients should be upright when swallowing risedronate, and should not lie down for at least 30 minutes. Because calcium and antacids (containing calcium, aluminum, or magnesium) greatly reduce absorption, these should not be administered within 2 hours of administering risedronate. Dosages are as follows:

- *Postmenopausal osteoporosis (prevention or treatment)*—5 mg once daily, 35 mg once weekly, 150 mg once a month, or 75 mg on 2 consecutive days each month
- *Osteoporosis in men*—35 mg once a week

- *Glucocorticoid-induced osteoporosis in men or women (prevention or treatment)*—5 mg once daily
- *Paget's disease in men or women*—30 mg once daily for 2 months; if needed, a second 2-month course can be given, provided at least 2 months have elapsed since completing the first course

75.3.4.3 Ibandronate

75.3.4.3.1 Actions and Uses.

Ibandronate [Boniva], available in oral and IV formulations, is approved for prevention and treatment of *postmenopausal osteoporosis*. Dosing may be done once a day, once a month, or once every 3 months. As with other bisphosphonates, benefits derive from inhibiting osteoclast-mediated resorption of bone. In clinical trials, ibandronate increased BMD in the lumbar spine and other sites, and reduced the risk of vertebral fractures. Although comparative studies have not been done, the drug is probably as effective as alendronate and risedronate, the only other bisphosphonates approved for oral therapy of osteoporosis.

75.3.4.3.2 Pharmacokinetics.

With oral dosing, bioavailability is extremely low—only 0.6%. Food decreases availability by another 90%. Once in the blood, ibandronate undergoes rapid binding to bone or excretion in the urine. Metabolism, if any, is minimal. The half-life in blood is 10 to 60 hours. However, because of binding to bone, active drug remains in the body for years.

75.3.4.3.3 Adverse Effects and Interactions.

With *oral administration*, ibandronate is generally well tolerated. Like other oral bisphosphonates, it can cause adverse GI effects, including esophagitis, dyspepsia, and abdominal pain. Ocular inflammation is rare. Musculoskeletal pain and BRONJ have not been reported. Multivalent cations (eg, calcium, aluminum, magnesium) can greatly decrease absorption.

With *IV administration*, ibandronate and other bisphosphonates may cause *renal damage*, especially if administered too rapidly. Accordingly, ibandronate should be injected slowly—over an interval of 15 to 30 seconds. Intravenous ibandronate should not be used by patients taking other nephrotoxic drugs, or by those with severe renal impairment, defined as serum creatinine above 2.3 mg/dL or creatinine clearance less than 30 mL/min. In addition to

causing renal damage, IV ibandronate may cause an acute reaction characterized by fever, joint pain, and myalgia, primarily with the first dose.

75.3.4.3.4 Preparations, Dosage, and Administration.

75.3.4.3.4.1 Oral.

Ibandronate [Boniva] for oral dosing is supplied in tablets (2.5 and 150 mg). The dosage for prevention and treatment of osteoporosis is either (1) 2.5 mg once a day or (2) 150 mg once a month, taken on the same day each month. Dosing is done on an empty stomach in the morning. Patients should swallow tablets whole with a full glass of water, while standing or sitting upright. For 60 minutes after dosing, patients must remain upright, and must not eat or drink anything, including medications and dietary supplements.

If a monthly dose is missed, and the next scheduled dose is *at least 7 days away*, then the missed dose should be taken in the morning, and the next dose should be taken as originally scheduled.

If the monthly dose is missed, and the next scheduled dose is *less than 7 days away*, then the missed dose should not be taken, and dosing should resume according to the original schedule.

To facilitate timely dosing, patients can sign up to receive a reminder of when their next dose is due. Enrollment can be done by phone (1-800-4BONIVA) or online (www.4Boniva.com). The reminder will come by phone, e-mail, or U.S. mail.

75.3.4.3.4.2 Intravenous.

Ibandronate [Boniva] for IV dosing is supplied in solution (1 mg/mL) in 5-mL, pre-filled syringes. The dosage is 3 mg every 3 months, administered by slow IV push (over 15 to 30 seconds). Kidney function should be determined before each dose and, if severe renal impairment is detected, the dose should be withheld.

75.3.4.4 Tiludronate

75.3.4.4.1 Actions and Uses.

Tiludronate [Skelid] is an oral bisphosphonate approved only for *Paget's disease of bone*. In Paget's disease patients, the drug decreases abnormal bone growth and, unlike etidronate, does so without interfering with bone mineralization. Like other bisphosphonates, tiludronate

undergoes incorporation into bone. When osteoclasts resorb this bone, they ingest the drug, which then inhibits further osteoclast-mediated bone resorption.

75.3.4.4.2 Pharmacokinetics.

Tiludronate is administered by mouth, and bioavailability is low. Food further decreases availability. In blood, about 90% of the drug is bound to serum proteins, mainly albumin. Tiludronate is eliminated largely unchanged in the urine.

75.3.4.4.3 Adverse Effects.

The most common side effects are nausea (9.3%), diarrhea (9.3%), and dyspepsia (5.3%). These are usually mild and rarely require cessation of treatment. Like alendronate, tiludronate poses a risk of esophagitis, ocular problems, and musculoskeletal pain. Other side effects include chest pain, edema, paresthesias, hyperparathyroidism, vomiting, and flatulence.

75.3.4.4.4 Preparations, Dosage, and Administration.

Tiludronate [Skelid] is supplied in 200-mg tablets. The dosage is 400 mg once a day for 3 months. Patients should be instructed to take tiludronate with a full glass of water. Also, they should not eat for 2 hours before or after taking the drug. Because calcium, aspirin, and antacids (containing calcium, aluminum, or magnesium) greatly reduce tiludronate absorption, these drugs should not be administered within 2 hours of administering tiludronate.

75.3.4.5 Etidronate

75.3.4.5.1 Actions, Uses, and Adverse Effects.

Etidronate [Didronel] is approved for *Paget's disease* and for prevention and treatment of *heterotopic ossification* (abnormal bone formation in extraskeletal soft tissue). The drug is also used for glucocorticoid-induced osteoporosis, although it is not approved for this disorder. In patients with highly active Paget's disease, etidronate can produce moderate clinical improvement. Unfortunately, when the drug is discontinued, relapse may occur rapidly. Side effects include abdominal cramps, diarrhea, nausea, and increased bone pain. In addition, etidronate causes defective mineralization of newly formed bone (osteomalacia), and can thereby increase the risk of fractures.

876

877

75.3.4.5.2 Preparations, Dosage, and Administration.

Etidronate [Didronel] is available in 200- and 400-mg tablets for oral dosing. As with all other oral bisphosphonates, bioavailability is low. To maximize absorption, patients should wait 2 hours before ingesting food, antacids high in metals (eg, calcium, iron, magnesium, aluminum), and vitamins that contain mineral supplements.

Patients with *Paget's disease* may be given either (1) 5 to 10 mg/kg/day (for no more than 6 months), or (2) 11 to 20 mg/kg/day (for no more than 3 months). Treatment can be repeated, but not until 90 days have elapsed since completing the prior course.

The dosage for prevention of *heterotrophic ossification* in patients undergoing total hip replacement is 20 mg/kg every day for 1 month before surgery and for 3 months after.

75.3.4.6 Zoledronate

75.3.4.6.1 Actions and Uses.

Zoledronate [Reclast, Zometa], also called zoledronic acid, is an IV bisphosphonate approved for *hypercalcemia of malignancy* (HCM), *postmenopausal osteoporosis*, and *Paget's disease of bone*. Like other bisphosphonates, zoledronate undergoes incorporation into bone, where it remains for years. When osteoclasts ingest the drug, it inhibits their activity, and thereby prevents bone resorption.

In patients with HCM, inhibition of bone resorption lowers calcium levels in blood. In one study, zoledronate normalized serum calcium in 88% of patients within 10 days of a single infusion. Compared with pamidronate, another bisphosphonate for HCM, zoledronate has three advantages. Specifically, onset is faster, duration is longer, and, perhaps most importantly, infusion time is shorter (15 minutes vs. 2 to 4 hours), making dosing much more convenient.

For management of postmenopausal osteoporosis, zoledronate differs from all other bisphosphonates, in that dosing is done just once a year. Compared with placebo treatment, once-yearly zoledronate decreases the incidence of vertebral fractures by 70%, hip fractures by 41%, and nonvertebral fractures by 25%. In addition, zoledronate improves BMD and markers of bone metabolism.

75.3.4.6.2 Adverse Effects.

The most common reaction is transient fever (44%), followed by nausea (29%), constipation (26%), dyspnea (22%), abdominal pain (16%), and bone and joint pain (12%). In addition, zoledronate can cause clinically significant reductions in serum levels of calcium, phosphorus, and magnesium. Accordingly, levels of these elements should be followed and corrected when indicated.

Zoledronate has been associated with bone injury, most often *bisphosphonate-related osteonecrosis of the jaw* (BRONJ), a condition characterized by local bone death and decreased bone strength. The underlying cause is impaired blood perfusion. (Bisphosphonates can impair perfusion by inhibiting growth of blood vessels.) Among patients using zoledronate, most cases of BRONJ developed after tooth extractions and other dental procedures, which can increase risk by promoting infection. Other risk factors include cancer, cancer chemotherapy, use of systemic glucocorticoids, and poor oral hygiene. To reduce BRONJ risk, a dental exam with appropriate preventive dentistry should be conducted before giving zoledronate, especially in patients with BRONJ risk factors. Patients should avoid elective dental work while using zoledronate.

Zoledronate can cause dose-dependent *kidney damage*, which can progress to outright renal failure. The risk is higher with shorter infusion times. To minimize risk, dosage should be kept low (4 mg or less per infusion) and the infusion should last 15 minutes or longer. In addition, the patient should be adequately hydrated before the infusion. To monitor for renal damage, creatinine clearance should be determined at baseline and periodically after the infusion. If renal impairment develops, zoledronate dosage should be reduced.

Rarely, zoledronate has been associated with serious *atrial fibrillation*, resulting in disability or hospitalization. In one trial, the incidence was 1.3%, compared with 0.5% in patients taking placebo. Most cases developed more than 30 days after zoledronate infusion.

75.3.4.6.3 Preparations, Dosage, and Administration.

Zoledronate is available in solution under two trade names: Reclast and Zometa. These solutions differ in concentration and indications.

Zometa, indicated for *hypercalcemia of malignancy*, is supplied as a *concentrated* solution (4 mg/5 mL) that must be diluted in 100 mL of 0.9% sodium chloride or 5% dextrose. The maximum recommended dose is 4 mg. In patients with renal impairment, dosage should be

reduced. All doses must be given as a single IV infusion over *no less than 15 minutes*. If hypercalcemia does not resolve, or if it resolves and then returns, a second infusion can be given, but no sooner than 7 days after the first infusion, and only if kidney function is adequate.

Reclast, indicated for *postmenopausal osteoporosis* and *Paget's disease*, is supplied as a *dilute* solution (5 mg/100 mL) in single-use vials. For postmenopausal osteoporosis, the dosage is 5 mg once a year, infused over 15 minutes or longer. For Paget's disease, the dosage is 5 mg infused over 15 minutes or more. Just one dose produces extended remission. Specific re-treatment data are not available.

75.3.4.7 Pamidronate

Pamidronate [Aredia] is a bisphosphonate approved for IV therapy of *Paget's disease*, *hypercalcemia of malignancy*, and *osteolytic bone metastases*. Because of dose-related GI intolerance (eg, mucosal erosion in the esophagus and stomach), pamidronate is not given orally.

75.3.4.7.1 Therapeutic Use and Dosage.

75.3.4.7.1.1 Hypercalcemia of Malignancy.

Many cancer cells release factors that stimulate resorption of bone by osteoclasts. The result is hypercalcemia, increased risk of fractures, and bone pain. By inhibiting osteoclast activity, pamidronate can blunt cancer-mediated bone resorption, and can thereby reduce blood levels of calcium. The recommended dosage is 60 to 90 mg infused over 2 to 24 hours. Longer infusion times reduce the risk of renal injury.

75.3.4.7.1.2 Paget's Disease of Bone.

Like other bisphosphonates, pamidronate can decrease bone resorption in patients with Paget's disease. The dosage is 30 mg infused slowly (over at least 4 hours) on 3 consecutive days. With this dosage, the mean duration of remission is 14 months.

75.3.4.7.1.3 Osteolytic Bone Metastases.

For osteolytic bone lesions of *multiple myeloma*, the dosage is 90 mg infused over 4 hours once a month. For bone metastases of *breast cancer*, the dosage is 90 mg infused over 2 hours every 3 to 4 weeks.

75.3.4.7.2 Adverse Effects.

Although IV pamidronate is generally safe, serious adverse effects can occur. Like zoledronate, pamidronate has been associated with BRONJ, usually after an invasive dental procedure. In some patients, the first dose causes transient flu-like symptoms. If pamidronate is not infused with sufficient fluid, venous irritation can occur. In contrast to etidronate, pamidronate does not interfere with bone mineralization. Because pamidronate inhibits accelerated bone resorption of Paget's disease, blood levels of calcium will fall, thereby triggering increased release of PTH; to prevent hyperparathyroidism, patients should receive supplemental calcium.

75.3.5 Raloxifene

Raloxifene [Evista] belongs to a class of agents known as *selective estrogen receptor modulators* (SERMs)—drugs that exert estrogenic effects in some tissues and antiestrogenic effects in others. Like estrogen, raloxifene preserves bone mineral density (BMD) and reduces plasma levels of cholesterol. However, in contrast to estrogen, which promotes cancer of the breast and endometrium, raloxifene confers protection against these cancers. Because of its effects on bone, raloxifene is used to prevent and treat postmenopausal osteoporosis. Because of its effects on breast tissue, the drug is used to reduce the risk of breast cancer. Another SERM—tamoxifen—is used to *treat* breast cancer as well as prevent it (see [Chapter 102](#)).

75.3.5.1 Mechanism of Action

Raloxifene and other SERMs are structurally similar to estrogen, and hence can bind to estrogen receptors. However, unlike estrogen itself, which functions as an agonist in all tissues, SERMs function as agonists in some tissues and antagonists in others. Hence, SERMs can either mimic or block the actions of estrogen, depending on the SERM and the tissue involved. Raloxifene mimics the effects of estrogen on bone, lipid metabolism, and blood clotting, and blocks estrogen effects in the breast and endometrium.

75.3.5.2 Pharmacokinetics

Raloxifene is administered by mouth, and 60% is absorbed. However, because of extensive first-pass metabolism, absolute bioavailability is below 2%. Excretion is fecal. The drug's half-life is about 28 hours.

877

75.3.5.3 Therapeutic Uses

Raloxifene offers significant benefits regarding osteoporosis and breast cancer, but also poses a risk of serious thromboembolic events. Accordingly, women must carefully weigh the risks and benefits before opting to use this drug.

75.3.5.3.1 Postmenopausal Osteoporosis.

Like estrogen, raloxifene is used prevent and treat osteoporosis in postmenopausal women. The drug can preserve or increase BMD, although not as effectively as estrogen. Raloxifene reduces the risk of *spinal* fractures by 55%, but does not reduce the risk of fractures at other sites. Use of raloxifene in osteoporosis is discussed further under *Osteoporosis*.

75.3.5.3.2 Breast Cancer.

Raloxifene protects against estrogen receptor (ER)–positive breast cancer. In the Multiple Outcomes of Raloxifene Evaluation (MORE) trial, which enrolled 7705 postmenopausal women with osteoporosis, taking raloxifene for a median of 40 months reduced the risk of ER–positive breast cancer by 76%—but only in women with high levels of estrogen. There was no reduction in the risk of ER–negative breast cancer. Encouraged by these results, the National Cancer Institute funded a large 5-year trial, called the Study of Tamoxifen and Raloxifene (STAR). STAR enrolled 19,747 women at high risk of breast cancer, with the objective of comparing risk reduction conferred by raloxifene or tamoxifen, a SERM already proved to reduce risk by 50%. The results of STAR, released in 2007, showed that raloxifene is just as effective as tamoxifen and also safer, causing fewer cases of uterine cancer and blood clots. As a result of these studies, raloxifene is now approved for reducing the risk of invasive breast cancer in postmenopausal women who either (1) have osteoporosis or (2) are at high risk of breast cancer, even if they don't have osteoporosis.

75.3.5.3.3 Cardiovascular Disease.

Preliminary data from the MORE trial indicate that, during the first 4 years of therapy, raloxifene reduces the risk of cardiovascular events (myocardial infarction [MI], unstable angina, coronary ischemia, and stroke) by 40% in women who are at high risk for such events, but not in women who are at low risk. In contrast to estrogen, raloxifene does not increase the risk of early cardiovascular events. Although these data suggest that raloxifene might be employed to protect against cardiovascular disease, more data are needed before the drug can be recommended for this use.

75.3.5.4 Adverse Effects and Interactions

Raloxifene is generally well tolerated, although it can cause fetal injury and thrombotic events. Raloxifene appears devoid of significant drug-drug and drug-food interactions.

75.3.5.4.1 Venous Thromboembolism.

Like estrogen, raloxifene increases the risk of deep vein thrombosis (DVT), pulmonary embolism, and stroke. Because inactivity promotes DVT, patients should discontinue raloxifene at least 72 hours before prolonged immobilization (eg, postsurgical recovery, extended bed rest), and should not resume the drug until full mobility has been restored. Also, patients should minimize periods of restricted activity, as can happen when traveling or revising a pharmacology text. Raloxifene is contraindicated for patients with a history of venous thrombotic events.

75.3.5.4.2 Fetal Harm.

Raloxifene is classified in *Food and Drug Administration (FDA) Pregnancy Risk Category X: The potential for fetal harm outweighs any possible benefits of use during pregnancy*. In animal studies, doses below those used in humans have resulted in abortion, retarded fetal development, decreased neonatal survival, and anatomic abnormalities, including hydrocephaly and uterine hypoplasia. Accordingly, raloxifene is contraindicated for use by pregnant women. Although use during pregnancy is obviously no concern for postmenopausal patients, it can be a concern for younger women taking the drug to prevent breast cancer.

75.3.5.4.3 Hot Flushes.

In contrast to estrogen, raloxifene does not reduce hot flushes (hot flashes) caused by estrogen deficiency after menopause. In fact, raloxifene may *cause* hot flushes in women who were previously asymptomatic.

75.3.5.5 Comparison with Estrogen

The SERMs were developed in hopes of creating a drug with all the benefits of estrogen and none of its drawbacks. Raloxifene partly fulfills this hope. Like estrogen, raloxifene increases BMD in postmenopausal women and reduces the risk of fractures. In contrast to estrogen, which increases the risk of breast cancer, raloxifene protects against breast cancer. Similarly, whereas estrogen stimulates endometrial growth, and thereby increases the risk of endometrial cancer, raloxifene does not stimulate the endometrium, and may actually protect against cancer.

Estrogen reduces plasma levels of low-density lipoprotein (LDL) cholesterol (bad cholesterol) and raises levels of high-density lipoprotein (HDL) cholesterol (good cholesterol). Like estrogen, raloxifene reduces LDL cholesterol, but it does not raise HDL cholesterol.

Nonetheless, raloxifene may offer superior protection against cardiovascular events. In postmenopausal women, estrogen can cause breast pain and resumption of menstruation, effects that are unlikely to be greeted with cheers. In contrast, raloxifene does not cause breast pain, and rarely causes return of menstruation. On the other hand, estrogen can alleviate symptoms of estrogen deficiency (eg, hot flashes, vaginal drying and itching), whereas raloxifene cannot.

Both drugs increase the risk of DVT and fetal harm. [Table 74-5](#) summarizes the ways in which estrogen and raloxifene are alike and different.

75.3.5.6 Preparations, Dosage, and Administration

Raloxifene [Evista] is available in 60-mg oral tablets. The dosage for all indications is 60 mg once a day, taken with or without food. Women taking raloxifene to prevent or treat postmenopausal osteoporosis should ensure adequate intake of calcium and vitamin D.

75.3.6 Teriparatide

Teriparatide [Forteo] is a form of parathyroid hormone (PTH) produced by recombinant DNA technology. Approved in 2002, teriparatide is the only drug for osteoporosis that increases bone formation; all others decrease bone resorption. In postmenopausal women with documented osteoporosis, daily subQ injections of teriparatide for 18 months increased BMD of the lumbar spine and femoral neck, and reduced the risk of vertebral fractures by 65%. Similar responses were seen in men. Teriparatide-induced increases in BMD are twice those seen with alendronate.

In clinical trials, two dosages were used: 20 mcg once daily and 40 mcg once daily. The larger dose produced a greater increase in vertebral BMD (13.7% vs. 9.7%), but did not produce a greater reduction in fractures. Moreover, it *did* produce a greater incidence of side effects.

Accordingly, the 20-mcg dose is recommended. With this dose, plasma levels peak about 20 minutes after subQ injection, and decline to undetectable within 3 hours.

878

879

TABLE 74-5 Comparison of Estrogen and Raloxifene

Drug Target	Estrogen	Raloxifene
Bone	Increases BMD and reduces fracture risk	Increases BMD (but not as much as estrogen) and reduces fracture risk
Breast	Increases risk of breast cancer; causes breast enlargement and pain	Protects against breast cancer; does <i>not</i> cause breast enlargement or pain
Endometrium	Increases risk of endometrial cancer	Does <i>not</i> promote endometrial cancer, and <i>may</i> offer protection
Plasma lipids	Lowers LDL cholesterol and raises HDL cholesterol	Lowers LDL cholesterol, but does not raise HDL cholesterol
Menopausal symptoms	Alleviates menopausal symptoms (eg, hot flashes, vaginal dryness and itching)	Does <i>not</i> alleviate menopausal symptoms, and may actually increase hot flashes
Menstruation	Causes bleeding in 45% of postmenopausal women	Causes bleeding in 3–5% of postmenopausal women
Blood clotting	Increases risk of DVT and pulmonary embolism	Same as estrogen
Coronary heart disease	Increases risk of MI early in therapy	No increase in MI risk early in therapy; lowers risk of MI in women with MI risk factors
Developing fetus	Contraindicated during pregnancy because of possible fetal harm	Same as estrogen

How does PTH affect bone? The drug has two actions: it increases bone resorption by osteoclasts, and it increases bone deposition by osteoblasts. The net effect—resorption or deposition—depends on how the drug is administered. When given by continuous IV infusion, which produces a *steady* elevation of serum PTH, the drug *decreases* BMD, primarily by accelerating calcium resorption by osteoclasts. In contrast, when given by daily subQ injections, which produce *transient* elevations in serum PTH, the drug *increases* BMD, primarily by increasing bone deposition by osteoblasts.

Teriparatide is generally well tolerated. In clinical trials, adverse effects included nausea, headache, back pain, and leg cramps. In addition, serum levels of calcium, magnesium, and uric acid rose early in treatment, but then returned to normal levels within 5 weeks. Initial doses may cause orthostatic hypotension and associated dizziness. The greatest concern is bone cancer: PTH has caused a rare form of bone cancer in rats—but not in monkeys. To date, cancer has not been detected in humans. Nonetheless, teriparatide should be avoided by patients with bone metastases or a history of skeletal cancer, and by patients at increased risk for bone cancer, including those with open epiphyses, Paget's disease of bone, or prior irradiation of bone.

75.3.6.1 Preparations, Dosage, and Administration.

Teriparatide [Forteo] is available in 3-mL, pre-filled pen injectors that contain 750 mcg of drug. The recommended dosage is 20 mcg once a day by subQ injection into the anterior thigh or abdomen. Each pen can be used up to 28 days after the first injection, after which it should be discarded, even if drug remains. Patients should store the pens cold—2°C to 8°C (36°F to 46°F)—but not frozen, and should take them out of the cold only to make an injection. Treatment costs over \$7600 a year.

75.3.7 Cinacalcet

75.3.7.1 Actions and Therapeutic Use.

Cinacalcet [Sensipar] is a “calcimimetic” drug approved for primary hyperparathyroidism (caused by parathyroid carcinoma) as well as secondary hyperparathyroidism (caused by chronic kidney disease [CKD]). In both cases, benefits derive from decreasing secretion of parathyroid hormone (PTH). How is secretion suppressed? Recall that extracellular calcium regulates PTH secretion by binding with calcium-sensing receptors on cells of the parathyroid gland, thereby signaling those cells to reduce PTH secretion. All that cinacalcet does is (somehow) increase the sensitivity of the calcium-sensing receptors to activation by extracellular calcium. As a result, the ability of calcium to suppress PTH release is amplified.

Clinical trials have shown that, in patients with hyperparathyroidism secondary to CKD, cinacalcet decreases serum PTH by 23% to 46%, and improves calcium and phosphorus homeostasis. Similarly, in patients with primary hyperparathyroidism, the drug decreases serum PTH and normalizes serum calcium.

75.3.7.2 Pharmacokinetics.

Dosing is oral, and absorption is increased by food. In the blood, cinacalcet is highly bound (93% to 97%) to plasma proteins. Cinacalcet undergoes extensive hepatic metabolism, followed by excretion in the urine (80%) and feces (15%). The drug's half-life is 30 to 40 hours.

75.3.7.3 Adverse Effects.

The most common adverse effects are nausea (31%), vomiting (27%), and diarrhea (21%). Because cinacalcet lowers calcium levels, hypocalcemia is an obvious concern. Accordingly, calcium levels should be monitored (see below), and patients should be informed about possible

manifestations of hypocalcemia (eg, cramping, convulsions, myalgias, paresthesias, tetany) and instructed to report them.

75.3.7.4 Drug Interactions.

Cinacalcet is metabolized in part by cytochrome P450 3A4, and hence inhibitors of this enzyme (eg, ketoconazole, itraconazole, erythromycin) can raise cinacalcet levels. If cinacalcet is used with one of these drugs, cinacalcet dosage may need an adjustment.

879

75.3.7.5 Monitoring.

880

In patients with *parathyroid carcinoma*, measure serum calcium within 1 week of the first dose and each dosage change. Once a maintenance dosage has been established, measure serum calcium every 2 months.

In patients with *secondary hyperparathyroidism*, measure serum calcium and phosphorus within 1 week of the first dose and each dosage change, and measure PTH within 4 weeks of the first dose and each dosage change. Once a maintenance dosage has been established, measure calcium and phosphorus monthly, and PTH every 1 to 3 months.

75.3.7.6 Preparations, Dosage, and Administration.

Cinacalcet [Sensipar] is available in tablets (30, 60, and 90 mg) for oral use. To enhance absorption, the drug should be taken with a meal or shortly after.

In patients with *parathyroid carcinoma*, the initial dosage is 30 mg twice daily. Then, every 2 to 4 weeks, dosage is increased as follows—60 mg twice daily, 90 mg twice daily, 90 mg 3 times/day, 90 mg 4 times a day—until the dosing goal (normalization of serum calcium) is achieved.

In patients with *secondary hyperparathyroidism*, the initial dosage is 30 mg once daily. Then, every 2 to 4 weeks, dosage is increased as follows—60 mg once daily, 90 mg once daily, 120 mg once daily, 180 mg once daily—until the dosing goal (PTH level between 150 and 300 pg/mL) is achieved.

75.3.8 Drugs for Hypercalcemia

75.3.8.1 Furosemide.

Furosemide, a loop diuretic, promotes renal excretion of calcium. This action is useful for treating hypercalcemic emergencies. In managing such emergencies, isotonic saline (IV) must

be given prior to furosemide. The dosage of furosemide for adults is 80 to 100 mg every 1 to 2 hours as needed, infused no faster than 4 mg/min. To avoid fluid and electrolyte imbalance, urinary losses must be measured and replaced. The basic pharmacology of furosemide is discussed in [Chapter 40](#) (Diuretics).

75.3.8.2 Glucocorticoids.

Glucocorticoids reduce intestinal absorption of calcium, and can thereby reduce hypercalcemia. For severe hypercalcemia, parenteral glucocorticoid therapy is indicated (eg, 100 to 500 mg hydrocortisone sodium succinate IV daily). Because glucocorticoids can produce serious adverse effects when taken chronically, the risks of long-term treatment must be carefully weighed against the benefits. The basic pharmacology of the glucocorticoids is discussed in [Chapter 71](#) (Glucocorticoids in Nonendocrine Diseases).

75.3.8.3 Gallium Nitrate.

Gallium nitrate [Ganite] is used to treat hypercalcemia of malignancy. In addition, the drug is used investigationally for Paget's disease of bone and postmenopausal osteoporosis. Gallium reduces calcium levels by preventing bone resorption. It may also increase bone formation. Gallium is highly nephrotoxic and must not be used with other nephrotoxic drugs, such as amphotericin B and the aminoglycosides. To minimize kidney damage, the patient must be hydrated with IV fluids before treatment. Renal function must be monitored. The usual single dose is 100 to 200 mg/m². This dose is diluted in 1 L of 5% dextrose or 0.9% sodium chloride and infused over 24 hours. Dosing is repeated daily for 5 days.

75.3.8.4 Bisphosphonates.

Pamidronate, etidronate, and zoledronate are approved for hypercalcemia of malignancy. The mechanism is suppression of bone resorption by osteoclasts. The pharmacology of these agents is discussed above.

75.3.8.5 Inorganic Phosphates.

Phosphates reduce plasma levels of calcium, and hence can be used to treat hypercalcemia. Suggested mechanisms for reducing plasma calcium include (1) decreased bone resorption, (2) increased bone formation, and (3) decreased intestinal absorption of calcium (secondary to decreased renal activation of vitamin D). Intravenous use of phosphates is hazardous and limited to patients with life-threatening hypercalcemia. Oral administration is considerably safer.

Oral phosphates are used for mild to moderate hypercalcemia. These agents should not be given to patients with renal impairment or elevated serum phosphate. Oral phosphates should not be combined with antacids that contain aluminum, magnesium, or calcium—agents that bind phosphate and thereby prevent its absorption. Initial treatment should provide 1 to 2 gm of phosphorus/day. Doses are reduced when serum calcium levels normalize.

75.3.8.6 Edetate Disodium.

EDTA is a chelating agent that binds calcium in the blood. As a result, it can rapidly reduce plasma levels of free calcium. The EDTA-calcium complex is filtered by the glomerulus but not reabsorbed by kidney tubules, and hence renal excretion of calcium is increased. Although EDTA is highly effective at reducing hypercalcemia, this agent is also very toxic: EDTA can cause profound hypocalcemia, resulting in tetany, convulsions, dysrhythmias, and possibly death. Severe nephrotoxicity can also occur. Because of its toxicity, EDTA is used only for life-threatening hypercalcemic crisis. The usual adult dose is 40 mg/kg infused over 4 to 6 hours. The total daily dose must not exceed 3 gm.

75.4 OSTEOPOROSIS

75.4.1 General Considerations

Osteoporosis is a serious medical problem characterized by low bone mass, altered bone architecture, and increased bone fragility. Because of bone fragility, patients are susceptible to fractures from minor traumatic events, such as coughing, rolling over in bed, or falling from a standing position. More than 10 million Americans have osteoporosis—80% of them older women—and another 34 million have reduced bone mass, a risk factor for osteoporosis. Every year, osteoporosis leads to 1.5 million fractures. The most common fracture sites are the vertebrae (spine), distal forearm (wrist), and femoral neck (hip). Vertebral fractures can result in loss of height, spinal deformity, chronic back pain, and impaired breathing. Complications from hip fractures are a significant cause of mortality: Of the 300,000 Americans who get hip fractures each year, about 50,000 die from complications.

The economic burden of osteoporosis is high. Each year in the United States, osteoporosis-related fractures lead to more than 432,000 hospital admissions, nearly 2.5 million medical office visits, and about 180,00 admissions to nursing homes—at an estimated cost of \$17 billion, or \$47 million a day.

75.4.1.1 Bone Mass

In men and women, bone mass changes across the life span. Bone mass peaks in the third decade, remains stable to age 50, and then slowly declines—at a rate that is usually less than 1% a year. In addition to this slow, aging-related decline, women go through a phase of *accelerated* bone loss (2% to 3% a year) that begins after menopause and continues for several years. In both the slow and accelerated phases of decline, bone is lost because resorption of old bone outpaces deposition of new bone.

75.4.1.2 Primary Prevention: Calcium, Vitamin D, and Lifestyle

The risk of osteoporosis can be reduced by lifelong implementation of measures that can help maximize bone strength. Specifically, we need to ensure sufficient intake of calcium and vitamin D, and we need to adopt a lifestyle that promotes bone health. Calcium is needed to maximize bone growth early in life and to maintain bone integrity later in life. Vitamin D is needed to ensure calcium absorption. The amount of calcium needed for optimal bone health is indicated in [Table 74-1](#). Note that, late in life, both men and women should take in at least 1200 mg of calcium daily. If the diet cannot provide this amount, supplements should be employed. According to the Institute of Medicine, daily vitamin D intake should be 200 IU prior to age 51, 400 IU from age 51 through age 70, and 600 IU thereafter. However, for adults over age 50, the National Osteoporosis Foundation (NOF) recommends much higher intake: 800 to 1000 IU/day. Lifestyle measures that promote bone health are

- Performing regular weight-bearing exercise (walking, jogging, dancing, racquet sports, team sports, stair climbing)
- Avoiding excessive alcohol
- Avoiding smoking

880

75.4.1.3 Diagnosing Osteoporosis and Assessing Fracture Risk

881

Osteoporosis is diagnosed by measuring bone mineral density (BMD), an important predictor of fracture risk. The U.S. Preventive Services Task Force recommends routine BMD testing for all *women* beginning either at age 60 (for women at increased risk for osteoporotic fractures) or at age 65 (for women who are not at increased risk). In addition, the NOF recommends testing of *men* age 70 and older. BMD testing is not recommended for children or adolescents, nor is routine testing indicated for premenopausal women or healthy young men.

The standard technique for measuring BMD is *dualenergy x-ray absorptiometry* (DEXA). DEXA scans only take a few minutes, and exposure to radiation is minimal—about one-tenth that of a standard chest x-ray. Results of DEXA scans are reported in terms of *standard deviations* (SD) below mean BMD values in young adults. A BMD value that is 1 SD below the mean indicates 10% bone loss, a value that is 2 SD below the mean indicates 20% bone loss, and so forth. Using this system, the World Health Organization (WHO) has defined *normal* BMD for women as being no more than 1 SD below the mean for young adults. BMD values between 1 SD below the mean and 2.5 SD below the mean define *osteopenia* (low bone mass). BMD values 2.5 SD or greater below the mean define *osteoporosis*. To simplify communication, we can talk about DEXA results in terms of a *T-score*, rather than using the phrase *SD above (or below) the mean*. For example, instead of saying that a BMD reading was 2.5 SD below the mean, we can simply say the T-score was -2.5 .

Although loss of bone at one site (eg, wrist) can predict the risk of fractures at other sites (eg, hip, spine), it is preferable to measure BMD at specific sites to predict the risk for those sites. Accordingly, a thorough evaluation would include BMD measurements in the wrist, spine, and hip—the sites at which osteoporotic fractures occur most often.

Although we use BMD values to diagnose osteoporosis, it is important to understand that low BMD is not the only predictor of fractures. Other important predictors include a family history of hip fractures, a personal history of fractures, low body mass index, and use of oral glucocorticoids. To account for these risk factors, the WHO developed an important tool, called FRAX, which can assess an *individual's* 10-year risk of experiencing a fracture. This web-based, interactive program, released in 2008, is available online at www.shef.ac.uk/FRAX/. Individual risk is calculated after entering the following data:

- Age
- Gender
- Weight
- Height
- Previous fracture
- Hip fracture in a parent

- Secondary osteoporosis (ie, malnutrition, hyperthyroidism, diabetes, and other disorders associated with osteoporosis)
- Rheumatoid arthritis
- Glucocorticoid use
- Current smoking
- Alcohol consumption
- Hip BMD

Of note, FRAX is tailored to specific countries, and, for the United States, to four specific subgroups: African Americans, Hispanics, Caucasians, and Asians.

75.4.1.4 Who Should Be Treated?

A new guideline—*Clinician's Guide to Prevention and Treatment of Osteoporosis*—was released by the NOF in 2008. According to this document, postmenopausal women and men age 50 and older should be considered for treatment if they present with

- A hip fracture or vertebral fracture
- Osteoporosis (T-score of -2.5 or less at the femoral neck or spine)
- Osteopenia (T-score between -1 and -2.5 at the femoral neck or spine) *and* a 10-year probability of a hip fracture of 3% or more or a 10-year probability of another major osteoporosis-related fracture of 20% or more, based on a U.S.-adapted FRAX calculation.

75.4.2 Treating Osteoporosis in Women

The objective of treatment is to reduce the occurrence of fractures. To do this, we need to maintain or increase bone strength. Two types of drugs can be used: (1) agents that decrease bone resorption and (2) agents that promote bone formation. Antiresorptive drugs—estrogen, raloxifene, bisphosphonates, and calcitonin—are used most often. These agents do a good job of preventing bone loss, but are not very good at restoring bone mass once it is gone. Accordingly, antiresorptive drugs are most beneficial when used early—before substantial loss has occurred. At this time, teriparatide [Forteo] is the only drug available that effectively promotes bone formation.

75.4.2.1 Antiresorptive Therapy

Bone resorption can be reduced with estrogen, raloxifene, bisphosphonates (eg, alendronate), and calcitonin, all of which inhibit osteoclast activity. These antiresorptive agents can retard bone loss, but are largely unable to reverse loss that has already occurred. When these agents are used, bone density may increase slightly during the first year or two, but then levels off. With all antiresorptive drugs, success requires a sufficiency of calcium and vitamin D.

75.4.2.1.1 Estrogen.

The basic pharmacology of estrogen as well as postmenopausal replacement therapy are discussed at length in [Chapter 60](#). Discussion here focuses on the role of estrogen in osteoporosis. *Because of new insight into the benefits and risks of estrogen, prolonged replacement is no longer considered appropriate for most women* (see below and [Chapter 60](#)).

Estrogen acts indirectly to suppress osteoclast proliferation, and thereby maintains a brake on bone resorption. Consequently, when estrogen levels decline, either because of natural menopause or surgical removal of the ovaries, osteoclasts increase in number, causing bone resorption to increase dramatically. Estrogen replacement can restore the brake on osteoclast proliferation, and can thereby suppress resorption.

Estrogen is approved for preventing and treating bone loss following menopause or surgical removal of the ovaries. Treatment reduces the overall risk of fractures by 24%. Estrogen is most effective when initiated immediately after menopause. However, treatment begun at age 60 and even later can still offer significant protection. If estrogen is discontinued, a period of accelerated bone loss will ensue.

The standard dosage for estrogen therapy is 0.625 mg/day of conjugated equine estrogens [Premarin] or its equivalent. However, less estrogen (eg, 0.3 mg/day) may be nearly as effective in osteoporosis, while causing fewer side effects (vaginal bleeding, breast tenderness, headache, nausea) and, in all probability, posing a lower risk of breast cancer.

As discussed in [Chapter 60](#), women with an intact uterus should also receive a progestin (eg, medroxyprogesterone) in order to minimize the risk of estrogen-induced endometrial cancer. For women without a uterus, the progestin is unnecessary.

For years, hormone replacement therapy (HRT)—estrogen with or without a progestin—had been considered the treatment of choice for preventing postmenopausal bone loss. Today, however, the benefits no longer appear to outweigh the risks. As discussed in [Chapter 60](#), data

881

882

from recent trials, including the first report from the Women's Health Initiative (WHI) and the Heart and Estrogen/progestin Replacement Study (HERS), indicate that HRT offers fewer benefits than previously thought, and carries greater risks. Yes, HRT does reduce bone loss and the risk of osteoporotic fractures. However, HRT increases the risk of breast cancer, cholecystitis, myocardial infarction, and stroke. Accordingly, in the fall of 2002, the U.S. Preventive Services Task Force recommended against using combination HRT (estrogen plus a progestin) to prevent osteoporosis or any other chronic disorder. (Using HRT short term to manage menopausal symptoms is still considered appropriate.) Fortunately, for prevention and treatment of osteoporosis, we have effective alternatives: raloxifene, bisphosphonates, calcitonin, and teriparatide. Women currently using HRT for osteoporosis are encouraged to consider a switch. For a more detailed discussion of the pros and cons of HRT, refer to [Chapter 60](#).

75.4.2.1.2 Raloxifene.

Raloxifene [Evista] is approved for prevention and treatment of postmenopausal osteoporosis. The drug reduces bone turnover, and thereby increases BMD, although not as well as estrogen. For maximal benefits, treatment must be accompanied by adequate intake of calcium and vitamin D. Raloxifene is somewhat less effective than estrogen, but is safer. Raloxifene is less effective than bisphosphonates. The basic pharmacology of raloxifene is discussed above.

In the MORE trial, treatment with raloxifene (60 or 120 mg once daily) for 36 months increased BMD and reduced the risk of fractures. The increase in BMD was 2.3% in the femoral neck and 2.7% in the spine. Increased BMD was associated with a reduced risk of spinal fractures: After 36 months, at least one new spinal fracture was seen in 10.1% of women taking placebo, compared with 6.6% of those taking 60 mg of raloxifene, and 5.4% of those taking 120 mg of raloxifene. This represents a 52% decrease in risk with raloxifene. However, although raloxifene reduced the risk of *spinal* fractures, it failed to reduce fractures at *nonspinal* sites (eg, wrist, hip).

75.4.2.1.3 Bisphosphonates.

At this time, four bisphosphonates—alendronate, risedronate, ibandronate, and zoledronate—are approved for prevention and treatment of osteoporosis in postmenopausal women. However, although other bisphosphonates are not approved, it is reasonable to assume they would also be effective.

75.4.2.1.3.1 Alendronate.

Alendronate [Fosamax] was the first bisphosphonate approved for postmenopausal osteoporosis. The drug is safe and helps prevent fractures. Alendronate was approved initially only for *treating* existing osteoporosis, and was later approved for *prevention*. In both cases, benefits derive from inhibiting bone resorption by osteoclasts. To be effective, alendronate must be accompanied by adequate intake of calcium and vitamin D. The basic pharmacology of alendronate is discussed above.

When studied in osteoporotic postmenopausal women (average age 65), alendronate produced a modest increase in BMD in the hip and spine. More importantly, treatment decreased the rate of new fractures: Compared with patients taking placebo, those taking alendronate experienced 51% fewer fractures of the hip, 47% fewer fractures of the spine, and 48% fewer fractures of the wrist. Furthermore, when spinal fractures did occur, loss of height was less than in women who got spinal fractures while taking placebo. The dosage for treatment of osteoporosis is 10 mg once a day or 70 mg once a week.

When given to *prevent* osteoporosis in postmenopausal women (ages 44 to 50), alendronate produced a small increase in BMD of the spine and hip. In contrast, women taking placebo *lost* BMD at both sites. The response to alendronate was basically the same as the response to estrogen. The dosage for prevention of osteoporosis is 5 mg once a day or 35 mg once a week—half the dosage used to *treat* osteoporosis.

75.4.2.1.3.2 Risedronate, Ibandronate, and Zoledronate.

Like alendronate, risedronate [Actonel] and ibandronate [Boniva] are approved for prevention and treatment of osteoporosis in postmenopausal women; zoledronate [Reclast] is approved for treatment, but not for prevention. In clinical trials, these drugs increased BMD and reduced the incidence of fractures. With risedronate, the dosage for prevention or treatment is 5 mg once daily, 35 mg once weekly, 75 mg on 2 consecutive days each month, or 150 mg once a month. With ibandronate, the *oral* dosage for prevention or treatment is 2.5 mg once daily or 150 mg once a month, and the *intravenous* dosage is 3 mg every 3 months. With zoledronate, the dosage is 5 mg *once a year*, given by slow IV push.

75.4.2.1.4 Calcitonin-Salmon.

Salmon calcitonin—either intranasal [Miacalcin, Fortical] or subQ [Miacalcin, Calcimar]—is used to treat established osteoporosis, but not to prevent osteoporosis. Benefits derive from

inhibiting osteoclastic bone resorption. By doing so, the drug decreases bone loss and the risk of fractures. In women ages 68 to 72, two years of treatment with calcitonin increased BMD in the spine by 3%. In contrast, spinal BMD decreased by 1% in women taking placebo. In younger postmenopausal women (mean age 53), calcitonin increased average BMD by 2%, whereas average BMD decreased by 7% in women taking placebo. Not only is calcitonin moderately effective, it is very safe: The drug has been used for over 20 years with no long-term adverse effects. For management of osteoporosis, the intranasal dosage is 1 spray (200 IU) a day (into alternating nostrils daily), and the subQ dosage is 100 IU/day. The basic pharmacology of calcitonin is discussed above.

75.4.2.2 Bone-Forming Therapy: Teriparatide

Teriparatide [Forteo], a recombinant form of PTH, promotes bone formation by increasing the activity of osteoblasts. In clinical trials, the drug increased BMD of the lumbar spine, femoral neck, and total body, and significantly reduced the risk of vertebral fractures. Teriparatide is the first and only drug for osteoporosis that works by increasing bone formation, rather than by decreasing bone resorption. As a rule, teriparatide should be reserved for patients at high risk of fractures. Why? Because the drug is expensive, inconvenient (it requires subQ injection), and potentially dangerous (it may promote bone cancer). The pharmacology of teriparatide is discussed above.

882

883

75.4.3 Treating Osteoporosis in Men

In the United States, about 2 million men have aging-related osteoporosis, and another 3 million are at risk. Hip fractures occur in 80,000 American men annually, compared with 269,000 American women. Of the men who get a hip fracture, 36% die within a year. Although rates of osteoporosis and fractures in men are significant, they are still much lower than in women. As discussed, bone mass in men peaks in the third decade, and begins progressive decline around age 50. The rate of decline in men is about equal to that in women—except that in men, there is no counterpart to the accelerated phase of bone loss that occurs following menopause. If men and women lose bone mass at similar rates, why do men experience less osteoporosis? The main reason is that bones in men, at their peak, are larger and stronger than bones in women. Hence, once decline begins, male bones can tolerate more loss before fractures are likely. Factors that contribute to the risk of osteoporosis in men include low testosterone, prolonged use of glucocorticoids, white race, calcium deficiency, vitamin D deficiency, smoking, excessive alcohol consumption, and insufficient exercise. As in women, 10-year fracture risk can be assessed using the FRAX calculator developed by the WHO.

Treatment of male osteoporosis is confounded by a paucity of research. (Osteoporosis is one of the few areas of therapeutics in which research in women has greatly exceeded research in men.) At this time, only three drugs—*alendronate* [Fosamax], *risedronate* [Actonel], and *teriparatide* [Forteo]—are approved for osteoporosis in men. In one study, 2 years of alendronate increased BMD of the lumbar spine and hip, and significantly decreased the incidence of vertebral fractures. Benefits with risedronate and teriparatide are similar. For alendronate and teriparatide, dosages are the same as those used in women. For risedronate, the dosage is 35 mg once a week. Calcitonin has been tried in men, but proof of efficacy is lacking. If testosterone deficiency underlies osteoporosis, testosterone replacement therapy is indicated, unless the patient has testicular cancer or some other disorder that contraindicates testosterone use. All men should ensure adequate intake of calcium and vitamin D.

75.4.3.1

KEY POINTS

- Calcium is critical to the function of the skeletal, nervous, muscular, and cardiovascular systems.
- More than 98% of calcium in the body is present in bone.
- Bone undergoes continuous remodeling, a process in which osteoclasts resorb old bone and osteoblasts lay down new bone.
- The body maintains calcium levels by adjusting the rates of calcium resorption from bone, calcium absorption from the intestine, and calcium excretion by the kidney. These processes are regulated by parathyroid hormone (PTH), vitamin D, and calcitonin.
- PTH elevates serum calcium by promoting resorption of calcium from bone, enhancing renal tubular resorption of calcium, and activating vitamin D, which then promotes absorption of calcium from the intestine.
- Like PTH, vitamin D increases serum calcium by increasing calcium resorption from bone, decreasing calcium excretion by the kidney, and increasing calcium absorption from the intestine.
- Calcitonin lowers calcium levels by inhibiting calcium resorption from bone and increasing calcium excretion by the kidney.
- The various calcium salts used for therapy differ widely in their percentage of calcium.

- Vitamin D is obtained through the diet and by exposure to sunlight.
- Vitamin D deficiency causes rickets in children and osteomalacia in adults. Deficiency may also contribute to certain autoimmune disorders and cancers.
- Calcitonin-salmon has the same metabolic effects as human calcitonin, but has a longer half-life and greater milligram potency.
- Calcitonin-salmon is used primarily for osteoporosis. Benefits derive from inhibiting bone resorption by osteoclasts.
- Calcitonin-salmon is very safe.
- Alendronate, our prototype for the bisphosphonates, has four approved indications: prevention and treatment of osteoporosis in postmenopausal women, treatment of osteoporosis in men, treatment of Paget's disease of bone in men and women, and treatment of glucocorticoid-induced osteoporosis in men and women.
- Bioavailability of alendronate is very low in the absence of food, and essentially zero in the presence of food. Accordingly, nothing should be eaten for at least 30 minutes after taking the drug.
- Following absorption, alendronate undergoes incorporation into bone, where it can remain for decades.
- Alendronate suppresses bone resorption by decreasing both the number and activity of osteoclasts.
- Alendronate can cause severe esophagitis if it stays in contact with the esophageal mucosa. Accordingly, patients should take the drug with a full glass of water and then remain upright for at least 30 minutes.
- Rarely, alendronate has been associated with musculoskeletal pain, ocular inflammation, and osteonecrosis of the jaw.
- Raloxifene belongs to the family of SERMs, drugs that are estrogenic in some tissues and antiestrogenic in others.
- Raloxifene mimics the effects of estrogen on bone, lipid metabolism, and blood clotting, and blocks the effects of estrogen in the breast and endometrium.

- Raloxifene is indicated for preventing and treating postmenopausal osteoporosis, and for reducing the risk of breast cancer in postmenopausal women.
- Raloxifene can cause DVT and fetal harm.
- Teriparatide is the first and only drug for osteoporosis that works by increasing bone formation. (All the others decrease bone resorption.)
- Teriparatide may increase the risk of bone cancer.
- Osteoporosis is characterized by low bone mass and increased bone fragility, which renders patients vulnerable to fractures from minor trauma.

883

- The most common sites of osteoporotic fractures are the vertebrae (spine), distal forearm (wrist), and femoral neck (hip).
- Osteoporosis occurs mainly in the elderly. Why? Because after age 50, men and women experience aging-related bone loss that is slow but relentless. In addition, women experience several years of accelerated bone loss following menopause. In both cases, bone is lost because bone resorption by osteoclasts outpaces bone deposition by osteoblasts.
- To maximize bone strength, and thereby minimize the risk of osteoporosis, we all need to (1) ensure lifelong sufficiency of calcium and vitamin D and (2) adopt lifestyle measures that promote bone health: regular weight-bearing exercise and avoidance of smoking and excessive alcohol.
- Osteoporosis is diagnosed by measuring BMD, which is done most commonly using dual-energy x-ray absorptiometry (DEXA).
- The World Health Organization's diagnostic criterion for osteoporosis is BMD that is more than 2.5 standard deviations below the mean BMD for young adults.
- The objective of osteoporosis therapy is to reduce fractures.
- Fracture risk, which can be calculated using the FRAX tool developed by the WHO, is based on BMD and other factors, including age, use of glucocorticoids, and a personal or family history of fractures.

884

- With currently available drugs, we are more able to prevent bone loss (using antiresorptive agents) than to rebuild bone that is already gone (using bone-forming agents).
- Antiresorptive drugs—estrogen, raloxifene, bisphosphonates (eg, alendronate), and calcitonin—decrease bone loss by inhibiting the activity of osteoclasts.
- Estrogen increases BMD and reduces fracture risk.
- In the past, estrogen was considered a treatment of choice for prevention and treatment of postmenopausal osteoporosis. Today, however, there is strong evidence that benefits in osteoporosis do not outweigh the risks (breast cancer, myocardial infarction, stroke, cholecystitis).
- Calcitonin is the safest drug for osteoporosis, but is less effective than estrogen or alendronate. Comparisons with raloxifene are not available.

75.4.3.2

Summary of Major Nursing Implications*

75.4.3.2.1

VITAMIN D

Calcifediol

Calcitriol

Cholecalciferol

Dihydrotachysterol

Doxercalciferol

Ergocalciferol

Paricalcitol

75.4.3.2...

Preadministration Assessment

75.4.3.2...

Therapeutic Goal

Treatment of rickets, osteomalacia, and hypoparathyroidism, and prevention of vitamin D deficiency.

75.4.3.2...

Baseline Data

The prescriber may order serum levels of vitamin D, calcium, phosphorus, and alkaline phosphatase as well as a 24-hour urinary calcium determination.

Assess dietary vitamin D and calcium content.

75.4.3.2...

Identifying High-Risk Patients

Vitamin D is *contraindicated* in patients with hypercalcemia, hypervitaminosis D, and malabsorption syndrome.

Exercise *caution* in patients taking digoxin.

75.4.3.2...

Implementation: Administration

75.4.3.2...

Routes

Oral, IM.

75.4.3.2...

Administration

Instruct the patient to swallow oral preparations intact, without crushing or chewing.

Therapeutic responses to vitamin D require adequate calcium intake. Assess dietary calcium content and adjust to ensure calcium sufficiency.

75.4.3.2...

Ongoing Evaluation and Interventions

75.4.3.2...

Monitoring Summary

Monitor serum calcium, serum phosphorus, and urinary calcium.

75.4.3.2...	Minimizing Adverse Interactions Digoxin. Vitamin D–induced hypercalcemia can cause dysrhythmias in patients taking digoxin. Monitor serum calcium and make certain it remains normal.	
75.4.3.2...	Management of Toxicity Large therapeutic doses may cause hypervitaminosis D, a syndrome characterized by hypercalcemia, hypercalciuria, decalcification of bone, and deposition of calcium in soft tissues. Monitor serum calcium content; levels should stay below 10 mg/dL. Monitor serum phosphorus and urinary calcium as well. If vitamin D toxicity develops, have the patient discontinue vitamin D immediately, increase fluid intake, and institute a low-calcium diet. In severe cases, calcium excretion can be accelerated with IV saline plus furosemide.	884
75.4.3.2.2	ORAL CALCIUM SALTS Calcium acetate Calcium carbonate Calcium citrate Calcium glubionate Calcium gluconate Calcium lactate Tricalcium phosphate	885

75.4.3.2...

Preadministration Assessment

75.4.3.2...

Therapeutic Goal

Treatment of mild hypocalcemia and supplementation of dietary calcium.

75.4.3.2...

Baseline Data

Obtain a serum calcium level.

75.4.3.2...

Identifying High-Risk Patients

Calcium salts are *contraindicated* for patients with hypercalcemia, renal calculi, and hypophosphatemia.

75.4.3.2...

Implementation: Administration

75.4.3.2...

Route

Oral.

75.4.3.2...

Dosage

Individual calcium salts differ with respect to percentage of elemental calcium. As a result, the dose required to provide a specific amount of calcium differs among the salts.

Advise patients against switching to a different preparation.

75.4.3.2...

Administration

Advise patients to take oral calcium salts with a large glass of water; administration with or after meals promotes absorption. Advise patients to avoid taking calcium with foods that can suppress calcium absorption (eg, spinach, Swiss chard, beets, bran, whole-grain cereals).

75.4.3.2...

Ongoing Evaluation and Interventions

75.4.3.2...

Minimizing Adverse Effects

Prolonged therapy can cause hypercalcemia. **Inform patients about signs of hypercalcemia (nausea, vomiting, constipation, frequent urination, lethargy, and**

depression), and instruct them to notify the prescriber if these occur.

Hypercalcemia can be minimized with frequent monitoring of serum calcium.

Minimizing Adverse Interactions

Glucocorticoids.

These drugs reduce calcium absorption; increased calcium dosage may be required.

Tetracyclines.

Calcium binds to tetracyclines, thereby reducing tetracycline absorption. **Instruct patients to separate administration of these agents by at least 1 hour.**

Thyroid Hormone.

Calcium interferes with absorption of thyroid hormone. **Instruct patients to separate administration of these agents by several hours.**

Thiazide Diuretics.

Thiazides decrease renal excretion of calcium. A reduction in calcium dosage may be needed to avoid hypercalcemia.

PARENTERAL CALCIUM SALTS

Calcium chloride

Calcium gluconate

Preadministration Assessment

Therapeutic Goal

Reversal of clinical manifestations of hypocalcemia.

Baseline Data

Assess for signs and symptoms of hypocalcemia (tetany, convulsions, laryngospasm, spasm of other muscles). Obtain measurement of serum calcium.

75.4.3.2...

Identifying High-Risk Patients

Parenteral calcium is *contraindicated* for patients with hypercalcemia or ventricular fibrillation.

Use with *extreme caution* in patients taking digoxin.

75.4.3.2...

Implementation: Administration

75.4.3.2...

Route

Intravenous.

75.4.3.2...

Administration

Warm solutions to body temperature prior to IV dosing. Perform IV injections slowly (0.5 to 2 mL/min).

Drugs that contain phosphate, carbonate, sulfate, and tartrate groups can precipitate calcium; do not mix these drugs with parenteral calcium solutions.

Calcium chloride may cause necrosis and sloughing if solutions become extravasated. Monitor the infusion closely.

75.4.3.2...

Ongoing Evaluation and Interventions

75.4.3.2...

Evaluating Therapeutic Effects

Evaluate the patient for reductions in tetany, muscle spasm, laryngospasm, paresthesias, and other symptoms of severe hypocalcemia.

75.4.3.2...

Minimizing Adverse Effects

75.4.3.2...

Hypercalcemia.

Overdose can produce acute hypercalcemia, resulting in nausea, vomiting, weakness, lethargy, coma, and possibly death. Avoid hypercalcemia through careful control of dosage.

75.4.3.2...	Minimizing Adverse Interactions	
75.4.3.2...	Digoxin. Parenteral calcium may cause severe bradycardia in patients taking digoxin. Infuse calcium slowly and cautiously in these patients.	885
75.4.3.2.4	CALCITONIN-SALMON	886
75.4.3.2...	Preadministration Assessment	
75.4.3.2...	Therapeutic Goal Treatment of postmenopausal osteoporosis, Paget's disease of bone, and hypercalcemia.	
75.4.3.2...	Baseline Data The prescriber may order measurements of serum alkaline phosphatase, calcium, and phosphorus, as well as a 24-hour urinary hydroxyproline.	
75.4.3.2...	Identifying High-Risk Patients Salmon calcitonin is <i>contraindicated</i> for patients allergic to this preparation.	
75.4.3.2...	Implementation: Administration	
75.4.3.2...	Routes	
75.4.3.2...	Intranasal. For osteoporosis only.	
75.4.3.2...	Parenteral (IM, subQ). For osteoporosis, Paget's disease, and hypercalcemia.	

75.4.3.2...

Administration

75.4.3.2...

Intranasal.

Instruct patients using Miacalcin to activate the metered-dose pump by holding the bottle upright and depressing the two white sidearms toward the bottle 6 times, which should produce a faint initial spray. The drug is then administered by placing the nozzle in the nostril and depressing the pump handle.

75.4.3.2...

Subcutaneous.

Teach patients how to inject calcitonin subQ, and instruct them to rotate sites of injection.

75.4.3.2...

Ongoing Evaluation and Interventions

75.4.3.2...

Evaluating Therapeutic Effects

75.4.3.2...

Postmenopausal Osteoporosis.

Measurement of BMD should indicate retardation of bone loss (and perhaps a small increase in BMD).

75.4.3.2...

Paget's Disease of Bone.

Monitor for reductions in bone pain, serum alkaline phosphatase levels, and 24-hour urinary hydroxyproline value.

75.4.3.2...

Hypercalcemia.

Monitor for reductions in serum calcium and phosphorus levels.

75.4.3.2.5

BISPHOSPHONATES USED FOR OSTEOPOROSIS

Alendronate

Ibandronate

Risedronate

Zoledronate

Preadministration Assessment

Therapeutic Goal

Prevention and treatment of osteoporosis.

Baseline Data

Obtain baseline values for BMD in the hip, spine, and wrist. For patients receiving zoledronate, obtain a baseline value for creatinine clearance.

Identifying High-Risk Patients

Oral bisphosphonates are *contraindicated* for patients with esophageal disorders that can impede swallowing and for patients who cannot sit or stand for at least 30 minutes (60 minutes with ibandronate).

Zoledronate, an IV bisphosphonate, should be used with *caution* in patients with renal impairment.

Implementation: Administration

Route

Oral.

Alendronate, risedronate, ibandronate.

Intravenous.

Zoledronate.

Dosing Schedule

Alendronate.

Daily or weekly.

75.4.3.2...

Risedronate.

Daily, weekly, or monthly.

75.4.3.2...

Ibandronate.

Daily, monthly, or every 3 months.

75.4.3.2...

Zoledronate.

Yearly.

75.4.3.2...

Administration

75.4.3.2...

Oral.

Proper administration is needed to maximize absorption and minimize the risk of esophagitis. Accordingly, **instruct patients to**

- **Administer in the morning before eating or drinking anything.**
- **Administer with a full glass of water.**
- **Administer while upright, either sitting or standing.**
- **Avoid chewing or sucking the tablet.**
- **After dosing, remain sitting or standing for at least 30 minutes (60 minutes with ibandronate).**
- **After dosing, postpone ingesting anything—including orange juice, coffee, calcium supplements, and antacids—for at least 30 minutes (60 minutes with ibandronate).**

75.4.3.2...

Intravenous.

Infuse zoledronate over a 15-minute span.

75.4.3.2...	Ongoing Evaluation and Interventions	
75.4.3.2...	Evaluating Therapeutic Effects Obtain periodic determinations of BMD. If BMD increases, or at least remains constant, treatment is a success. Conversely, a significant decline in BMD indicates failure.	
75.4.3.2...	Minimizing Adverse Effects	
75.4.3.2...	Esophagitis. Oral bisphosphonates can cause severe esophagitis, sometimes resulting in ulceration. To minimize risk, instruct patients to (1) administer the drug in accord with the guidelines described above, (2) avoid lying down after dosing, and (3) discontinue the drug and contact the prescriber if they experience symptoms of esophageal injury (difficulty swallowing, pain upon swallowing, new or worsening heartburn). Avoid these drugs in patients with esophageal disorders that could impede swallowing and in patients who are unable to sit or stand for 30 minutes (60 minutes with ibandronate).	886
75.4.3.2...	Musculoskeletal Pain. Rarely, bisphosphonates cause muscle, bone, and joint pain. Severe pain may require an opioid or ketorolac for relief. As a rule, pain gradually diminishes when bisphosphonates are withdrawn. In most cases, pain does not return when bisphosphonates are resumed. If it does resume, osteoporosis should be managed with a different drug (eg, calcitonin-salmon, teriparatide, raloxifene).	887
75.4.3.2...	Ocular Problems. Rarely, bisphosphonates cause conjunctivitis, scleritis, blurred vision, eye pain, and other ocular problems. Inform patients about these effects and instruct them to report any vision changes or eye pain.	
75.4.3.2...	Bisphosphonate-Related Osteonecrosis of the Jaw. BRONJ occurs primarily with IV bisphosphonates when they are used in cancer patients, and not with oral bisphosphonates used for osteoporosis.	

75.4.3.2...

Renal Toxicity.

Intravenous zoledronate may cause renal damage, especially if administered too rapidly. Ensure adequate hydration before the infusion, and infuse zoledronate slowly—over 15 minutes or more. Make periodic determinations of creatinine clearance, and if the results indicate renal impairment, decrease zoledronate dosage.

75.4.3.2.6

RALOXIFENE

75.4.3.2...

Preadministration Assessment

75.4.3.2...

Therapeutic Goals

Prevention and treatment of postmenopausal osteoporosis, and reducing the risk of invasive breast cancer in postmenopausal women who have osteoporosis and/or a high risk for breast cancer.

75.4.3.2...

Baseline Data

Obtain baseline values for BMD in the hip, vertebrae, and forearm.

75.4.3.2...

Identifying High-Risk Patients

Raloxifene is *contraindicated* for use by patients who are pregnant or have a history of venous thrombotic events.

75.4.3.2...

Implementation: Administration

75.4.3.2...

Route

Oral.

75.4.3.2...

Administration

Take once daily without regard to meals.

75.4.3.2... Ongoing Evaluation and Interventions

75.4.3.2... Promoting Therapeutic Effects

Advise women taking raloxifene for osteoporosis to ensure adequate intake of calcium and vitamin D.

75.4.3.2... Evaluating Therapeutic Effects

For women taking raloxifene to prevent or treat osteoporosis, obtain periodic determinations of BMD. If BMD increases, or at least remains constant, treatment is a success. Conversely, a significant decline in BMD indicates failure.

75.4.3.2... Minimizing Adverse Effects

75.4.3.2... Venous Thromboembolism.

Raloxifene increases the risk of DVT, pulmonary embolism, and thrombotic stroke.

Advise patients to discontinue raloxifene at least 72 hours prior to prolonged immobilization (eg, postsurgical recovery, extended bed rest), and to resume treatment only after full mobility has been restored. Advise patients to avoid extended periods of restricted activity, as can happen when traveling. Do not give raloxifene to patients with a history of venous thrombotic events.

75.4.3.2... Fetal Harm.

Raloxifene can cause fetal harm, and must not be used during pregnancy.

75.4.3.2.7 ESTROGEN

Nursing implications for estrogen are summarized in [Chapter 60](#).

* Patient education information is highlighted as **blue text**.

⁷⁶CHAPTER 75 Drugs for Asthma

^{76.1}BASIC CONSIDERATIONS

Asthma is a common, chronic disorder that occurs in children and adults. In the United States, more than 22 million people have the disease. Characteristic signs and symptoms are a sense of breathlessness and tightness in the chest, together with wheezing, dyspnea, and cough. The underlying cause is immune-mediated airway inflammation. In 2004, asthma led to 13.6 million physician office visits and 1 million outpatient department visits. Each year, the disease kills about 5000 Americans. However, despite these sobering statistics, with proper treatment, most patients can lead full lives with no limitations.

^{76.2}PATHOPHYSIOLOGY OF ASTHMA

Asthma is a *chronic inflammatory* disorder of the airways. In about 50% of children with asthma and in some adults, airway inflammation results from an immune response to known allergens. In the remaining children and in most adults, the cause of airway inflammation is unknown—although as-yet unidentified allergens are suspected.

[Figure 75-1](#) depicts the events that lead to inflammation and bronchoconstriction in patients whose asthma is caused by specific allergens. Although this model may not apply completely to all asthma patients, it nonetheless provides a basis for understanding the drugs used for treatment. The inflammatory process begins with binding of allergen molecules (eg, house dust mite feces) to immunoglobulin E (IgE) antibodies on mast cells. This causes mast cells to release an assortment of mediators, including histamine, leukotrienes, prostaglandins, and interleukins. These mediators have two effects. They act immediately to cause *bronchoconstriction*. In addition, they promote infiltration and activation of inflammatory cells (eosinophils, leukocytes, macrophages). These inflammatory cells then release mediators of their own. The end result is *airway inflammation*, characterized by edema, mucus plugging, and smooth muscle hypertrophy, all of which obstruct airflow. In addition, inflammation produces a state of *bronchial hyperreactivity*. Because of this state, mild trigger factors (eg, cold air, exercise, tobacco smoke) are able to cause intense bronchoconstriction.

From a therapeutic perspective, the important message here is that symptoms of asthma result from a combination of inflammation and bronchoconstriction. Accordingly, treatment must address both components.

76.3 OVERVIEW OF DRUGS FOR ASTHMA

The major drugs for asthma are listed in [Table 75-1](#). As indicated, they fall into two main pharmacologic classes: *antiinflammatory agents* and *bronchodilators*. The principal anti-inflammatory drugs are the *glucocorticoids*. The principal bronchodilators are the *beta₂ agonists*. For chronic asthma, glucocorticoids are administered on a fixed schedule, almost always by inhalation. Beta₂ agonists may be administered on a fixed schedule (for long-term control) or PRN (to manage an acute attack). Like the glucocorticoids, beta₂ agonists are usually inhaled. As discussed in [Box 75-1](#), the drugs we use for asthma are also used for chronic obstructive pulmonary disease (COPD).

888

889

Figure 75-1 Allergen-induced inflammation and bronchospasm in asthma.

76.4 ADMINISTERING DRUGS BY INHALATION

Most antiasthma drugs can be administered by inhalation, a route with three obvious advantages: (1) therapeutic effects are enhanced (by delivering drugs directly to their site of action), (2) systemic effects are minimized, and (3) relief of acute attacks is rapid. Three types of inhalation devices are employed: metered-dose inhalers, dry-powder inhalers, and nebulizers.

76.4.1 Metered-Dose Inhalers

Metered-dose inhalers (MDIs) are small, hand-held, pressurized devices that deliver a measured dose of drug with each actuation. Dosing is usually accomplished with 1 or 2 puffs. When 2 puffs are needed, an interval of at least 1 minute should separate the first puff from the second. When using an MDI, the patient must begin to inhale prior to activating the device. Hence, hand-lung coordination is required. MDIs can be difficult to use correctly. Hence patients will need a demonstration as well as written and verbal instruction. Even with optimal use, only about 10% of the dose reaches the lungs. About 80% impacts the oropharynx and is swallowed, and the remaining 10% is left in the device or exhaled.

Several kinds of *spacers* are available for use with MDIs. All of these devices, which attach directly to the MDI, serve to increase delivery of drug to the lungs and decrease deposition of drug on the oropharyngeal mucosa ([Fig. 75-2](#)). Some spacers contain a one-way valve that activates upon inhalation, thereby obviating the need for good hand-lung coordination. Some spacers also contain an alarm whistle that sounds off when inhalation is too rapid. The ability of spacers to reduce drug deposition in the oropharynx is especially important for inhaled glucocorticoids.

Prior to January 1, 2009, MDIs employed two kinds of propellants: *chlorofluorocarbons* (CFCs) and *hydrofluoroalkane* (HFA). Today, however, nearly all MDIs use HFA. Most MDIs made with CFCs have been banned. Why? Because CFCs can deplete the Earth's ozone layer, which protects us from ultraviolet radiation. HFA does not affect ozone.

76.4.2 Dry-Powder Inhalers

Dry-powder inhalers (DPIs) are used to deliver drugs in the form of a dry, micronized powder directly to the lungs. No propellant is employed. Hence, DPIs pose no environmental risk. Unlike MDIs, DPIs are breath activated. As a result, DPIs don't require the hand-lung coordination needed with MDIs, and hence DPIs are much easier to use. Compared with MDIs, DPIs deliver more drug to the lungs (20% of the total released vs. 10%) and less to the oropharynx.

889

TABLE 75-1 Overview of Major Drugs for Asthma

ANTI-INFLAMMATORY DRUGS
Glucocorticoids
Inhaled
Beclomethasone dipropionate [QVAR]
Budesonide [Pulmicort Turbohaler, Pulmicort Respules]
Ciclesonide [Alvesco]
Flunisolide [Aerobid]
Fluticasone propionate [Flovent HFA, Flovent Diskus]
Mometasone furoate [Asmanex Twisthaler]
Triamcinolone acetonide [Azmacort]
Oral
Prednisone
Prednisolone
Leukotriene Modifiers
Montelukast, oral [Singulair]
Zafirlukast, oral [Accolate]
Zileuton, oral [Zyflo, Zyflo CR]
Cromolyn and Nedocromil
Cromolyn, inhaled [Intal]
Nedocromil, inhaled [Tilade] [*]
IgE Antagonist
Omalizumab [Xolair]
BRONCHODILATORS
Beta₂-Adrenergic Agonists
Inhaled: Short Acting
Albuterol [AccuNeb, ProAir HFA, Proventil HFA,

Ventolin HFA] Bitolterol [Tornalate]*- Levalbuterol [Xopenex, Xopenex HFA] Pirbuterol [Maxair Autohaler] Inhaled: Long Acting Arformoterol [Brovana] Formoterol [Foradil Aerolizer, Perforomist] Salmeterol [Serevent Diskus] Oral Albuterol [VoSpire] Terbutaline [Brethine] Methylxanthines Theophylline, oral [Theo-24, Theochron, Uniphyll, Elixophyllin] Anticholinergics Ipratropium, inhaled [Atrovent, Atrovent HFA] Tiotropium, inhaled [Spiriva]
--

* Not available in the United States.

76.4.3 Nebulizers

A nebulizer is a small machine used to convert a drug solution into a mist. The droplets in the mist are much finer than those produced by inhalers. Inhalation of the nebulized mist can be done through a face mask or through a mouthpiece held between the teeth. Nebulizers take several minutes to deliver the same amount of drug contained in 1 puff from an inhaler. For some patients, a nebulizer may be more effective than an inhaler. Although nebulizers are usually used at home or in a hospital, these devices, which weigh under 10 pounds, are sufficiently portable for use in other locations.

76.5 ANTI-INFLAMMATORY DRUGS

Anti-inflammatory drugs—especially inhaled glucocorticoids—are the foundation of asthma therapy. These drugs are taken daily for long-term control. Most people with asthma should receive one.

76.6 GLUCOCORTICOIDS

Glucocorticoids (eg, budesonide, fluticasone) are the most effective antiasthma drugs available. Administration is usually by inhalation, but may also be IV or oral. Adverse reactions to inhaled glucocorticoids are generally minor, as are reactions to systemic glucocorticoids taken *acutely*. However, when *systemic* glucocorticoids are used *long term*, severe adverse effects are likely. The basic pharmacology of the glucocorticoids is presented in [Chapter 71](#). Discussion here is limited to their use in asthma.

76.6.1 Mechanism of Antiasthma Action

Glucocorticoids reduce asthma symptoms by *suppressing inflammation*. Specific anti-inflammatory effects include (1) decreased synthesis and release of inflammatory mediators (eg, leukotrienes, histamine, prostaglandins); (2) decreased infiltration and activity of inflammatory cells (eg, eosinophils, leukocytes); and (3) decreased edema of the airway mucosa (secondary to a decrease in vascular permeability). By suppressing inflammation, glucocorticoids reduce bronchial hyperreactivity. In addition to reducing inflammation, glucocorticoids decrease airway mucus production and increase the number of bronchial β_2 receptors as well as their responsiveness to β_2 agonists.

76.6.2 Use in Asthma

Glucocorticoids are used for *prophylaxis* of chronic asthma. Accordingly, administration must be done on a fixed schedule—not PRN. Because beneficial effects develop slowly, these drugs cannot be used to abort an ongoing attack. Glucocorticoids do not alter the natural course of asthma, even when used in young children.

76.6.2.1 Inhalation Use.

Inhaled glucocorticoids are first-line therapy for asthma. All patients with moderate to severe asthma should use these drugs daily. In addition to being highly effective, inhaled glucocorticoids are very safe.

76.6.2.2 Oral Use.

Oral glucocorticoids are reserved for patients with severe asthma. Because of their potential for toxicity, these drugs are prescribed only when symptoms cannot be controlled with safer medications (inhaled glucocorticoids, inhaled β_2 agonists). Because the risk of toxicity increases with duration of use, treatment should be as brief as possible.

76.6.3 Adverse Effects

76.6.3.1 Inhaled Glucocorticoids.

These preparations are largely devoid of serious toxicity, even when used in high doses. The most serious concerns are adrenal suppression and bone loss.

890

76.6.3.1.1 BOX 75-1 Special Interest Topic

891

76.6.3.1.1.1 CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) is a progressive, largely irreversible disorder that restricts airflow in the lungs. Smoking cigarettes is almost always the cause. Symptoms include chronic cough, excessive sputum production, wheezing, dyspnea, and poor exercise tolerance. In the United States, COPD affects about 24 million people, and is the *fourth leading cause of death*. COPD is treated with the same drugs we use for asthma. Unfortunately, although these drugs are highly effective in asthma, benefits in COPD are minimal, being limited to a small improvement in symptoms. Drug therapy does not slow disease progression, reduce hospitalizations, or prolong life.

Symptoms of COPD result largely from two pathologic processes: *chronic bronchitis* and *emphysema*. In most cases, both processes are caused by an exaggerated inflammatory reaction to cigarette smoke. Chronic bronchitis—defined by chronic cough and excessive sputum production—results from hypertrophy of mucus-secreting glands in the epithelium of the larger airways. Emphysema is defined as enlargement of the air space within the bronchioles and alveoli brought on by deterioration of the walls of these air spaces. Among individuals with COPD, the relative contribution of these two processes can vary. That is, some patients may suffer primarily from chronic bronchitis, some primarily from emphysema, and some from both disease processes.

Diagnosis and treatment of COPD was addressed in two clinical guidelines released in 2007. The first guideline—*Global Strategy for the Diagnosis, Management, and*

Prevention of Chronic Obstructive Pulmonary Disease—was issued by the Global Initiative for Chronic Obstructive Lung Disease (GOLD). The second guideline—*Diagnosis and Management of Stable Chronic Obstructive Pulmonary Disease*—was issued by the American College of Physicians (ACP). The GOLD guideline is large and comprehensive. The ACP guideline, which is much smaller, was written as a practical guide for primary care clinicians. The recommendations below reflect those in the ACP guideline.

76.6.3.1.1....

Diagnosis Based on Symptoms and Spirometry.

Patients who have symptoms of COPD—especially dyspnea—should be tested with a *spirometer* to measure the degree of airway obstruction. As noted in our discussion of asthma management, a spirometer measures *forced expiratory volume* (FEV). Test results are expressed as a percent of the FEV that would be predicted for a healthy person of the same age, sex, height, and weight. To diagnose COPD, we need a value for FEV_1 , that is, the FEV measured during the first second of exhalation into the spirometer. According to the ACP guidelines, treatment of stable COPD should be reserved for patients with an FEV_1 that is below 60% of the predicted value. However, it is important to note that diagnosis is not based on spirometry alone. Rather, the patient must have respiratory symptoms as well. In fact, in the absence of COPD symptoms, the guidelines recommend against using spirometry in the first place.

76.6.3.1.1....

Initial Monotherapy.

Symptomatic patients with an FEV_1 less than 60% of predicted should receive maintenance therapy with *one* of the following: (1) a long-acting inhaled β_2 agonist (eg, salmeterol), (2) a long-acting inhaled anticholinergic drug (eg, tiotropium), or (3) an inhaled glucocorticoid (eg, budesonide). Drugs in all three classes can reduce exacerbations. Evidence is insufficient to recommend one class over the other.*

76.6.3.1.1....

Combination Therapy.

Prescribers *may* consider combination inhaled therapies for symptomatic patients with an FEV_1 less than 60% of predicted. However, research on combination therapy has not shown a consistent benefit over monotherapy.

76.6.3.1.1....

Use of Oxygen.

Supplemental oxygen given 15 or more hours a day can improve survival in patients with resting hypoxemia (PaO_2 of 55 mm Hg or less) and severe airway obstruction (FEV_1 less than 30% of predicted). Accordingly, oxygen should be prescribed for these people.

76.6.3.1.1....

Pulmonary Rehabilitation.

For symptomatic patients with an FEV_1 less than 50% of predicted, pulmonary rehabilitation (eg, exercise therapy) can reduce hospitalizations, improve health status, and increase exercise capacity. Accordingly, a program of pulmonary rehabilitation may be considered for these patients. Benefits are not clear for patients with an FEV_1 that is above 50% of predicted.

- * Other drugs for COPD, which are not addressed in the guidelines, include albuterol (a short-acting inhaled β_2 agonist), theophylline (a methylxanthine), and systemic glucocorticoids (eg, prednisone).

The most common adverse effects are *oropharyngeal candidiasis* and *dysphonia* (hoarseness, speaking difficulty). Both effects result from local deposition of inhaled glucocorticoids. To minimize these effects, patients should (1) gargle after each administration and (2) employ a spacer device during administration, which will greatly reduce drug deposition in the oropharynx. If candidiasis develops, it can be treated with an antifungal drug.

With long-term, high-dose therapy, some *adrenal suppression* may develop, although the degree of suppression is generally low. In contrast, with prolonged use of *oral* glucocorticoids, adrenal suppression can be profound. As noted below, *patients who have been switched from oral glucocorticoids to inhaled glucocorticoids must be given supplemental oral or IV doses at times of stress*. (At times of stress, inhaled glucocorticoids can control symptoms of asthma, but cannot replace the glucocorticoids required to support life.)

Like oral glucocorticoids, inhaled glucocorticoids can promote *bone loss*—at least in premenopausal women. Fortunately, the amount of loss is much lower than the amount caused by oral glucocorticoids. To minimize bone loss, patients should (1) use the lowest dose possible, (2) ensure adequate intake of calcium and vitamin D, and (3) participate in weight-bearing exercise.

Glucocorticoids can *slow* growth in children and adolescents—but these drugs do *not* decrease adult height. *Short-term* studies have shown that inhaled glucocorticoids retard growth. However, *long-term* studies indicate that adult

891

892

Figure 75-2 Impact of a spacer device on the distribution of inhaled medication. Note that, when a spacer is used, more medication reaches its site of action in the lungs, and less is deposited in the mouth and throat.

height is not reduced. Two studies reported in the October 12, 2000, issue of the *New England Journal of Medicine* demonstrated that inhaled budesonide does indeed slow growth in children—but only temporarily. Despite continued budesonide use, growth rate returns to normal within a year, and children eventually achieve their expected adult height. Moreover, adult height is not affected by either the duration of budesonide use or the total cumulative dose. Unfortunately, these studies focused only on *skeletal* growth, and hence we still don't know if glucocorticoids suppress growth and development of the brain, lungs, and other organs. Until more is known about how glucocorticoids affect organs, it would seem prudent to reserve these drugs for older children and for young children whose asthma is relatively severe; young children whose asthma is very mild, and hence can be treated effectively without glucocorticoids, should probably not receive these drugs.

Prolonged therapy may increase the risk of *cataracts* and *glaucoma*.

76.6.3.2 Oral Glucocorticoids.

When used acutely (less than 10 days), even in very high doses, oral glucocorticoids do not cause significant adverse effects. However, prolonged therapy, even in moderate doses, can be

hazardous. Potential adverse effects include *adrenal suppression*, *osteoporosis*, *hyperglycemia*, *peptic ulcer disease*, and, in young patients, *suppression of growth*.

Adrenal suppression is of particular concern. As discussed in [Chapter 71](#), prolonged glucocorticoid use can decrease the ability of the adrenal cortex to produce glucocorticoids of its own. Because high levels of glucocorticoids are required to survive severe stress (eg, surgery, trauma, infection), and because adrenal suppression prevents production of endogenous glucocorticoids, *patients must be given increased doses of oral or IV glucocorticoids at times of stress. Failure to do so can prove fatal!* Following withdrawal of oral glucocorticoids (or transfer to inhaled glucocorticoids), several months are required for recovery of adrenocortical function. Throughout this time, all patients—including those switched to inhaled glucocorticoids—must be given supplemental oral or IV glucocorticoids at times of severe stress.

A complete list of contraindications to oral glucocorticoids is presented in the *Summary of Major Nursing Implications* at the end of this chapter.

76.6.4 Preparations, Dosage, and Administration

76.6.4.1 Inhaled Glucocorticoids.

Eight glucocorticoids are available for inhalation ([Table 75-2](#)). Six are available in MDIs, two are available in DPIs, and one is available in suspension for nebulization. Inhaled glucocorticoids are administered on a regular schedule—not PRN. Pediatric and adult dosages are summarized in [Table 75-2](#). In all cases, the dosage should be kept as low as possible so as to minimize bone loss, adrenal suppression, and other adverse effects.

76.6.4.1.1 Glucocorticoids in MDIs

As discussed earlier, two propellants—CFCs and HFA—are used in MDIs. Currently, only two glucocorticoids—beclomethasone [QVAR] and fluticasone [Flovent HFA]—come in MDIs that use HFA. The others come in MDIs that use CFCs. Patients using MDIs that employ CFCs should be instructed to use a *spacer device* (holding chamber) in order to (1) increase the amount of glucocorticoid delivered to the lungs (thereby increasing therapeutic effects), and (2) reduce the amount deposited in the oropharynx (thereby reducing the risk of candidiasis and dysphonia). Patients using HFA-based MDIs do not need a spacer device. Why? Because HFA produces smaller droplets than do CFCs, and hence delivery of drugs to the lungs is greatly improved. Regardless of which type of MDI is employed, penetration to the lungs can be increased by inhaling a beta₂ agonist 5 minutes prior to inhaling the glucocorticoid.

76.6.4.1.2 Nebulized Budesonide.

Budesonide suspension [Pulmicort Respules] is the first inhaled glucocorticoid formulated for nebulized dosing. The product is approved for maintenance therapy of persistent asthma in children 1 to 8 years old—that is, children too young to use an MDI or DPI. Improvement should begin in 2 to 8 days; maximal benefits may take 4 to 6 weeks to develop. Budesonide suspension is available in 2-mL ampules containing 250 or 500 mcg of the drug.

Administration is done with a jet nebulizer equipped with a mouthpiece or face mask; ultrasonic nebulizers should not be used. Administration takes 5 to 10 minutes. For children

who are *not* taking an oral glucocorticoid, the initial dosage is 500 mcg/day in one or two doses. For children who *are* taking an oral glucocorticoid, the initial dosage is 1000 mcg/day in one or two doses. After 1 week, dosage of the oral glucocorticoid should be tapered off.

892

893

TABLE 75-2 Inhaled Glucocorticoids: Formulations and Dosages

Drug	Formulation	Dosage	
		Adults	Children
Beclomethasone dipropionate			
[QVAR]	MDI (40 or 80 mcg/puff)	40–320 mcg twice daily	40–80 mcg twice daily (5–11 yr)
Budesonide			
[Pulmicort Flexhaler]	DPI (90 or 180 mcg/inhalation)	360–720 mcg twice daily	180–360 mcg twice daily (6–17 yr)
[Pulmicort Respules]	Suspension for nebulization	250–500 mcg once or twice daily <i>or</i> 1000 mcg once daily	500–1000 mcg/day (1–8 yr)
Ciclesonide			
[Alvesco]	MDI (80 or 160 mcg/puff)	80–320 mcg twice daily	80–320 mcg twice daily (12 yr and up)
Flunisolide			
[Aerobid, Aerobid-M]	MDI (250 mcg/puff)	500–1000 mcg twice daily	500 mcg twice daily (6–15 yr)
Flunisolide hemihydrate			
[AeroSpan]	MDI (80 mcg/puff)	160–320 mcg twice daily	80–160 mcg twice daily (6–11 yr)
Fluticasone propionate			
[Flovent HFA]	MDI (44, 110, or 220 mcg/puff)	88–880 mcg twice daily	88 mcg twice daily (4–11 yr)
[Flovent Diskus]	DPI (50, 100, or 250 mcg/puff)	100–1000 mcg twice daily	50–100 mcg twice daily (4–11 yr)
Mometasone furoate			
[Asmanex Twisthaler]	DPI (110 or 220 mcg/puff)	220–440 mcg once or twice daily	110 mcg once daily (4–11 yr)
Triamcinolone acetonide			

[Azmacort]	MDI (75 mcg/ puff)	150 mcg 3–4 times a day <i>or</i> 300 mcg twice daily	75–150 mcg 3–4 times daily <i>or</i> 150–300 mcg twice daily (6–12 yr)
MDI = metered-dose inhaler, DPI = dry powdered inhaler.			

76.6.4.2 Oral Glucocorticoids.

Prednisone and *prednisolone* are preferred glucocorticoids for oral therapy of asthma. For acute therapy, the usual adult dosage for either drug is 30 to 40 mg twice daily for 5 to 7 days.

For *long-term* treatment, *alternate-day dosing* is recommended (to minimize adrenal suppression). The *initial adult* dosage is 40 to 60 mg (of prednisone or prednisolone) administered every other morning. The *initial pediatric* dosage is 20 to 40 mg every other morning. After symptoms have been controlled for a month, dosages should be reduced by 5 to 10 mg every 2 weeks to establish the lowest dosage that can keep the patient free of symptoms. As discussed above, supplemental doses are required at times of stress.

76.7 LEUKOTRIENE MODIFIERS

When they were introduced in the late 1990s, the leukotriene modifiers were the first new drugs for asthma in over 20 years. All of these agents suppress the effects of leukotrienes, compounds that promote bronchoconstriction as well as eosinophil infiltration, mucus production, and airway edema. In patients with asthma, these drugs can decrease inflammation, bronchoconstriction, edema, mucus secretion, and recruitment of eosinophils and other inflammatory cells.

Currently, three leukotriene modifiers are available: zileuton, zafirlukast, and montelukast. Zileuton blocks leukotriene synthesis; zafirlukast and montelukast block leukotriene receptors. Leukotriene modifiers are less effective than inhaled glucocorticoids, and should not be used as first-line therapy for most patients.

76.7.1 Zileuton

Zileuton [Zyflo, Zyflo CR], an inhibitor of leukotriene synthesis, is approved for asthma prophylaxis and maintenance therapy in adults and children age 12 years and older. Benefits derive from inhibiting 5-lipoxygenase, the enzyme that converts arachidonic acid into leukotrienes. Symptomatic improvement can be seen within 1 to 2 hours of dosing. Because effects are not immediate, zileuton cannot be used to abort an ongoing attack. Zileuton is less effective than an inhaled glucocorticoid alone, and appears to be less effective than a long-acting inhaled β_2 agonist as adjunctive therapy in patients not adequately controlled with an inhaled glucocorticoid.

Zileuton is given orally and undergoes rapid absorption, both in the presence and absence of food. Plasma levels peak 2 to 3 hours after dosing. Zileuton is rapidly metabolized by the liver, and the metabolites are excreted in the urine. Its plasma half-life is 2.5 hours.

Zileuton can injure the liver, as evidenced by increased plasma levels of alanine aminotransferase (ALT) activity. A few patients have developed symptomatic hepatitis, which reversed following drug withdrawal. To reduce the risk of serious liver injury, ALT activity should be monitored. The recommended schedule is once a month for 3 months, then every 2 to 3 months for the remainder of the first year, and periodically thereafter. In addition to liver injury, zileuton can cause dyspepsia. In mice taking 4 times the human dose, the drug increased the incidence of liver, kidney, and vascular tumors.

Zileuton is metabolized by cytochrome P450, and hence can compete with other drugs for metabolism, thereby increasing their levels. Combined use with theophylline can markedly increase theophylline levels. Accordingly, dosage of theophylline should be reduced. Zileuton can also increase levels of warfarin and propranolol.

Zileuton is available in 600-mg immediate-release (IR) tablets, sold as Zylflo, and 600-mg extended-release (ER) tablets sold as Zylflo CR. With the IR tablets, the recommended dosage is 600 mg 4 times a day. With the ER tablets, the recommended dosage is 600 mg twice a day, taken within 1 hour of the morning and evening meals.

76.7.2 Zafirlukast

Zafirlukast [Accolate], approved in 1996, was the first representative of a unique group of anti-inflammatory agents, the *leukotriene receptor antagonists*. The drug is approved for maintenance therapy of chronic asthma in adults and children 5 years of age and older. Benefits derive in part from reduced infiltration of inflammatory cells and decreased bronchoconstriction. In clinical trials, zafirlukast produced modest symptomatic relief in patients with mild to moderate asthma. The drug is less effective than inhaled beclomethasone.

Zafirlukast is administered orally, and absorption is rapid. Food reduces absorption by 40%. Hence, the drug should be administered at least 1 hour before meals or 2 hours after. Zafirlukast undergoes hepatic metabolism followed by fecal excretion. The half-life is about 10 hours, but may be as long as 20 hours in the elderly.

Zafirlukast causes few adverse effects—although there is concern about liver injury and Churg-Strauss syndrome. The most common side effects are headache and GI disturbances, both of which are infrequent. Arthralgia and myalgia may also occur. A few patients have developed Churg-Strauss syndrome, a potentially fatal disorder characterized by weight loss, flu-like

893

894

symptoms, and pulmonary vasculitis (blood vessel inflammation). However, in all cases, symptoms developed when glucocorticoids were being withdrawn, suggesting that glucocorticoid withdrawal—and not zafirlukast—may be the underlying cause.

Rarely, patients develop clinical signs of liver injury (eg, abdominal pain, jaundice, fatigue). If these occur, zafirlukast should be discontinued, and liver function tests (especially serum ALT) should be performed immediately. If test results are consistent with liver injury, zafirlukast should not be resumed. Curiously, signs of liver injury have developed mainly in females.

Zafirlukast inhibits two isozymes of cytochrome P450, and hence can suppress metabolism of other drugs, thereby causing their levels to rise. Concurrent use can raise serum theophylline to toxic levels. Accordingly, serum theophylline should be closely monitored, especially when zafirlukast is started or stopped. Zafirlukast can also raise levels of warfarin (an anticoagulant), and may thereby cause bleeding.

Zafirlukast is available in 10- and 20-mg tablets. The dosage for adults and children age 12 and older is 20 mg twice a day. The dosage for children 5 to 11 years old is 10 mg twice a day. Zafirlukast should not be administered with food.

76.7.3 Montelukast

Montelukast [Singulair], a leukotriene receptor blocker, is the most commonly used leukotriene modulator. The drug has three approved indications: (1) prophylaxis and maintenance therapy of asthma in patients at least 1 year old; (2) prevention of exercise-induced bronchospasm (EIB) in patients at least 15 years old; and (3) relief of allergic rhinitis (see [Chapter 76](#)). Montelukast cannot be used for quick relief of an asthma attack because effects develop too slowly. For prophylaxis and maintenance therapy of asthma, maximal effects develop within 24 hours of the first dose, and are maintained with once-daily dosing in the evening. In clinical trials, montelukast decreased asthma-related nocturnal awakening, improved morning lung function, and decreased the need for a short-acting inhaled beta₂ agonist throughout the day. As monotherapy, montelukast is less effective than inhaled glucocorticoids. However, when combined with an inhaled glucocorticoid, montelukast can improve symptoms and may permit a reduction in glucocorticoid dosage. Although montelukast is approved for preventing EIB, short-acting beta₂ agonists are preferred.

Montelukast is rapidly absorbed following oral administration. Bioavailability is about 64%. Blood levels peak 3 to 4 hours after ingestion. The drug is highly bound (over 99%) to plasma proteins. Montelukast undergoes extensive metabolism by hepatic P450 enzymes followed by excretion in the bile. The plasma half-life ranges from 2.7 to 5.5 hours.

Montelukast is generally well tolerated. In clinical trials, adverse effects were equivalent to those of placebo. In contrast to zileuton and zafirlukast, montelukast does not seem to cause liver injury. As with zafirlukast, Churg-Strauss syndrome has occurred when glucocorticoid dosage was reduced. Postmarketing reports suggest a link between montelukast and neuropsychiatric effects, especially mood changes and suicidality. However, these effects are rare, and a causal relationship has not been established.

Montelukast appears devoid of serious drug interactions. Unlike zileuton and zafirlukast, it does not increase levels of theophylline or warfarin. Concurrent use of phenytoin (an anticonvulsant that induces P450 enzymes) can decrease levels of montelukast.

Montelukast is available in three formulations: standard tablets (10 mg), chewable tablets (4 and 5 mg), and oral granules (4 mg/packet). The oral granules may be put directly in the mouth or may be mixed with one spoonful of either applesauce, carrots, rice, or ice cream. For prophylaxis or chronic treatment of asthma, dosing is done once a day in the evening, with or without food.

Dosage is based on patient age as follows:

- Age 15 years and older—one 10-mg tablet daily
- Age 6 to 14 years—one 5-mg chewable tablet daily
- Age 2 to 5 years—one 4-mg chewable tablet *or* 4 mg of oral granules daily
- Age 12 to 23 months—4 mg of oral granules daily

To prevent EIB, patients should take one 10-mg tablet at least 2 hour before exercising. No additional dose should be taken for at least 24 hours. Patients already taking montelukast daily should not take any more to prevent EIB.

^{76.8} CROMOLYN AND NEDOCROMIL

Cromolyn and nedocromil are inhalational agents that suppress bronchial inflammation. Both drugs are used for prophylaxis—not quick relief—in patients with mild to moderate asthma. Anti-inflammatory effects are less than with glucocorticoids.

^{76.8.1} Cromolyn

Cromolyn [Intal] is a very safe and effective drug for *prophylaxis* of asthma, but is not useful for aborting an ongoing attack. Administration is by inhalation.

76.8.1.1 Effects on the Lung.

Cromolyn suppresses inflammation; it is not a bronchodilator. The drug acts in part by stabilizing the cytoplasmic membrane of mast cells, thereby preventing release of histamine and other mediators. In addition, cromolyn inhibits eosinophils, macrophages, and other inflammatory cells.

76.8.1.2 Pharmacokinetics.

Cromolyn is administered by inhalation. The fraction absorbed from the lungs is small (about 8%) and produces no systemic effects. Absorbed cromolyn is excreted unchanged in the urine.

76.8.1.3 Therapeutic Uses.

76.8.1.3.1 Chronic Asthma.

Cromolyn is an alternative to inhaled glucocorticoids for prophylactic therapy of mild persistent asthma. The drug produces adequate control in 60% to 70% of patients. When administered on a fixed schedule, cromolyn reduces both the frequency and intensity of attacks. No tolerance to effects is seen with long-term use. To be of benefit, cromolyn must be administered *prior* to the onset of an attack; the drug is without benefit if taken after an episode has begun. In patients with chronic asthma, maximal effects may take several weeks to develop. Cromolyn is especially effective for prophylaxis of seasonal allergic attacks and for acute prophylaxis immediately prior to allergen exposure (eg, before mowing the lawn).

76.8.1.3.2 Exercise-Induced Bronchospasm.

Cromolyn can prevent bronchospasm in patients at risk for EIB. For best results, cromolyn should be administered 15 minutes prior to anticipated exertion.

76.8.1.3.3 Allergic Rhinitis.

Intranasal cromolyn [Nasalcrom] can relieve symptoms of allergic rhinitis, as discussed in [Chapter 76](#).

76.8.1.4 Adverse Effects.

Cromolyn is the safest of all antiasthma medications. Significant adverse effects occur in fewer than 1 of every 10,000 patients. Occasionally, cough or bronchospasm occurs in response to cromolyn inhalation.

76.8.1.5 Preparations, Dosage, and Administration.

Cromolyn for inhalation [Intal] can be administered with two devices: (1) a power-driven nebulizer and (2) an MDI. Patients will need instruction on using both. With the nebulizer, the *initial* dosage for adults and children is 20 mg 4 times a day. With the MDI, the *initial* dosage for adults and children is 2 to 4 puffs (1.6 to 3.2 mg) 4 times a day. For *maintenance* therapy with either device, the lowest effective dosage should be established. For therapy of chronic asthma, cromolyn must be administered on a fixed schedule.

76.8.2 Nedocromil

Nedocromil [Tilade] has actions and uses similar to those of cromolyn. Like cromolyn, nedocromil has anti-inflammatory and antiallergic actions that derive in part from suppressing the release of histamine and other substances from mast cells. Nedocromil is administered with an MDI. The drug is indicated for prophylactic therapy only; it cannot abort an ongoing asthma attack. Like cromolyn, nedocromil decreases the incidence and severity of attacks. The most common adverse effect is an unpleasant taste, which about 5% of patients find intolerable. Otherwise, nedocromil is generally well tolerated. The usual dosage is 2 puffs (3.5 mg) 4 times a day. Once symptoms are controlled, 2 puffs a day may suffice. Maximal effects may take several weeks to develop. Nedocromil is no longer available in the United States.

76.9 OMALIZUMAB

Omalizumab [Xolair] is a monoclonal antibody with a unique mechanism of action: antagonism of IgE. The drug is a second-line agent indicated only for allergy-related asthma and only when preferred options have failed. Omalizumab offers modest benefits and has significant drawbacks: The drug poses a small risk of anaphylaxis and cancer, must be given subQ, and costs over \$10,000 a year. Furthermore, its long-term safety is unknown. Use of omalizumab for seasonal allergic rhinitis and other allergic disorders is under investigation.

76.9.1 Mechanism of Action.

Omalizumab forms complexes with free IgE in the blood and thereby reduces the amount of IgE available to bind with its receptors on mast cells. This greatly reduces the number of IgE molecules on the mast cell surface, and hence limits the ability of allergens to trigger release of histamine, leukotrienes, and other mediators that promote bronchospasm and airway inflammation. At recommended doses, omalizumab decreases free IgE in serum by 96%. When treatment stops, about 1 year is required for free IgE to return to its pretreatment level.

894

895

76.9.2 Therapeutic Use.

Omalizumab is approved only for patients age 12 years and older with moderate to severe asthma that (1) is allergy related and that (2) cannot be controlled with an inhaled glucocorticoid. In clinical trials, the drug produced a modest decrease in the number of exacerbations, and often permitted a reduction in glucocorticoid use. Because of its mechanism of action, omalizumab can only help patients whose asthma is caused by a specific allergen (eg, pet dander, dust mite feces). Accordingly, a skin test or blood test proving allergen reactivity is required. Unless instructed otherwise, patients should continue all asthma medications they were using prior to starting omalizumab.

76.9.3 Pharmacokinetics.

Omalizumab is administered subQ, and absorption is slow, producing peak plasma levels in 7 to 8 days. Degradation occurs in the liver. The drug's half-life is prolonged, about 26 days.

76.9.4 Adverse Effects.

Omalizumab can cause a variety of adverse effects. The most common are injection-site reactions (45%), viral infection (23%), upper respiratory infection (20%), sinusitis (16%), headache (15%), and pharyngitis (11%). The most severe adverse effects are *malignancy* and *anaphylaxis*.

Fortunately, both are rare. During clinical trials, malignancy was seen in 0.5% of omalizumab recipients, compared with 0.2% of controls. Life-threatening anaphylaxis, characterized by urticaria and edema of the throat and/or tongue, was seen in less than 0.1% of patients.

Anaphylaxis is most likely with the first dose, but can also occur after the patient has received repeated doses with no apparent sensitivity. To minimize injury from anaphylaxis, patients should be observed for 2 hours after the injection, and facilities for managing anaphylaxis should be immediately available. Patients who experience a severe reaction should not be given the drug again. Possible adverse consequences of long-term IgE suppression are unknown.

76.9.5 Preparations, Dosage, and Administration.

Omalizumab [Xolair] is available as a powder (202.5 mg) in single-use vials for reconstitution with 1.4 mL of sterile water. Dissolving the powder, which can take 20 minutes or longer, yields a final solution of 150 mg/1.2 mL. Administration is by subQ injection, which may take 5 to 10 seconds (because the solution is somewhat viscous). The reconstituted solution should be used within 4 hours (if stored at room temperature) or 8 hours (if stored cold). Omalizumab powder should be stored cold.

The size of each dose and the dosing interval are determined by body weight and total serum IgE, measured at baseline. Dosages range from 150 to 300 mg every 4 weeks to 225 to 375 mg every 2 weeks. No more than 150 mg should be injected at any site. If a dose exceeds 150 mg, it should be divided among two or more sites.

76... BRONCHODILATORS

Bronchodilators provide symptomatic relief in patients with asthma, but they do not alter the underlying disease process (inflammation). Accordingly, in almost all cases, patients taking a bronchodilator should be taking an inhaled glucocorticoid for long-term suppression of inflammation. Monotherapy with a bronchodilator is appropriate only when asthma is very mild and attacks are infrequent.

76... BETA₂-ADRENERGIC AGONISTS

Beta₂ agonists, given by inhalation, are the most effective drugs available for relieving acute bronchospasm and preventing exercise-induced bronchospasm (EIB). In addition, long-acting formulations (given orally or by inhalation) can protect against bronchospasm over an extended time. Because of these beneficial effects, virtually all patients with asthma use these drugs. Keep in mind, however, that their use is not without risk. Specifically, there is evidence that *long-acting inhaled* beta₂ agonists can increase the risk of asthma-related death—but only when used *alone*. The basic pharmacology of the beta₂ agonists is presented in [Chapter 17](#). Discussion here is limited to their use in asthma.

76.11.1 Mechanism of Antiasthma Action

The beta₂ agonists are sympathomimetic drugs that produce “selective” activation of beta₂-adrenergic receptors. By activating beta₂ receptors in smooth muscle of the lung, these drugs promote *bronchodilation*, and thereby relieve bronchospasm. In addition, beta₂ agonists suppress histamine release in the lung and increase ciliary motility. The beta₂-selective agents have replaced older, less selective sympathomimetics (eg, epinephrine, isoproterenol) for asthma therapy.

76.11.2 Classification by Route and Time Course

Beta₂ agonists may be administered orally or by inhalation, and their effects may be brief or prolonged. All of the oral agents are long acting. Among the inhaled agents, some are short acting and some are long acting. With the short-acting inhaled preparations, effects begin almost

immediately, peak in 30 to 60 minutes, and persist for 3 to 5 hours. Because of this time course, the short-acting beta₂ agonists (SABAs) can be used to abort an ongoing attack, but cannot be used for prolonged prophylaxis. With the inhaled long-acting beta₂ agonists (LABAs), onset depends on the drug: With formoterol, onset is relatively rapid, whereas with salmeterol, onset is delayed. Both drugs can be used for prolonged prophylaxis, but only formoterol can also be used to abort an ongoing attack.

76.11.3 Use in Asthma

Beta₂ agonists are employed for quick relief and long-term control. Drug selection depends on the goal.

76.11.3.1 Short-Acting Inhaled Beta₂ Agonists.

Virtually all patients with asthma use these drugs. They are taken PRN to relieve an ongoing attack. And, in patients with EIB, they are taken before exercise to prevent an attack from occurring. For patients undergoing a severe acute attack, a nebulized SABA is the traditional treatment of choice. However, delivery with an MDI may be equally effective.

76.11.3.2 Long-Acting Inhaled Beta₂ Agonists.

Patients who experience frequent attacks can inhale a LABA for long-term control. Dosing is done on a fixed schedule, not PRN. Please note, however, that LABAs are not first-choice agents for long-term control, and should *not be used alone*. Rather, they should be *added* to the regimen when control has been inadequate with an inhaled glucocorticoid.

76.11.3.3 Oral Beta₂ Agonists.

These drugs are used only for long-term control. Onset is too slow to abort an ongoing attack. Like the long-acting inhaled beta₂ agonists, the oral agents are not first-line therapy, and should not be used alone.

76.11.4 Adverse Effects

76.11.4.1 Inhaled Preparations: Short Acting.

Inhaled SABAs are well tolerated. Systemic effects—tachycardia, angina, and tremor—can occur, but are usually minimal.

76.11.4.2 Inhaled Preparations: Long Acting.

Inhaled LABAs may increase the risk of severe asthma and asthma-related death—but only when used incorrectly (ie, as monotherapy for long-term control). When used as recommended, they are very safe. The potential danger of these drugs was documented in the Salmeterol 895

Multicenter Asthma Research Trial (SMART), which showed that, compared with patients taking a placebo, patients taking salmeterol for 28 weeks experienced more serious adverse events, including severe asthma attacks and asthma-related death. However, although the increase was statistically significant, it was also small. Furthermore, the increase was seen only in patients who were not taking a recommended first-line control drug (eg, an inhaled glucocorticoid). To minimize risk, LABAs should be used only in patients taking a recommended medication for long-term control, and only if that medication has been inadequate by itself. LABAs should never be used as first-line therapy for prolonged control, and should never be used alone. 896

TABLE 75-3 Beta₂-Adrenergic Agonists Used in Asthma

		Initial Dosage	
Drug [Trade Name]	Formulation	Adults	Children
Inhaled Agents: Short Acting			
Albuterol			
[ProAir HFA, Proventil HFA, Ventolin HFA]	MDI (90 mcg/puff)	2 puffs every 4–6 hr PRN	2 puffs every 4–6 hr PRN
[Proventil, AccuNeb]	Solution for nebulization	1.25–5 mg every 4–8 hr PRN	0.63–2.5 mg/kg every 4–6 hr PRN
Bitolterol mesylate†			
[Tornalate]	Solution for nebulization	1.5–3.5 mg 2–4 times/day PRN	1.5 mg 2–4 times/day PRN
Levalbuterol			
[Xopenex HFA]	MDI (45 mcg/puff)	2 puffs every 4–6 hr PRN	2 puffs every 4–6 hr PRN
[Xopenex]	Solution for nebulization		0.31–1.25 mg every 4–6 hr PRN
Pirbuterol			
[Maxair Autohaler]	BA-MDI (200 mcg/puff)	2 puffs every 4–6 hr PRN	2 puffs every 4–6 hr PRN
Inhaled Agents: Long Acting			
Arformoterol			
[Brovana]	Solution for nebulization	15 mcg every 12 hr	Safety and efficacy not established
Formoterol			
[Foradil Aerolizer]	DPI (12 mcg/puff)	1 puff every 12 hr	1 puff every 12 hr
[Perforomist]*	Solution for nebulization	20 mcg every 12 hr	Safety and efficacy not established
Salmeterol			
[Serevent Diskus]	DPI (50 mcg/inhalation)	1 inhalation every 12 hr	1 inhalation every 12 hr
Oral Agents			
Albuterol			

Pharmacology for Nursing Care, 7th Edition

Generic	Tablets, syrup	2 or 4 mg 3–4 times/day	2 mg 3–4 times/day
[VoSpire ER]	Tablets (extended release)	8 mg every 12 hr	4 mg every 12 hr
Terbutaline			
[Brethine]	Tablets	5 mg 3 times/day	2.5 mg 3 times/day
BA-MDI = breath-activated metered-dose inhaler, DPI = dry-powder inhaler, HFA = hydrofluoroalkane propellant, MDI = metered-dose inhaler.			

* Perforomist is approved only for chronic obstructive pulmonary disease, not for asthma.

† Not available in the United States.

76.11.4.3 Oral Preparations.

The selectivity of the beta₂-adrenergic agonists is only relative, not absolute. Accordingly, when these drugs are administered orally, they are likely to produce some activation of beta₁ receptors in the heart. If dosage is excessive, stimulation of cardiac beta₁ receptors can cause *angina pectoris* and *tachydysrhythmias*. Patients should be instructed to report chest pain or changes in heart rate or rhythm.

Oral beta₂ agonists often cause *tremor* by activating beta₂ receptors in skeletal muscle. Tremor can be reduced by lowering the dosage. With continued drug use, tremor declines spontaneously.

76.11.5 Preparations, Dosage, and Administration

Eight selective beta₂ agonists are available ([Table 75-3](#)). Some are used for quick relief, some for long-term control, and some for both, depending on their route of administration.

76.11.5.1 Inhaled Preparations for Quick Relief.

To provide quick relief, beta₂ agonists must be administered by inhalation. Three types of devices may be used: MDIs, DPIs, and nebulizers.

For drugs administered with an MDI or DPI, the usual dosing schedule is 1 or 2 puffs 3 or 4 times a day. When 2 puffs are needed, an interval of 1 minute or longer should separate them. During this interval, some bronchodilation develops, thereby facilitating penetration of the second puff.

For certain patients, nebulizers may be superior to inhalers. Experience has shown that some patients who have become unresponsive to a β_2 agonist delivered with an inhaler may respond to the same drug when it is given with a nebulizer. Why? Because the nebulizer delivers the dose slowly (over several minutes); as the bronchi gradually dilate, the drug gains deeper and deeper access to the lungs.

76.11.5.2 Inhaled Preparations for Long-Term Control.

Three inhaled LABAs are available for treatment of asthma: salmeterol [Serevent Diskus], formoterol [Foradil Aerolizer], and arformoterol [Brovana], the (*R,R*)-enantiomer of formoterol. All three have a long duration of action, and hence are suited for long-term control. Dosing is done every 12 hours. If supplemental bronchodilation is needed between doses, a SABA should be employed. As discussed above, LABAs are not first-choice agents for long-term control, and they should not be used alone. Rather, they should always be used in conjunction with an inhaled glucocorticoid.

896

897

Bronchodilation develops faster with formoterol than with salmeterol (1 to 3 minutes vs. 10 to 30 minutes). Accordingly, in addition to being used for long-term control, formoterol can be taken prior to exertion to prevent EIB. It is important to note, however, that despite its relatively rapid onset, formoterol should *not* be used to treat an ongoing asthma attack. Rather, a SABA should be taken.

Although salmeterol is usually inhaled twice daily (every 12 hours), with continuous use, more frequent dosing may be needed. Why? Because benefits seem to persist for a shorter time as the duration of treatment increases.

76.11.5.3 Oral Preparations for Long-Term Control.

Two oral β_2 agonists—albuterol and terbutaline—are approved for long-term control of asthma. Dosing is done 3 or 4 times a day.

76... METHYLYXANTHINES

We first encountered the methylxanthines (theophylline, caffeine, others) in [Chapter 36](#) (Central Nervous System Stimulants and Attention-Deficit/Hyperactivity Disorder). As discussed in that chapter, the most prominent actions of these drugs are (1) central nervous system (CNS) excitation and (2) bronchodilation. Other actions include cardiac stimulation, vasodilation, and diuresis.

76.12.1 Theophylline

Theophylline [Theo-24, Theochron, Uniphy1, Elixophyllin] is the principal methylxanthine employed in asthma. Benefits derive primarily from bronchodilation. Theophylline has a narrow therapeutic range, and hence dosage must be carefully controlled. The drug is usually administered by mouth. Theophylline is not administered by inhalation because it is not active by this route.

In the past, theophylline was a first-line drug for asthma and nearly all patients with chronic asthma took it. However, use of theophylline has declined sharply, largely because we now have safer and more effective medications (eg, inhaled glucocorticoids, inhaled beta₂ agonists).

76.12.1.1 Mechanism of Action

Theophylline produces bronchodilation by relaxing smooth muscle of the bronchi. Although the mechanism of bronchodilation has not been firmly established, the most probable is blockade of receptors for adenosine.

One frequently discussed mechanism suggests that methylxanthines act by inhibiting an enzyme called phosphodiesterase, and thereby elevate intracellular levels of cyclic AMP. This mechanism was proposed based on the ability of methylxanthines, in high concentrations, to inhibit phosphodiesterase in the test tube. However, since these high concentrations are not achieved in the body, it seems unlikely that inhibition of phosphodiesterase underlies the effects of methylxanthines in humans.

76.12.1.2 Use in Asthma

Oral theophylline is used for maintenance therapy of chronic stable asthma. Although less effective than beta₂ agonists, theophylline has a longer duration of action (when administered in a sustained-release formulation). With regular use, theophylline can decrease the frequency and severity of asthma attacks. Because its effects are prolonged, theophylline may be most appropriate for patients who experience nocturnal attacks.

Intravenous theophylline has been employed in emergencies. However, the drug is no more effective than beta₂ agonists and glucocorticoids, and is clearly more dangerous.

76.12.1.3 Pharmacokinetics

76.12.1.3.1 Absorption.

Oral theophylline is available in sustained-release formulations only. Immediate-release products have been discontinued. Absorption from sustained-release preparations is slow, but the resulting plasma levels are stable, being free of the wide fluctuations that characterized the immediate-release products. Absorption from some sustained-release preparations can be affected by food.

76.12.1.3.2 Metabolism.

Theophylline is metabolized in the liver. Rates of metabolism are affected by multiple factors—age, disease, drugs—and show wide individual variation. As a result, the plasma half-life of theophylline varies considerably among patients. For example, while the average half-life in nonsmoking adults is about 8 hours, the half-life can be as short as 2 hours in some adults and as long as 15 hours in others. Smoking cigarettes (one to two packs a day) accelerates metabolism and decreases the half-life by about 50%. The *average* half-life in children is 4 hours. Metabolism is slowed in patients with certain pathologies (eg, heart disease, liver disease, prolonged fever). Some drugs (eg, cimetidine, fluoroquinolone antibiotics) decrease theophylline metabolism. Other drugs (eg, phenobarbital) accelerate metabolism. Because of these variations in metabolism, individualization of dosage is essential.

76.12.1.3.3 Plasma Drug Levels.

Safe and effective therapy requires periodic measurement of theophylline blood levels. Traditionally, dosage has been adjusted to produce theophylline levels between 10 and 20 mcg/mL. However, many patients respond well at 5 mcg/mL, and, as a rule, there is little benefit to increasing levels above 15 mcg/mL. Hence, levels between 5 and 15 mcg/mL are appropriate for most patients. At levels above 20 mcg/mL, the risk of significant adverse effects is high.

76.12.1.4 Toxicity

76.12.1.4.1 Symptoms.

Toxicity is related to theophylline levels. Adverse effects are uncommon at plasma levels below 20 mcg/mL. At 20 to 25 mcg/mL, relatively mild reactions occur (eg, nausea, vomiting, diarrhea, insomnia, restlessness). Serious adverse effects are most likely at levels above 30 mcg/mL. These reactions include severe dysrhythmias (eg, ventricular fibrillation) and

convulsions that can be highly resistant to treatment. Death may result from cardiorespiratory collapse.

76.12.1.4.2 Treatment.

At the first indication of toxicity, dosing with theophylline should stop. Absorption can be decreased by administering activated charcoal together with a cathartic. Ventricular dysrhythmias respond to lidocaine. Intravenous diazepam may help control seizures.

76.12.1.5 Drug Interactions

76.12.1.5.1 Caffeine.

Caffeine is a methylxanthine with pharmacologic properties like those of theophylline (see [Chapter 36](#)). Accordingly, caffeine can intensify the adverse effects of theophylline on the CNS and heart. In addition, caffeine can compete with theophylline for drug-metabolizing enzymes, thereby causing theophylline levels to rise. Because of these interactions, individuals taking theophylline should avoid caffeine-containing beverages (eg, coffee, many soft drinks) and other sources of caffeine.

76.12.1.5.2 Drugs That Reduce Theophylline Levels.

Several agents—including *phenobarbital*, *phenytoin*, and *rifampin*—can lower theophylline levels by inducing hepatic drug-metabolizing enzymes. Concurrent use of these agents may necessitate an increase in theophylline dosage.

76.12.1.5.3 Drugs That Increase Theophylline Levels.

Several drugs—including *cimetidine* and the *fluoroquinolone antibiotics* (eg, ciprofloxacin)—can elevate plasma levels of theophylline, primarily by inhibiting hepatic metabolism. To avoid theophylline toxicity, the dosage of theophylline should be reduced when the drug is combined with these agents.

76.12.1.6 Oral Formulations

Oral theophylline is available as an elixir (80 mg/15 mL), sold as Elixophyllin, and in the following sustained-release formulations:

- 12-hour extended-release tablets (100, 200, 300, and 400 mg) sold as Theochron
- 12-hour extended-release capsules (125 and 200 mg) sold generically

- 24-hour controlled-release tablets (400 and 600 mg) sold as Uniphyl
- 24-hour controlled-release capsules (100, 200, 300, and 400 mg) sold as Theo-24

Unlike the elixir, the sustained-release tablets and capsules produce drug levels that are relatively stable. Accordingly, the sustained-release formulations are preferred for routine therapy.

76.12.1.7 Dosage and Administration

76.12.1.7.1 Oral.

Dosage must be individualized. Traditionally, dosage has been adjusted to maintain plasma theophylline levels between 10 and 20 mcg/mL. However, levels between 5 and 15 mcg/mL are appropriate for most patients. To minimize chances of toxicity, doses should be low initially and then gradually increased. If a dose is missed, the following dose should *not* be doubled, because doing so could produce toxicity. Smokers require higher than average doses. Conversely, patients with heart disease, liver dysfunction, or prolonged fever are likely to require relatively low doses. Patients should be instructed not to chew the sustained-release tablets or capsules. Product information should be consulted for compatibility with food.

897

898

The initial dosage is based on the age and weight of the patient, and on the presence or absence of factors that can impair theophylline elimination. For specific initial dosages, consult the package insert. As noted above, maintenance doses should be adjusted to produce drug levels in the therapeutic range—typically 5 to 15 mcg/mL.

76.12.1.7.2 Intravenous.

Intravenous theophylline is reserved for emergencies. Administration must be done slowly, because rapid injection can cause fatal cardiovascular reactions. Intravenous theophylline is incompatible with many other drugs. Accordingly, compatibility should be verified prior to mixing theophylline with other IV agents. For specific IV dosages, refer to the discussion of *aminophylline* below.

76.12.2 Other Methylxanthines

76.12.2.1 Aminophylline

Aminophylline (formerly available as Truphylline) is a theophylline salt that is considerably more soluble than theophylline itself. In solution, each molecule of aminophylline dissociates to yield two molecules of theophylline. Hence, the pharmacologic properties of aminophylline and

theophylline are identical. Aminophylline is available in formulations for oral and IV dosing. Intravenous administration is employed most often.

76.12.2.1.1 Administration and Dosage.

76.12.2.1.1.1 Intravenous.

Because of its relatively high solubility, aminophylline is the preferred form of theophylline for IV use. Infusions should be done *slowly* (no faster than 25 mg/min), because rapid injection can produce severe hypotension and death. The usual loading dose is 6 mg/kg. The maintenance infusion rate should be adjusted to provide plasma levels of theophylline that are within the therapeutic range (10 to 20 mcg/mL). Aminophylline solutions are incompatible with a number of other drugs. Accordingly, compatibility must be verified before mixing aminophylline with other IV agents.

76.12.2.1.1.2 Oral.

Aminophylline is available in 100- and 200-mg tablets. Dosing guidelines are the same as for theophylline.

76.12.2.2 Dyphylline

Although structurally similar to theophylline, dyphylline [Dylix, Lufyllin] is nonetheless a completely distinct compound, and is not converted to theophylline in the body. The drug has a half-life of 2 hours and is eliminated unchanged in the urine. Dyphylline is available in tablets (200 and 400 mg) and an elixir (100 mg/15 mL) for oral dosing. The usual adult dosage is 15 mg/kg every 6 hours.

76... ANTICHOLINERGIC DRUGS

Anticholinergic drugs improve lung function by blocking muscarinic receptors in the bronchi, thereby causing bronchial dilation. Two agents are currently available: ipratropium and tiotropium. These drugs are approved only for chronic obstructive pulmonary disease (COPD), but are used off-label for asthma. Both drugs are administered by inhalation. The principal difference between the two is pharmacokinetic: Tiotropium has a much longer duration of action, and hence can be administered less often. With both drugs, systemic effects are minimal.

76.13.1 Ipratropium

76.13.1.1 Actions and Use in Asthma.

Ipratropium [Atrovent, Atrovent HFA] is an atropine derivative administered by inhalation to relieve bronchospasm. The drug is approved only for bronchospasm associated with COPD, but is used for asthma nonetheless. Like atropine, ipratropium is a muscarinic antagonist. By blocking muscarinic cholinergic receptors in the bronchi, ipratropium promotes *bronchodilation*. Therapeutic effects begin within 30 seconds, reach 50% of their maximum in 3 minutes, and persist about 6 hours. Ipratropium is effective against allergen-induced asthma and exercise-induced bronchospasm, but is less effective than the beta₂ agonists. However, because ipratropium and the beta₂-adrenergic agonists promote bronchodilation by different mechanisms, their beneficial effects are additive, hence combined use makes sense.

76.13.1.2 Adverse Effects.

Systemic effects are minimal. Ipratropium is a quaternary ammonium compound, and therefore always carries a positive charge. As a result, the drug is not readily absorbed from the lungs or from the digestive tract. Hence, systemic effects are rare. The most common adverse reactions are dry mouth and irritation of the pharynx. If systemic absorption is sufficient, the drug may raise intraocular pressure in patients with glaucoma. Ipratropium has been associated with adverse cardiovascular events (heart attack, stroke, death). However, since absorption is minimal, it seems unlikely that ipratropium is the cause.

Patients with peanut allergy should avoid two ipratropium products: Atrovent HFA (ipratropium alone) and Combivent (ipratropium/albuterol). Both products contain soya lecithin as a carrier. Soya is in the same plant family as peanuts, and about 10% of people with peanut allergy are cross-allergic to soya. As a result, if these people are exposed to soya proteins, they are at risk of a life-threatening anaphylactic reaction.

76.13.1.3 Preparations, Dosage, and Administration.

Ipratropium is available alone as Atrovent and Atrovent HFA and in combination with albuterol as Combivent and DuoNeb.

Ipratropium by itself is supplied in (1) solution (500 mcg/vial) and (2) MDIs that deliver either 17 or 18 mcg per actuation. For patients using either of the MDIs, the usual dosage is 2 inhalations 4 times a day, and the maximum dosage is 12 inhalations in 24 hours. For patients

using the solution, the usual dosage is 500 mcg 3 or 4 times a day, administered by oral inhalation using a nebulizer.

Ipratropium plus albuterol is available in two formulations: an MDI [Combivent] and solution for nebulization [DuoNeb]. With each actuation, the Combivent MDI delivers 18 mcg of ipratropium and 90 mcg of albuterol. The recommended dosage is 2 inhalations 4 times a day. DuoNeb solution contains 500 mcg of ipratropium and 2500 mcg of albuterol in 3-mL, single-use vials. The recommended dosage is 3 mL administered 4 times a day by oral inhalation using a nebulizer.

76.13.2 Tiotropium

76.13.2.1 Actions and Therapeutic Use.

Tiotropium [Spiriva] is a *long-acting*, inhaled anticholinergic agent approved for maintenance therapy of bronchospasm associated with COPD. The drug is not approved for asthma, but has been used off-label for patients who have not responded to other medications. Like ipratropium, tiotropium relieves bronchospasm by blocking muscarinic receptors in the lung. Therapeutic effects begin about 30 minutes after inhalation, peak in 3 hours, and persist about 24 hours. With subsequent doses, bronchodilation gets better and better, reaching a plateau after eight consecutive doses (8 days). Compared with ipratropium, tiotropium is more effective and its dosing schedule is more convenient (once daily vs. 4 times daily). Benefits of tiotropium and inhaled salmeterol (a long-acting beta₂ agonist) appear about equal. Inform patients that tiotropium is indicated only for long-term maintenance. For rapid relief of ongoing bronchospasm, they should inhale a short-acting beta₂ agonist.

76.13.2.2 Adverse Effects.

The most common adverse effect is *dry mouth*, which develops in 16% of patients. Fortunately, this response is generally mild and diminishes over time. Patients can suck on sugarless candy for relief.

Systemic anticholinergic effects (eg, constipation, urinary retention, tachycardia, blurred vision) are minimal. Why? Because, like ipratropium, tiotropium is a quaternary ammonium compound, and hence absorption into the systemic circulation is very limited. Like ipratropium, tiotropium has been associated with adverse cardiovascular events. However, since absorption is low, tiotropium is not likely to be the cause.

76.13.2.3 Preparations, Dosage, and Administration.

Tiotropium [Spiriva] is supplied in 18-mcg capsules along with a *HandiHaler* DPI device. Administration is by inhalation only. The capsules should not be swallowed. The dosage is 18 mcg once a day.

76... GLUCOCORTICOID/LABA COMBINATIONS

Fluticasone/salmeterol [Advair] and *budesonide/formoterol* [Symbicort] are available in fixed-dose combinations for inhalational therapy of asthma. The glucocorticoids (fluticasone and budesonide) provide anti-inflammatory benefits and the LABAs (salmeterol and formoterol) provide bronchodilation. Both products are indicated for long-term maintenance in adults and children.

898

These combinations are more convenient than taking a glucocorticoid and LABA separately, but have the disadvantage of restricting dosage flexibility. These products are not recommended for initial therapy. Rather, they should be reserved for patients whose asthma has not been adequately controlled with an inhaled glucocorticoid alone. Because the LABA in these products is combined with a glucocorticoid, it should pose little or no risk of increasing asthma severity or asthma-related death. (Recall that use of LABAs alone can increase these adverse events.)

899

76.14.1 Fluticasone/Salmeterol

Fluticasone and salmeterol are available in a DPI sold as *Advair Diskus* and an MDI sold as *Advair HFA*. Advair Diskus is approved for patients age 4 years and older, whereas Advair HFA is approved for patients age 12 years and older.

Advair Diskus is available in three strengths that deliver the following doses of salmeterol/fluticasone per inhalation: 50/100 mcg, 50/250 mcg, and 50/500 mcg. Dosing consists of 1 inhalation every morning and evening. The dose of fluticasone selected should be equivalent to the dose of the glucocorticoid already in use.

Advair HFA is available in three strengths that deliver the following doses of salmeterol/fluticasone per inhalation: 21/45 mcg, 21/115 mcg, and 21/230 mcg. Dosing consists of 2 inhalations every morning and evening. As with Advair Diskus, the fluticasone dosage should be equivalent to the dosage of glucocorticoid in current use.

76.14.2 Budesonide/Formoterol

Budesonide/formoterol [Symbicort] is supplied in an MDI for use by patients age 12 years and older. Symbicort is available in two strengths that deliver either 4.5/80 mcg or 4.5/160 mcg of formoterol/budesonide. Dosing consists of 2 inhalations every morning and evening. Patients

currently taking low to medium glucocorticoid doses should start with the 4.5/80 mcg formulation, and patients taking medium to high glucocorticoid doses should start with the 4.5/160 mcg formulation.

76... MANAGEMENT OF ASTHMA

In 2007, the National Asthma Education and Prevention Program (NAEPP) of the National Heart, Lung, and Blood Institute issued revised guidelines for asthma management. These guidelines—*Expert Panel Report 3 (EPR-3): Guidelines for the Diagnosis and Management of Asthma*—update the EPR-2 guidelines issued in 1997 (as well as the selected updates to EPR-2 issued in 2002). The discussion below reflects recommendations in EPR-3, which is available online at www.nhlbi.nih.gov/guidelines/asthma.

In EPR-3, management recommendations are made for three age groups: 0 to 4 years, 5 to 11 years, and 12 years and older. Recommendations for all three groups are similar, although there are some important differences. *Discussion here is limited to the oldest group*, consisting of adults and older children. For recommendations that apply to younger patients, please consult EPR-3.

76.15.1 Measuring Lung Function

Before considering asthma therapy, we need to address tests of lung function. Three tests are described below.

Forced expiratory volume in 1 second (FEV_1) is the single most useful test of lung function. Unfortunately, the instrument required—a *spirometer*—is both expensive and cumbersome, and therefore not suited for use at home. To determine FEV_1 , the patient inhales completely, and then exhales as completely and forcefully as possible into the spirometer. The spirometer measures how much air was expelled during the first second of exhalation. Results are then compared to a “predicted normal value” for a healthy person of similar age, sex, height, and weight. Hence, for a patient with asthma, the FEV_1 might be 75% of the predicted value.

Forced vital capacity (FVC), also measured with a spirometer, is defined as the total volume of air the patient can exhale following a full inhalation.

FEV_1/FVC (ie, FEV_1 divided by FVC) is the fraction (percentage) of vital capacity exhaled during the first second of forced expiration. Normal values for FEV_1/FVC range from 85% (for people 8 to 19 years old) down to 70% (for people 60 to 80 years old). In patients with asthma, the value for FEV_1/FVC may be in the normal range or it may be reduced by 5% or more, depending on asthma severity.

Peak expiratory flow (PEF) is defined as the maximal rate of airflow during expiration. To determine PEF, the patient exhales as forcefully as possible into a *peak flowmeter*, a relatively inexpensive, hand-held device. Patients should measure their peak flow every morning. If the value is less than 80% of their personal best, more frequent monitoring should be done.

76.15.2 Classification of Asthma Severity

As described in the EPR-3, chronic asthma has four classes of increasing severity: (1) intermittent, (2) mild persistent, (3) moderate persistent, and (4) severe persistent. Diagnostic criteria for these classes are summarized in [Table 75-4](#). Note that severity classification is based on two separate “domains”: *impairment* and *risk*. Impairment refers to the impact of asthma on quality of life and functional capacity *in the present*. Risk refers to possible adverse events *in the future*, such as exacerbations and progressive loss of lung function. As shown in [Table 75-4](#), as we progress from intermittent asthma to severe persistent asthma, both impairment and risk increase: asthma symptoms occur more often and last longer, use of SABAs for symptomatic control increases, limitations on physical activity become more substantial, FEV₁ decreases to less than 60% of predicted, FEV₁/FVC drops to 5% or more below normal, and the number of exacerbations that require oral glucocorticoids gets larger. It is important to note that the two domains of asthma—impairment and risk—may respond differently to drugs. Furthermore, patients can be at high risk of future events, even if their current level of impairment is low.

76.15.3 Treatment Goals

Treatment of chronic asthma is directed at two basic goals: reducing impairment and reducing risk. Components of each goal are listed below.

76.15.3.1 Reducing Impairment

- Preventing chronic and troublesome symptoms (eg, coughing or breathlessness after exertion and at all other times)
- Reducing use of SABAs for symptom relief to 2 days a week or less

899

TABLE 75-4 Classification of Asthma Severity and Recommended Step for Initial Treatment

		Persistent Asthma		
	Intermittent Asthma	Mild	Moderate	Severe
Current Impairment				
Symptoms	≤2 days/week	>2 days/week, but not daily	Daily	Throughout the day
Nighttime awakenings	≤2 times/month	3–4 times/month	>Once a week, but not nightly	Often 7 times/week
SABA used to control symptoms (but not to prevent EIB)	≤2 days/week	>2 days/week, but not daily, and not more than once on any day	Daily	Several times a day
Impact on normal activity	None	Minor limitation	Some limitation	Severe limitation
Lung function tests	• Normal FEV₁ between exacerbations • FEV₁ >80% of predicted • FEV₁/FVC normal*	• FEV₁ >80% of predicted • FEV₁/FVC normal*	• FEV₁ >60% but <80% of predicted • FEV₁/FVC reduced 5%*	• FEV₁ <60% of predicted • FEV₁/FVC reduced >5%*
Future Risk				
Exacerbations requiring oral glucocorticoids	0–1/year	≥2/year	≥2/year	≥2/year
Recommended Step for Initial Treatment[†]	Step 1	Step 2	Step 3	Step 4 or 5
Adapted from National Asthma Education and Prevention Program: Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute, 2007. EIB = exercise-induced bronchospasm, FEV ₁ = forced expiratory volume in 1 second, FVC = forced vital capacity, SABA = short-acting beta ₂ agonist.				

* Normal values for FEV₁/FVC by age group: 8 to 19 years = 85%; 20 to 39 years = 80%, 40 to 59 years = 75%, 60 to 80 years = 70%.

† See [Table 75-6](#) and text for drugs used at each step.

- Maintaining normal (or near-normal) pulmonary function
- Maintaining normal activity levels, including exercise and attendance at school or work
- Meeting patient and family expectations regarding asthma care

76.15.3.2 Reducing Risk

- Preventing recurrent exacerbations
- Minimizing the need for emergency department visits or hospitalizations
- Preventing progressive loss of lung function (for children, preventing reduced lung growth)
- Providing maximum benefits with minimum adverse effects

76.15.4 Chronic Drug Therapy

In patients with chronic asthma, drugs are employed in two ways: some agents are taken to establish *long-term control* and some are taken for *quick relief* of an ongoing attack ([Table 75-5](#)). The long-term control drugs are taken every day, whereas the quick-relief drugs are taken PRN. Of the long-term control agents in current use, inhaled glucocorticoids are by far the most important. With regular dosing, these drugs reduce the frequency and severity of attacks, as well as the need for quick-relief medications. Of the quick-relief drugs in current use, inhaled SABAs are the most important. These drugs act promptly to reverse bronchoconstriction, and thereby provide rapid relief from cough, chest tightness, and wheezing.

For chronic drug therapy, EPR-3 recommends a *stepwise* approach, in which drug dosages and drug classes are stepped up as needed, and stepped down when possible. Six steps are described ([Table 75-6](#)). The basic concept is simple. First, all patients, starting with step 1, should use an inhaled SABA as needed for quick relief. Second, all patients—except those on step 1—should use a long-term control medication (preferably an inhaled glucocorticoid) to provide baseline control. Third, when patients move up a step, owing to increased impairment and risk, dosage of the control medication is increased and/or another control medication is added (typically a LABA). And fourth, after a period of sustained control, moving down a step should be tried.

For patients just beginning drug therapy, the step they start on is determined by the pretreatment classification of asthma severity. For example, a patient diagnosed with intermittent asthma would begin at step 1 (PRN use of an inhaled SABA), whereas a patient diagnosed with moderate

persistent asthma would begin at step 3 (daily inhalation of a low-dose glucocorticoid plus daily inhalation of a LABA, supplemented with an inhaled SABA as needed).

After treatment has been ongoing, stepping up or down is based on *assessment of asthma control*.

Like the diagnosis of pretreatment severity, assessment of control is based on two domains:

current impairment and future risk. In EPR-3, three classes of control are defined: well controlled, 900
not well controlled, and very poorly controlled. Diagnostic criteria for each class are summarized 901
in [Table 75-7](#). Recommended actions for treatment are presented as well.

76.15.5 Drugs for Acute Severe Exacerbations

Acute severe exacerbations of asthma require immediate attention. The goal is to relieve airway obstruction and hypoxemia, and normalize lung function as quickly as possible. Initial therapy consists of (1) oxygen to relieve hypoxemia, (2) a systemic glucocorticoid to reduce airway inflammation, (3) a nebulized high-dose SABA to relieve airflow obstruction, and (4) nebulized ipratropium to further reduce airflow obstruction. Severe cases may benefit from IV magnesium sulfate or inhalation of heliox (79% helium/21% oxygen). Following resolution of the crisis and hospital discharge, an oral glucocorticoid is taken for 5 to 10 days. All patients should also take a medium-dose inhaled glucocorticoid. Full recovery of lung function may take weeks.

TABLE 75-5 Drugs for Asthma: Agents for Long-Term Control Versus Quick Relief

Long-Term Control Medications
Anti-inflammatory Drugs
Glucocorticoids (inhaled or oral)
Leukotriene modifiers
Cromolyn and nedocromil
Omalizumab
Bronchodilators
Long-acting inhaled beta ₂ agonists
Long-acting oral beta ₂ agonists
Theophylline
Quick-Relief Medications
Bronchodilators
Short-acting inhaled beta ₂ agonists
Anticholinergics
Anti-inflammatory Drugs
Glucocorticoids, systemic*

* Considered quick-relief drugs when used in a short burst (3 to 10 days) at the start of therapy or during a period of gradual deterioration. Glucocorticoids are not used for immediate relief of an ongoing attack.

^{76.15.6} Drugs for Exercise-Induced Bronchospasm

Exercise increases airway obstruction in practically all people with chronic asthma. The cause is bronchospasm secondary to loss of heat and/or water from the lung. Exercise-induced bronchospasm usually starts either during or immediately after exercise, peaks in 5 to 10 minutes, and resolves 20 to 30 minutes later.

With proper medication, most asthmatic patients can be as active as they wish. Indeed, many world-class athletes have had asthma, including Jackie Joyner-Kersey, Greg Louganis, and other

Olympic gold medalists. To prevent EIB, patients can inhale a SABA or cromolyn prophylactically. Inhaled SABAs, which prevent EIB in more than 80% of patients, are more effective than cromolyn, and hence are preferred. Beta₂ agonists should be inhaled immediately before exercise; cromolyn should be inhaled 15 minutes before exercise.

76.15.7 Reducing Exposure to Allergens and Triggers

For patients with chronic asthma, the treatment plan should include measures to control allergens and other factors that can cause airway inflammation and exacerbate symptoms. Important sources of asthma-associated allergens include the house dust mite, warm-blooded pets, cockroaches, and molds. Factors that can exacerbate asthma include tobacco smoke, wood smoke, and household sprays. To the extent possible, exposure to these factors should be reduced or eliminated. For patients who are reluctant to part with Fluffy (the family cat) or Ralph (the family dog), weekly washing of the critter may help. More importantly, the pet should be banned from the patient's bedroom.

901
902

TABLE 75-6 Stepwise Approach to Managing Asthma in Patients Age 12 Years and Older

Long-Term Control Drugs (Taken Daily)		Quick-Relief Drugs (Taken PRN)
Preferred	Alternative	
Step 1 No daily medication needed		SABA
Step 2 Low-dose IGC	Cromolyn, nedocromil, LTRA, or theophylline	SABA
Step 3 Low-dose IGC + LABA OR Medium-dose IGC	Low-dose IGC + either LTRA, theophylline, or zileuton	SABA
Step 4 Medium dose IGC + LABA	Medium-dose IGC + either LTRA, theophylline, or zileuton	SABA
Step 5 High-dose IGC + LABA		SABA
Step 6 High-dose IGC + LABA + oral glucocorticoid		SABA
Adapted from National Asthma Education and Prevention Program: Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute, 2007. IGC = inhaled glucocorticoid; LABA = long-acting beta ₂ agonist; LTRA = leukotriene receptor antagonist; SABA = short-acting beta ₂ agonist.		

TABLE 75-7 Assessment of Asthma Control in Patients Age 12 and Older and Recommended Action for Treatment

Components of Control	Classification of Control [*]		
	Well Controlled	Not Well Controlled	Very Poorly Controlled
Current Impairment			
Symptoms	≤2 days/week	>2 days/week	Throughout the day
Nighttime awakenings	≤2 times/month	1–3 times/week	≥4 times/week
SABA used to control symptoms (not to prevent EIB)	≤2 days/week	>2 days/week	Several times a day
Impact on normal activity	None	Some limitation	Severe limitation
Lung function tests:			
FEV ₁ (% of predicted)	FEV ₁ >80% <i>or</i>	FEV ₁ 60–80% <i>or</i>	FEV ₁ <60% <i>or</i>
PEF (% of personal best)	PEF >80%	PEF 60–80%	PEF <60%
Questionnaire Scores			
ATAQ	0	1–2	3–4
ACQ	≤0.75	≥1.5	N/A
ACT	≥20	16–19	≤15
Future Risk			
Exacerbations requiring oral glucocorticoids	0–1/year	≥2/year [†]	≥2/year [†]
Progressive loss of lung function	Evaluation requires long-term follow-up care.		
Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		

Pharmacology for Nursing Care, 7th Edition

Recommended Action for Treatment†	Maintain current treatment step	Move up 1 step and reassess in 2–6 weeks	Consider short course of oral glucocorticoids
	Follow up every 1–6 months to maintain control	To reduce side effects, consider changing drugs	Move up 1 or 2 steps and reassess in 2 weeks
	Consider step down if well controlled for 3 months or longer		To reduce side effects, consider changing drugs

Adapted from National Asthma Education and Prevention Program: Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: National Heart, Lung, and Blood Institute, 2007.

ACQ = Asthma Control Questionnaire, ACT = Asthma Control Test, ATAQ = Asthma Therapy Assessment Questionnaire; EIB = exercise-induced bronchospasm, FEV₁ = forced expiratory volume in 1 second; N/A = not applicable, PEF = peak expiratory flow rate, SABA = short acting beta agonist.

* The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2 to 4 weeks and by FEV₁ or PEF. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.

† At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or intensive care unit admission) indicate poorer disease control. For treatment purposes, patients who had two or more exacerbations requiring oral glucocorticoids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.

‡ Treatment steps are summarized in [Table 75-6](#).

The house dust mite is the most notorious cause of asthma. Allergy develops not to the microscopic mite itself, but rather to its even more microscopic feces. Measures to control or avoid dust mites and their feces include

- Encasing the patient's pillow, mattress, and box spring with covers that are impermeable to allergens
- Washing all bedding and stuffed animals weekly in a hot-water wash cycle (130°F)
- Removing carpeting or rugs from the bedroom
- Avoiding sleeping or lying on upholstered furniture
- Keeping indoor humidity below 50%

Unfortunately, even when these measures are implemented, their impact on asthma symptoms is generally small.

902

903

76.15.7.1

KEY POINTS

- Asthma is a chronic inflammatory disease characterized by inflammation of the airways, bronchial hyperreactivity, and bronchospasm. Allergy is often the underlying cause.
- Asthma is treated with anti-inflammatory drugs and bronchodilators.
- Most drugs for asthma are administered by inhalation, a route that increases therapeutic effects (by delivering drugs directly to their site of action), reduces systemic effects (by minimizing drug levels in blood), and facilitates rapid relief of acute attacks.
- Three devices are used for inhalation: metered-dose inhalers (MDIs), dry-powder inhalers (DPIs), and nebulizers. Patients will need instruction on their use.
- Glucocorticoids are the most effective antiasthma drugs available.
- Glucocorticoids reduce symptoms of asthma by suppressing inflammation. As an added bonus, glucocorticoids promote synthesis of bronchial β_2 receptors, and increase their responsiveness to β_2 agonists.
- Inhaled and systemic glucocorticoids are used for long-term prophylaxis of asthma—not for aborting an ongoing attack. Accordingly, they are administered on a fixed schedule—not PRN.
- Unless asthma is severe, glucocorticoids should be administered by inhalation.
- Inhaled glucocorticoids are generally very safe. Their principal side effects are oropharyngeal candidiasis and dysphonia, which can be minimized by employing a spacer device during administration and by gargling after.
- Inhaled glucocorticoids can promote bone loss. To minimize loss, dosage should be as low as possible, and patients should perform regular weight-bearing exercise and should ensure adequate intake of calcium and vitamin D.
- Inhaled glucocorticoids can slow the growth rate of children, but they do not reduce adult height.

- Prolonged therapy with oral glucocorticoids can cause serious adverse effects, including adrenal suppression, osteoporosis, hyperglycemia, peptic ulcer disease, and growth suppression.
- Because of adrenal suppression, patients taking oral glucocorticoids (and patients who have switched from oral glucocorticoids to inhaled glucocorticoids) must be given supplemental doses of oral or IV glucocorticoids at times of stress.
- Cromolyn is an inhaled anti-inflammatory drug used for prophylaxis of asthma.
- Cromolyn reduces inflammation primarily by preventing release of mediators from mast cells.
- For long-term prophylaxis, cromolyn is taken daily on a fixed schedule. For prophylaxis of exercise-induced bronchospasm, cromolyn is taken 15 minutes before anticipated exertion.
- Cromolyn is the safest drug for asthma. Serious adverse effects are extremely rare.
- Beta₂ agonists promote bronchodilation by activating beta₂ receptors in bronchial smooth muscle.
- Inhaled short-acting beta₂ agonists (SABAs) are the most effective drugs for relieving acute bronchospasm and preventing exercise-induced bronchospasm.
- Three inhaled beta₂ agonists—arformoterol, formoterol, and salmeterol—have a long duration of action, and hence are indicated for long-term control.
- Inhaled SABAs rarely cause systemic side effects.
- Excessive dosing with oral beta₂ agonists can cause tachycardia and angina by activating beta₁ receptors on the heart. (Selectivity is lost at high doses.)
- Inhaled long-acting beta₂ agonists (LABAs) can increase the risk of asthma-related death, but only when used incorrectly. Accordingly, LABAs should be used only by patients taking an inhaled glucocorticoid for long-term control, and only if the glucocorticoid has been inadequate by itself.
- Theophylline, a member of the methylxanthine family, relieves asthma by causing bronchodilation.

- Although theophylline was used widely in the past, it has been largely replaced by safer and more effective medications.
- There are four classes of chronic asthma: intermittent, mild persistent, moderate persistent, and severe persistent. Diagnosis is based on current impairment *and* future risk.
- For therapeutic purposes, asthma drugs can be classified as long-term control medications (eg, inhaled glucocorticoids) and quick-relief medications (eg, inhaled SABAs).
- In the stepwise approach to asthma therapy, treatment becomes more aggressive as impairment and/or risk become more severe.
- The goals of stepwise therapy are to prevent symptoms, maintain near-normal pulmonary function, maintain normal activity, prevent recurrent exacerbations, minimize the need for SABAs, minimize drug side effects, minimize emergency room visits, prevent progressive loss of lung function, and meet patient and family expectations about treatment.
- The step chosen for initial therapy is based on the pretreatment classification of asthma severity, whereas moving up or down a step is based on ongoing assessment of asthma control.
- Intermittent asthma is treated PRN, using an inhaled SABA to abort the few acute episodes that occur.
- For persistent asthma (mild, moderate, or severe), the foundation of therapy is daily inhalation of a glucocorticoid. An inhaled LABA is added to the regimen when asthma is more severe. A SABA is inhaled PRN to suppress breakthrough attacks.
- For acute severe exacerbations of asthma, patients should receive oxygen (to reduce hypoxemia), a systemic glucocorticoid (to reduce airway inflammation), and a nebulized SABA plus nebulized ipratropium (to relieve airflow obstruction).
- To prevent exercise-induced bronchospasm, patients can inhale a SABA just prior to strenuous activity.
- Patients should avoid allergens that can cause airway inflammation and triggers that can provoke exacerbations. Important sources of allergens are the house dust mite, warm-

blooded pets, cockroaches, and molds. Important triggers are tobacco smoke, wood smoke, and household sprays.

903

904

76.15.7.2 Summary of Major Nursing Implications*

76.15.7.... GLUCOCORTICOIDS

76.15.7.... Inhaled

Beclomethasone

Budesonide

Ciclesonide

Flunisolide

Fluticasone

Mometasone

Triamcinolone

76.15.7.... Oral

Prednisolone

Prednisone

The nursing implications summarized below refer specifically to the use of glucocorticoids in asthma. A full summary of nursing implications for glucocorticoids is presented in [Chapter 71](#).

76.15.7....

Preadministration Assessment

76.15.7....

Therapeutic Goal

Glucocorticoids are used on a fixed schedule to suppress inflammation. They are not used to abort an ongoing attack.

76.15.7....

Baseline Data

Determine FEV₁ and the frequency and severity of attacks, and attempt to identify trigger factors.

76.15.7....

Identifying High-Risk Patients

76.15.7....

Inhaled Glucocorticoids.

These preparations are *contraindicated* for patients with persistently positive sputum cultures for *Candida albicans*.

76.15.7....

Oral Glucocorticoids.

These preparations are *contraindicated* for patients with systemic fungal infections and for individuals receiving live virus vaccines.

Use with *caution* in pediatric patients and in women who are pregnant or breast-feeding. Also, exercise *caution* in patients with hypertension, heart failure, renal impairment, esophagitis, gastritis, peptic ulcer disease, myasthenia gravis, diabetes mellitus, osteoporosis, or infections that are resistant to treatment and in patients receiving potassium-depleting diuretics, digitalis glycosides, insulin, oral hypoglycemics, or nonsteroidal anti-inflammatory drugs.

76.15.7....

Implementation: Administration

76.15.7....

Routes

Inhalation, oral.

76.15.7....

Administration

Inform patients that glucocorticoids are intended for preventive therapy—not for aborting an ongoing attack. Instruct patients to administer glucocorticoids on a regular schedule—not PRN.

76.15.7....

Inhalation.

Inhaled glucocorticoids are administered with an MDI, DPI, or nebulizer. **Teach patients how to use these devices. Advise patients using MDIs to employ a spacer device—unless they are using beclomethasone [QVAR] or fluticasone [Flovent HFA], which employ HFA as a propellant. Inform patients that delivery of glucocorticoids to the bronchial tree can be enhanced by inhaling a SABA 5 minutes prior to inhaling the glucocorticoid.**

76.15.7....

Oral.

Alternate-day therapy is recommended to minimize adrenal suppression; instruct patients to take one dose every other day in the morning. During long-term treatment, supplemental doses must be given at times of severe stress.

76.15.7....

Ongoing Evaluation and Interventions

76.15.7....

Evaluating Therapeutic Effects

Teach patients with chronic asthma to monitor and record PEF, symptom frequency and symptom intensity, nighttime awakenings, impact on normal activity, and SABA use.

76.15.7....

Minimizing Adverse Effects

76.15.7....

Inhaled Glucocorticoids.

Advise patients to gargle after each administration and to use a spacer with the MDI (except the QVAR inhaler). These measures will minimize *dysphonia* and *oropharyngeal candidiasis*. If candidiasis develops, it can be treated with antifungal medication.

Warn patients who have switched from long-term oral glucocorticoids to inhaled glucocorticoids that, because of adrenal suppression, they must take

supplemental systemic glucocorticoids at times of severe stress (eg, trauma, surgery, infection); failure to do so can be fatal.

To minimize *bone loss*, patients should use the lowest dose possible. Also, **advise patients to ensure adequate intake of calcium and vitamin D, and to perform weight-bearing exercise.**

Oral Glucocorticoids.

Prolonged therapy can cause *adrenal suppression* and other serious adverse effects, including *osteoporosis*, *hyperglycemia*, *peptic ulcer disease*, and *growth suppression*. These effects can be reduced with alternate-day dosing. To compensate for adrenal suppression, patients taking glucocorticoids long term must be given supplemental oral or IV glucocorticoids at times of stress (eg, trauma, surgery, infection); failure to do so can be fatal. Additional nursing implications that apply to adverse effects of long-term glucocorticoid therapy are summarized in [Chapter 71](#).

BETA₂-ADRENERGIC AGONISTS

Inhaled, Short Acting

Albuterol

Bitolterol

Levalbuterol

Pirbuterol

Inhaled, Long Acting

Arformoterol

Formoterol

Salmeterol

76.15.7....	Oral Albuterol Terbutaline	905
76.15.7....	Preadministration Assessment	
76.15.7....	Therapeutic Goal Short-acting inhaled beta₂ agonists are used PRN for prophylaxis of EIB and to relieve ongoing asthma attacks. Oral and inhaled long-acting beta₂ agonists are used for maintenance therapy.	
76.15.7....	Baseline Data Determine FEV₁ and the frequency and severity of attacks, and attempt to identify trigger factors.	
76.15.7....	Identifying High-Risk Patients Systemic (oral, parenteral) beta₂ agonists are <i>contraindicated</i> for patients with tachydysrhythmias or tachycardia associated with digitalis toxicity. Use systemic beta₂ agonists with <i>caution</i> in patients with diabetes, hyperthyroidism, organic heart disease, hypertension, or angina pectoris.	
76.15.7....	Implementation: Administration	
76.15.7....	Routes	
76.15.7....	Usual. Inhalation.	
76.15.7....	Occasional. Oral, subcutaneous.	

76.15.7....

Administration

76.15.7....

Inhalation.

Inhaled beta₂ agonists are administered with an MDI, DPI, or nebulizer. **Teach patients how to use these devices. For patients who have difficulty with hand-lung coordination, using a spacer with a one-way valve may improve results.**

Inform patients who are using MDIs or DPIs that, when 2 puffs are needed, an interval of at least 1 minute should elapse between puffs.

Warn patients against exceeding recommended dosages.

Inform patients that inhaled *formoterol* and *salmeterol* (long-acting beta₂ agonists) should be taken on a fixed schedule—not PRN.

76.15.7....

Oral.

Instruct patients to take oral beta₂ agonists on a fixed schedule—not PRN.

Instruct patients to swallow sustained-release preparations intact, without crushing or chewing.

76.15.7....

Ongoing Evaluation and Interventions

76.15.7....

Evaluating Therapeutic Effects

Teach patients with chronic asthma to monitor and record PEF, symptom frequency and symptom intensity, nighttime awakenings, impact on normal activity, and SABA use.

76.15.7....

Minimizing Adverse Effects

76.15.7....

Inhaled Short-Acting Beta₂ Agonists.

When used at recommended doses, SABAs are generally devoid of adverse effects. Cardiac stimulation and tremors are most likely with systemic therapy.

76.15.7....

Inhaled Long-Acting Beta₂ Agonists.

When used correctly, LABAs are very safe. When used *alone* for prophylaxis, they may *increase* the risk of severe asthma attacks and asthma-related death. To minimize risk, these drugs should be used only by patients taking an inhaled glucocorticoid, and only if the glucocorticoid has been inadequate by itself.

76.15.7....

Oral Beta₂ Agonists.

Excessive dosing can activate beta₁ receptors on the heart, resulting in anginal pain and tachydysrhythmias. **Instruct patients to report chest pain and changes in heart rate or rhythm.**

Tremor is common with systemic beta₂ agonists, and usually subsides with continued drug use. If necessary, tremor can be reduced by lowering the dosage.

76.15.7....

CROMOLYN

76.15.7....

Preadministration Assessment

76.15.7....

Therapeutic Goal

Cromolyn is used for acute and long-term prophylaxis of asthma. The drug will not abort an ongoing asthma attack.

76.15.7....

Baseline Data

Determine FEV₁ and the frequency and severity of attacks, and attempt to identify trigger factors.

76.15.7....

Identifying High-Risk Patients

Cromolyn is *contraindicated* for the rare patient who has experienced an allergic response to cromolyn in the past.

76.15.7....

Implementation: Administration

76.15.7....

Route

Inhalation.

76.15.7....	Administration	
76.15.7....	Administration Devices. Cromolyn is administered with either an MDI or a nebulizer. Instruct patients on the proper use of these devices.	
76.15.7....	Acute Prophylaxis. Instruct patients to administer cromolyn 15 minutes prior to exercise and exposure to other precipitating factors (eg, cold, environmental agents).	
76.15.7....	Long-Term Prophylaxis. Instruct patients to administer cromolyn on a regular schedule, and inform them that full therapeutic effects may take several weeks to develop.	
76.15.7....	Ongoing Evaluation and Interventions	
76.15.7....	Evaluating Therapeutic Effects Teach patients with chronic asthma to monitor and record PEF, symptom frequency and symptom intensity, nighttime awakenings, impact on normal activity, and SABA use.	
76.15.7....	Minimizing Adverse Effects and Interactions Cromolyn is devoid of significant adverse effects and drug interactions.	905
76.15.7....	THEOPHYLLINE	906
76.15.7....	Preadministration Assessment	
76.15.7....	Therapeutic Goal Theophylline is a bronchodilator taken on a regular schedule to decrease the intensity and frequency of moderate to severe asthma attacks.	
76.15.7....	Baseline Data Determine FEV ₁ and the frequency and severity of attacks.	

76.15.7....

Identifying High-Risk Patients

Theophylline is *contraindicated* for patients with untreated seizure disorders or peptic ulcer disease.

Use with *caution* in patients with heart disease, liver or kidney dysfunction, or severe hypertension.

76.15.7....

Implementation: Administration

76.15.7....

Routes

Oral, intravenous.

76.15.7....

Administration

76.15.7....

Oral.

Dosage must be individualized. Doses are low initially and then increased gradually. The dosing objective is to produce plasma theophylline levels in the therapeutic range, which for most patients is 5 to 15 mcg/mL. **Warn patients that, if a dose is missed, the following dose should *not* be doubled.**

Instruct patients to swallow enteric-coated and sustained-release formulations intact, without crushing or chewing.

Warn patients not to switch from one sustained-release formulation to another without consulting the prescriber.

Consult product information regarding compatibility with food, and advise the patient accordingly.

76.15.7....

Intravenous.

Administer slowly. Verify compatibility with other IV drugs prior to mixing.

76.15.7....

Ongoing Evaluation and Interventions

76.15.7....

Evaluating Therapeutic Effects

Monitor theophylline levels to ensure that they are in the therapeutic range (5 to 15 mcg/mL for most patients).

Teach patients with chronic asthma to monitor and record PEF, symptom frequency and symptom intensity, nighttime awakenings, impact on normal activity, and SABA use.

76.15.7....

Minimizing Adverse Effects

Mild adverse effects (eg, nausea, vomiting, diarrhea, insomnia, restlessness) develop as plasma drug levels rise above 20 mcg/mL. Severe effects (convulsions, ventricular fibrillation) can occur at drug levels above 30 mcg/mL. Dosage should be adjusted to keep theophylline levels below 20 mcg/mL.

76.15.7....

Minimizing Adverse Interactions

76.15.7....

Caffeine.

Caffeine can intensify the adverse effects of theophylline on the heart and CNS and can decrease theophylline metabolism. **Caution patients against consuming caffeine-containing beverages (eg, coffee, many soft drinks) and other sources of caffeine.**

76.15.7....

Drugs That Reduce Theophylline Levels.

Phenobarbital, phenytoin, rifampin, and other drugs can lower theophylline levels. In the presence of these drugs, the dosage of theophylline may need to be increased.

76.15.7....

Drugs That Increase Theophylline Levels.

Cimetidine, fluoroquinolone antibiotics, and other drugs can elevate theophylline levels. When combined with these drugs, theophylline should be used in reduced dosage.

76.15.7....

Managing Toxicity.

Theophylline overdose can cause severe dysrhythmias and convulsions. Death from cardiorespiratory collapse may occur. Manage toxicity by (1) discontinuing theophylline, and (2) administering activated charcoal (to decrease theophylline absorption) plus a cathartic (to accelerate fecal excretion). Give lidocaine to control ventricular dysrhythmias and IV diazepam to control seizures.

* Patient education information is highlighted as **blue text**.

⁷⁷CHAPTER 76 Drugs for Allergic Rhinitis, Cough, and Colds

The drugs addressed in this chapter are given to alleviate symptoms of common respiratory disorders. Our principal focus is allergic rhinitis.

^{77.1}DRUGS FOR ALLERGIC RHINITIS

Allergic rhinitis is an inflammatory disorder that affects the upper airway, lower airway, and eyes. Major symptoms are sneezing, rhinorrhea (runny nose), pruritus (itching), and nasal congestion (caused by dilation and increased permeability of nasal blood vessels). In addition, some patients experience conjunctivitis, sinusitis, and even asthma. Symptoms are triggered by airborne allergens, which bind to immunoglobulin E (IgE) antibodies on mast cells, and thereby cause release of inflammatory mediators, including histamine, leukotrienes, and prostaglandins. Allergic rhinitis is the most common allergic disorder, affecting 20 to 40 million Americans (10% to 30% of adults and up to 40% of children).

Allergic rhinitis has two forms: seasonal and perennial. Seasonal rhinitis, also known as *hay fever* or *rose fever*, occurs in the spring and fall in reaction to outdoor allergens, including fungi and pollens from weeds, grasses, and trees. Perennial (nonseasonal) rhinitis is triggered by indoor allergens, especially the house dust mite and pet dander.

Several classes of drugs are used for allergic rhinitis ([Table 76-1](#)). Principal among these are (1) oral antihistamines, (2) intranasal glucocorticoids, and (3) sympathomimetics (oral and intranasal). Antihistamines and glucocorticoids are considered first-line therapies. Of the two, glucocorticoids are much more effective. Sympathomimetics are used in conjunction with other agents to help relieve nasal congestion.

^{77.1.1}Antihistamines

The antihistamines are discussed at length in [Chapter 69](#). Consideration here is limited to their use in allergic rhinitis.

^{77.1.1.1}Oral Antihistamines

Antihistamines (histamine₁ [H₁] receptor antagonists) are first-line drugs for allergic rhinitis. These agents are used more frequently than any others. Antihistamines can relieve sneezing, rhinorrhea, and nasal itching. However, they do not reduce nasal congestion. Because histamine is only one of several mediators of allergic rhinitis, antihistamines are less effective than

glucocorticoids. Because histamine does not contribute to symptoms of infectious rhinitis, antihistamines are of no value against the common cold.

For therapy of allergic rhinitis, antihistamines are most effective when taken *prophylactically*, and less helpful when taken after symptoms appear. Accordingly, antihistamines should be administered on a regular basis throughout the allergy season, even when symptoms are absent.

Adverse effects are usually mild. The most frequent complaint is *sedation*, which occurs often with first-generation antihistamines (eg, diphenhydramine), and much less with the second-generation agents (eg, fexofenadine). Accordingly, second-generation agents are preferred. *Anticholinergic effects* (eg, dry mouth, constipation, urinary hesitancy) are common with first-generation agents, and relatively rare with the second-generation agents.

Dosages for some popular H₁ antagonists are presented in [Table 76-2](#). A more complete list appears in [Table 69-2](#).

77.1.1.2 Intranasal Antihistamines

Two second-generation antihistamines—*azelastine* [Astelin, Astepro] and *olopatadine* [Patanase]—are available for intranasal administration. Both drugs are indicated for allergic rhinitis in adults and children over 12 years old. Benefits equal those of oral antihistamines. Both drugs are supplied in metered-spray devices. The usual dosage is two sprays in each nostril twice daily. All products are generally well tolerated. However, with one product—the Astelin formulation of azelastine—about 20% of patients complain of a bitter taste. In comparison tests, patients generally prefer the taste of Astepro and Patanase. Although azelastine and olopatadine are considered nonsedating antihistamines, somnolence develops in a significant fraction of users. With olopatadine, some patients experience nose bleeds (3.2%) and headache (4.4%).

907

TABLE 76-1 Overview of Drugs for Allergic Rhinitis

Drug or Class	Route	Actions	Adverse Effects
Antihistamines	Oral/nasal	Block H ₁ receptors and thereby decrease itching, sneezing, and rhinorrhea; do <i>not</i> reduce congestion.	<i>Oral:</i> Sedation and anticholinergic effects (mostly with first-generation agents) <i>Nasal:</i> Bitter taste
Glucocorticoids	Nasal	Prevent inflammatory response to allergens and thereby reduce all symptoms.	Nasal irritation; possible slowing of linear growth in children
Cromolyn	Nasal	Prevents release of inflammatory mediators from mast cells, and thereby can decrease all symptoms. However, benefits are modest.	None
Sympathomimetics	Oral/nasal	Activate vascular alpha ₁ receptors and thereby cause vasoconstriction, which reduces nasal congestion; they do <i>not</i> decrease sneezing, itching, or rhinorrhea.	<i>Oral:</i> Restlessness, insomnia, increased blood pressure <i>Nasal:</i> Rebound nasal congestion
Anticholinergics	Nasal	Block nasal cholinergic receptors and thereby reduce secretions; do <i>not</i> decrease sneezing, nasal congestion, or postnasal drip.	Nasal drying and irritation
Antileukotrienes	Oral	Block leukotriene receptors and thereby reduce nasal congestion.	None

TABLE 76-2 Some Antihistamines for Allergic Rhinitis

Generic Name	Trade Name	Dosage
Oral Antihistamines		
First-Generation (Sedating)		
Chlorpheniramine	Chlor-Trimeton, others	<i>Adults and children 12 yr and older:</i> 4 mg q 4–6 h <i>Children 6–11 yr:</i> 2 mg q 4–6 h
Diphenhydramine	Benadryl, others	<i>Adults:</i> 25–50 mg q 4–6 h <i>Children under 10 kg:</i> 12.5–25 mg 3 or 4 times/day
Second-Generation (Nonsedating)		
Cetirizine	Zyrtec	<i>Adults and children 6 yr and older:</i> 5 or 10 mg once daily
Levocetirizine	Xyzal	<i>Adults and children 12 yr and older:</i> 5 mg once daily <i>Children 6–11 yr:</i> 2.5 mg once daily
Fexofenadine	Allegra	<i>Adults and children 12 yr and older:</i> 60 mg twice daily or 180 mg once daily
Loratadine	Claritin, Alavert	<i>Adults and children 6 yr and older:</i> 10 mg once daily
Desloratadine	Clarinex	<i>Adults and children 12 yr and older:</i> 5 mg once daily
Intranasal Antihistamines		
Azelastine*	Astelin, Astepro	<i>Adults and children 12 yr and older:</i> 2 sprays/nostril twice daily <i>Children 5–11 yr:</i> 1 spray/nostril twice daily†
Olopatadine*	Patanase	<i>Adults and children 12 yr and older:</i> 2 sprays/nostril twice daily (665 mcg/spray)

* A second-generation agent.

† Astelin only. Astepro is not approved for children under 12 years.

77.1.2 Intranasal Glucocorticoids

The basic pharmacology of the glucocorticoids is discussed in [Chapter 71](#). Consideration here is limited to their use in allergic rhinitis.

77.1.2.1 Actions and Uses.

Intranasal glucocorticoids are the most effective drugs for prevention and treatment of seasonal and perennial rhinitis. With proper use, over 90% of patients respond. Because of their anti-inflammatory actions, these drugs can prevent or suppress all of the major symptoms of allergic rhinitis: congestion, rhinorrhea, sneezing, nasal itching, and erythema. In the past, intranasal steroids were reserved for patients whose symptoms could not be controlled with more conventional drugs (sympathomimetics, antihistamines, intranasal cromolyn). However, because of their proven safety and superior efficacy, glucocorticoids have now joined the H₁ antagonists as a first-line therapy. Seven agents are available ([Table 76-3](#)). All are equally effective.

77.1.2.2 Adverse Effects.

Adverse effects are generally mild. The most common are *drying of the nasal mucosa* and a *burning or itching sensation*. *Sore throat*, *epistaxis* (nosebleed), and *headache* may also occur.

Systemic effects are possible, but are rare at recommended doses. Of greatest concern are adrenal suppression and slowing of linear growth in children (whether final adult height is reduced is unknown). Systemic effects are least likely with fluticasone and mometasone, which have very low bioavailability (see [Table 76-3](#)).

908

909

TABLE 76-3 Some Glucocorticoid Nasal Sprays for Allergic Rhinitis

Drug	Trade Name	Intranasal Bioavailability (%)	Dose/Spray (mcg)	Patient Age (yr)	Initial Dosage (Sprays/Nostril)
Beclomethasone	Beconase AQ	44	42	12 and older	1 or 2 twice daily
Budesonide	Rhinocort Aqua	34	32	6–11	1 or 2 once daily
				12 and older	1–4 once daily
Ciclesonide	Omnaris	—	50	12 and older	2 once daily
Flunisolide	Nasarel	49	25	6–13	2 twice daily or 1 thrice daily
				14 and older	2 twice or 2 thrice daily
Fluticasone propionate	Flonase	0.5–2	50	4–11	1 once daily
				12 and older	2 once daily
Fluticasone furoate	Veramyst	—	27.5	2–11	1 once daily
				12 and older	2 once daily
Mometasone	Nasonex	0.1	50	2–11	1 once daily
				12 and older	2 once daily
Triamcinolone	Nasacort AQ	46	55	6 and older	1 or 2 once daily

77.1.2.3 Preparations, Dosage, and Administration.

Intranasal glucocorticoids are administered using a metered-dose spray device. Full doses are given initially (see [Table 76-3](#)). After symptoms are under control, the dosage should be reduced to the lowest effective amount. For patients with seasonal allergic rhinitis, maximal effects may require a week or more to develop. However, an initial response can be seen within hours. For patients with perennial rhinitis, maximal responses may take 2 to 3 weeks to develop. If nasal passages are blocked, they should be cleared with a topical decongestant prior to glucocorticoid administration.

In the past, some products contained an aqueous vehicle and some contained a nonaqueous vehicle (eg, Freon, alcohol). Adverse effects were more intense with the nonaqueous vehicles. Today, nonaqueous vehicles have been abandoned.

77.1.3 Intranasal Cromolyn Sodium

The basic pharmacology of cromolyn sodium is discussed in [Chapter 75](#) (Drugs for Asthma). Consideration here is limited to its use in allergic rhinitis.

77.1.3.1 Actions and Uses.

For treatment of allergic rhinitis, intranasal cromolyn [NasalCrom] is extremely safe, but only moderately effective. Benefits are much less than those of intranasal glucocorticoids. Cromolyn reduces symptoms by suppressing release of histamine and other inflammatory mediators from mast cells. Accordingly, the drug is best suited for prophylaxis—not treatment—and hence should be given before symptoms start. Responses may take a week or two to develop; patients should be informed of this delay. Adverse reactions are minimal—less than with any other drug for allergic rhinitis.

77.1.3.2 Preparations, Dosage, and Administration.

For treatment of allergic rhinitis, cromolyn sodium [NasalCrom] is available in a metered-dose spray device that delivers 5.2 mg/actuation. The usual dosage for adults and children over 2 years is 1 spray (5.2 mg) per nostril 4 to 6 times a day. If nasal congestion is present, a topical decongestant should be used before cromolyn. Like the antihistamines, cromolyn should be dosed on a regular schedule throughout the allergy season.

77.1.4 Sympathomimetics (Decongestants)

77.1.4.1 Actions and Uses

Sympathomimetics (eg, phenylephrine, pseudoephedrine) reduce nasal congestion. How? By activating α_1 -adrenergic receptors on nasal blood vessels, which causes vasoconstriction, which in turn causes shrinkage of swollen membranes followed by nasal drainage. With *topical* administration, vasoconstriction is both rapid and intense. With *oral* administration, responses are delayed, moderate, and prolonged.

In patients with allergic rhinitis, sympathomimetics only relieve stuffiness. They do not reduce rhinorrhea, sneezing, or itching. In addition to their use in allergic rhinitis, sympathomimetics

can reduce congestion associated with sinusitis and colds. Routes and dosages are summarized in [Table 76-4](#).

77.1.4.2 Adverse Effects

77.1.4.2.1 Rebound Congestion.

Rebound congestion develops when *topical* agents are used more than a few days. With prolonged use, as the effects of each application wear off, congestion becomes progressively worse. To overcome this rebound congestion, the patient must use progressively larger and more frequent doses. Hence, once established, rebound congestion can lead to a cycle of escalating congestion and increased drug use. The cycle can be broken by abrupt decongestant withdrawal. However, this tactic can be extremely uncomfortable. A less drastic option is to discontinue the drug in one nostril at a time. An even better option is to use an intranasal glucocorticoid (in both nostrils) for 2 to 6 weeks, starting one week before discontinuing the decongestant. Development of rebound congestion can be minimized by limiting topical application to 3 to 5 days. Accordingly, topical sympathomimetics are not appropriate for individuals with chronic rhinitis.

77.1.4.2.2 Central Nervous System Stimulation.

Central nervous system (CNS) excitation is the most common adverse effect of the *oral* sympathomimetics. Symptoms include restlessness, irritability, anxiety, and insomnia. These responses are unlikely with topical agents.

909

910

TABLE 76-4 Sympathomimetics Used for Nasal Decongestion

Decongestant	Mode of Use	Dosing Interval	Dosage Size*
Phenylephrine [Neo-Synephrine, others]	Drops	q 4 or more h	6 yr and older: 2–3 drops (0.25–1%)
			2–6 yr: 2–3 drops (0.125%)
	Spray	q 4 or more h	12 yr and older: 2–3 sprays (0.25–1%)
			6–12 yr: 2–3 sprays (0.25%)
Pseudoephedrine [Sudafed, others]	Oral	q 4 h	2–6 yr: Not recommended
			12 yr and older: 10 mg
			6–12 yr: 10 mg
	Oral	q 4–6 h	2–6 yr: 1 mL (0.25% drops)
			12 yr and older: 60 mg
			6–12 yr: 30 mg
Naphazoline [Privine]	Oral SR	q 12 h	Less than 6 yr: 15 mg
			12 yr and older: 120 mg
			Less than 12 yr: Not recommended
	Oral CR	q 24 h	12 yr and older: 240 mg
			Less than 12 yr: Not recommended
			Less than 12 yr: Not recommended
Naphazoline [Privine]	Drops	q 6 or more h	12 yr and older: 1 or 2 drops (0.05%)
			Less than 12 yr: Not recommended
	Spray	q 6 or more h	12 yr and older: 1 or 2 sprays (0.05%)
			Less than 12 yr: Not recommended

Oxymetazoline [Afrin 12-Hour, Neo-Synephrine 12-Hour, others] Tetrahydrozoline [Tyline]	Spray	q 10–12 h	6 yr and older: 2–3 sprays (0.05%) Less than 6 yr: Not recommended
	Drops	q 3 or more h	6 yr and older: 2–4 drops (0.1%) 2–6 yr: 2–3 drops (0.05%)
	Spray	q 3 or more h	6 yr and older: 3–4 sprays (0.1%) Less than 6 yr: Not recommended
	Drops	q 8–10 h	12 yr and older: 2–3 drops (0.1%) 2–12 yr: 2–3 drops (0.05%)
Xylometazoline [Natu-Vent, Otrivin]	Spray	q 8–10 h	12 yr and older: 1–3 sprays (0.1%) 2–12 yr: 1 spray (0.05%)

CR = controlled release, SR = sustained release.

* For drops and sprays, dosage listed is applied to *each* nostril; numbers in parentheses indicate concentration of solution employed.

77.1.4.2.3 Cardiovascular Effects.

By activating α_1 -adrenergic receptors on systemic blood vessels, sympathomimetics can cause widespread vasoconstriction. For most patients, effects on systemic vessels are inconsequential. However, for individuals with hypertension or coronary artery disease, widespread vasoconstriction can be hazardous. Generalized vasoconstriction is most likely with *oral* agents. However, if taken in excess, even the topical agents can cause significant systemic vasoconstriction.

77.1.4.2.4 Hemorrhagic Stroke.

On November 6, 2000, the Food and Drug Administration (FDA) ordered that *phenylpropanolamine*, an α -adrenergic agonist, be removed from the market because it was shown to cause subarachnoid and intracerebral hemorrhage in women (but not in men). Although the risk of stroke is small, the FDA ruled that the risk was not justified by the

relatively benign disorders for which phenylpropanolamine was used. (In addition to its use as a nasal decongestant, phenylpropanolamine had been used widely as an over-the-counter weight loss aid.) We do not know if other alpha agonists (eg, phenylephrine, ephedrine, pseudoephedrine) also pose a risk of hemorrhagic stroke.

77.1.4.2.5 Abuse.

Two sympathomimetics—*pseudoephedrine* and *ephedrine*—are associated with abuse. Why? First, by causing CNS stimulation, these sympathomimetics can produce subjective effects similar to those of amphetamine. Second, both drugs can be readily converted to methamphetamine, a widely used drug of abuse. To reduce the availability of these drugs for methamphetamine production, Congress passed the *Combat Methamphetamine Epidemic Act of 2005*, which requires that all products containing ephedrine and pseudoephedrine be placed behind the counter (even though they can still be purchased without a prescription). Furthermore, purchasers must present identification and sign a log. Also, individuals can purchase no more than 9 gm a month or 3.6 gm on any day. Because of these constraints, many products are being reformulated to contain phenylephrine rather than ephedrine and pseudoephedrine. Unfortunately, when taken orally, phenylephrine is not very effective.

77.1.4.3 Factors in Topical Administration

77.1.4.3.1 General Considerations.

Because of the risk of rebound congestion, topical sympathomimetics should be used for no more than 5 consecutive days. To avoid systemic effects, doses should not exceed those recommended by the manufacturer. The applicator should be cleansed after each use to prevent contamination.

910

911

77.1.4.3.2 Drops.

Drops should be administered with the patient in a lateral, head-low position. This causes the drops to spread slowly over the nasal mucosa, thereby promoting beneficial effects while reducing the amount that is swallowed. Because the number of drops can be precisely controlled, drops allow better control of dosage than do sprays. Accordingly, since young children are particularly susceptible to toxicity, drops are preferred for these patients.

77.1.4.3.3 Sprays.

Sprays deliver the decongestant in a fine mist. Although convenient, sprays are less effective than an equal volume of properly instilled drops.

77.1.4.4 Summary of Contrasts Between Oral and Topical Agents

Oral and topical sympathomimetics differ in several important respects: (1) Topical agents act faster than the oral agents and are usually more effective. (2) Oral agents act longer than topical preparations. (3) Systemic effects (vasoconstriction, CNS stimulation) occur primarily with oral agents; topical agents elicit these responses only when dosage is too high. (4) Rebound congestion is common with prolonged use of topical agents, but is rare with oral agents.

77.1.4.5 Comparison of Phenylephrine, Ephedrine, and Pseudoephedrine

Phenylephrine is one of the most widely used nasal decongestants. The drug is administered topically (by itself) and orally (as a component of combination preparations). When administered topically, phenylephrine is both fast and effective. When taken orally, the drug is much less effective, in large part because of extensive first-pass metabolism. However, even though absorption is poor, phenylephrine can still cause adverse cardiovascular effects.

Ephedrine and *pseudoephedrine* are only used orally. They are not available for intranasal administration. Ephedrine causes a high incidence of CNS stimulation. With pseudoephedrine, a stereoisomer of ephedrine, CNS stimulation is much lower. Compared with oral phenylephrine, pseudoephedrine is better absorbed and has a longer half-life, and hence is more effective. As noted, although ephedrine and pseudoephedrine are available without a prescription, both drugs are kept behind the counter to reduce diversion to labs that make methamphetamine.

77.1.5 Antihistamine/Sympathomimetic Combinations

Some patients require combined therapy with a sympathomimetic and an antihistamine. Although antihistamines alone are a first-line treatment, they do not relieve nasal congestion, and hence may be inadequate for some patients. For these patients, addition of a sympathomimetic may be indicated. This can be accomplished in two ways: by giving the antihistamine and sympathomimetic separately, or by using a combination product. Some popular antihistamine/sympathomimetic combinations are listed in [Table 76-5](#).

77.1.6 Ipratropium, an Anticholinergic Agent

Ipratropium bromide [Atrovent] is an anticholinergic agent similar to atropine. The drug is indicated for allergic rhinitis, asthma, and the common cold. To treat allergic rhinitis, ipratropium is administered as a nasal spray (0.05% and 0.06%). Blockade of cholinergic receptors inhibits glandular secretions, and thereby decreases rhinorrhea. The drug does not decrease sneezing, nasal congestion, or postnasal drip. At the doses used for allergic rhinitis, side effects are minimal. The most common are nasal drying and irritation. Ipratropium does not readily cross membranes (it's a quaternary ammonium compound), and hence systemic effects are absent. Dosage for allergic rhinitis in patients 12 years and older range from 2 sprays of 0.03% ipratropium (42 mcg total) per nostril 2 to 3 times a day to 2 sprays of 0.06% ipratropium (84 mcg total) per nostril 4 times a day. Use of ipratropium for asthma is discussed in [Chapter 75](#).

77.1.7 Montelukast, a Leukotriene Antagonist

Montelukast [Singulair], originally approved for asthma, is now approved for seasonal and perennial allergic rhinitis as well. Benefits derive from blocking binding of leukotrienes to their receptors. In people with allergic rhinitis, leukotrienes act primarily to cause nasal congestion (by promoting vasodilation and by increasing vascular permeability). Hence, by blocking leukotriene receptors, montelukast relieves nasal congestion, having little impact on sneezing or itching. When used alone or in combination with an antihistamine, montelukast is less effective than intranasal glucocorticoids. Because beneficial effects are limited, it's probably best to reserve montelukast for patients who don't respond to or can't tolerate nasal glucocorticoids, antihistamines, or both. Montelukast appears devoid of significant adverse effects. Administration is oral. Dosage, which varies with age, is the same as that used for asthma (see [Chapter 75](#)).

77.1.8 Omalizumab

Omalizumab [Xolair] is a monoclonal antibody directed against IgE, an immunoglobulin that plays a central role in the allergic release of inflammatory mediators from mast cells and basophils. In patients with ragweed-induced seasonal allergic rhinitis, omalizumab can greatly decrease nasal symptoms. In one study, patients received a 300-mg subQ dose just prior to ragweed season, followed by additional 300-mg subQ doses every 3 to 4 weeks during the season. The result? Omalizumab decreased serum levels of IgE by 95%, and prevented practically all symptoms of rhinitis. At this time, omalizumab is approved only for asthma (see [Chapter 75](#)).

TABLE 76-5 Some Antihistamine/Sympathomimetic Combinations

Antihistamine/Sympathomimetic	Trade Name	Dosage
Acrivastine/pseudoephedrine	Semprex-D Capsules	8 mg/60 mg 4 times daily
Chlorpheniramine/pseudoephedrine	Allarest Maximum Strength Tablets	4 mg/60 mg q 4–6 h
Fexofenadine/pseudoephedrine	Allegra-D Tablets	60 mg/120 mg twice daily
Loratadine/pseudoephedrine	Claritin-D 12-Hour Tablets	5 mg/120 mg q 12 h
Desloratadine/pseudoephedrine	Clarinex-D 12-Hour Tablets	2.5 mg/120 mg q 12 h
Triprolidine/pseudoephedrine	Actifed Cold & Allergy Tablets	2.5 mg/60 mg q 4–6 h

911

912

77.2 DRUGS FOR COUGH

Cough is a complex reflex involving the CNS, the peripheral nervous system, and the muscles of respiration. The cough reflex can be initiated by irritation of the bronchial mucosa as well as by stimuli arising at sites distant from the respiratory tract. Cough is often beneficial, serving to remove foreign matter and excess secretions from the bronchial tree. Productive cough is characteristic of chronic lung disease (eg, emphysema, asthma, bronchitis) and should not be suppressed. Not all cough, however, is useful; cough frequently serves only to deprive us of comfort or sleep. Under these conditions, antitussive medication is appropriate. The most common use of cough medicines is suppression of nonproductive cough associated with the common cold and other upper respiratory infections.

77.2.1 Antitussives

Antitussives are drugs that suppress cough. Some agents act within the CNS; others act peripherally. The antitussives fall into two major groups: (1) opioid antitussives and (2) nonopioid antitussives. Interestingly, although the major antitussives—codeine, dextromethorphan, and diphenhydramine—are clearly effective against chronic nonproductive cough and experimentally induced cough, there is no good evidence that these drugs can suppress cough associated with the common cold.

77.2.1.1 Opioid Antitussives

All of the opioid analgesics have the ability to suppress cough. The two opioids used most often for cough suppression are *codeine* and *hydrocodone*. Both drugs act in the CNS to elevate cough threshold. Hydrocodone is somewhat more potent than codeine and carries a greater liability for abuse. The basic pharmacology of the opioids is discussed in [Chapter 28](#).

77.2.1.1.1 Codeine.

Codeine is the most effective cough suppressant available. The drug is active orally and can decrease both the frequency and intensity of cough. Doses are low, about one-tenth those needed to relieve pain. At these doses, the risk of physical dependence is small.

Like all other opioids, codeine can suppress respiration. Accordingly, the drug should be employed with caution in patients with reduced respiratory reserve. In the event of overdose, respiratory depression may prove fatal. An opioid antagonist (eg, naloxone) should be used to reverse toxicity.

When dispensed by itself, codeine has a significant potential for abuse, and therefore is classified under Schedule II of the Controlled Substances Act. However, the abuse potential of the antitussive mixtures that contain codeine is low. Accordingly, these mixtures are classified under Schedule V.

For treatment of cough, the adult dosage is 10 to 20 mg orally, 4 to 6 times a day. Codeine is rarely recommended for children.

77.2.1.2 Nonopioid Antitussives

77.2.1.2.1 Dextromethorphan.

Dextromethorphan is the most effective nonopioid cough medicine, and the most widely used of all cough medicines. Benefits equal those of codeine, except against acute severe cough. Like the opioids, dextromethorphan acts in the CNS. Although dextromethorphan is a derivative of the opioids, it does not produce typical opioid-like euphoria or physical dependence. Nonetheless, when taken in high doses, dextromethorphan can cause euphoria, and is abused for this effect (see [Chapter 39](#)). Depending on the dose, subjective effects can range from mild inebriation to a state of mind-body dissociation, much like that caused by phencyclidine (PCP). At therapeutic doses, dextromethorphan does not depress respiration. Adverse effects are mild and rare. Dextromethorphan is the active ingredient in over 140 nonprescription cough medicines. The usual adult dosage is 10 to 30 mg every 4 to 8 hours.

In the past, dextromethorphan was considered devoid of analgesic actions; however, it now appears the drug *can* reduce pain. The mechanism is blockade of receptors for *N*-methyl-D-aspartate (NMDA) in the brain and spinal cord. In contrast, opioids relieve pain primarily through activation of mu receptors. Although dextromethorphan has minimal analgesic effects when used alone, it can enhance analgesic effects of the opioids. For example, we can double

the analgesic response to 30 mg of morphine by combining morphine with 30 mg of dextromethorphan.

When taken in high doses, dextromethorphan can cause euphoria, and is abused for this effect (see [Chapter 39](#)).

77.2.1.2.2 Other Nonopioid Antitussives.

Diphenhydramine is an antihistamine with the ability to suppress cough. The mechanism is unclear. Like other antihistamines, diphenhydramine has sedative and anticholinergic properties. Cough suppression is achieved only at doses that produce prominent sedation. The usual adult dosage is 25 mg every 4 hours.

Benzonatate [Tessalon] is a structural analog of tetracaine, a local anesthetic. The drug is believed to suppress cough by decreasing the sensitivity of respiratory tract stretch receptors (components of the cough-reflex pathway); CNS mechanisms may also be involved. Adverse effects are usually mild (eg, sedation, dizziness, constipation). Benzonatate is supplied in capsules for oral administration. The capsules should be swallowed intact, because chewing will anesthetize the mouth and pharynx. The usual adult dosage is 100 mg 3 times a day. Safety and efficacy have not been established in children under 10 years old.

77.2.2 Expectorants and Mucolytics

77.2.2.1 Expectorants.

An expectorant is a drug that renders cough more productive by stimulating the flow of respiratory tract secretions. A variety of compounds (eg, terpin hydrate, ammonium chloride, iodide products) have been promoted for their supposed expectorant actions. However, in almost all cases, efficacy is doubtful. One agent—*guaifenesin* [Mucinex, Humibid]—may be an exception. However, for this drug to be effective, doses higher than those normally employed may be needed.

77.2.2.2 Mucolytics.

A mucolytic is a drug that reacts directly with mucus to make it more watery. This action should help make cough more productive. Two preparations—*hypertonic saline* and *acetylcysteine* [Mucomyst]—are employed for their mucolytic actions. Both are administered by inhalation. Unfortunately, both can trigger bronchospasm. Because of its sulfur content, acetylcysteine [Mucomyst] has the additional drawback of smelling like rotten eggs.

77.3 COLD REMEDIES: COMBINATION PREPARATIONS

77.3.1 Basic Considerations

The common cold is an acute upper respiratory infection of viral origin. Causative agents include rhinoviruses, adenoviruses, respiratory syncytial virus, and parainfluenza virus. Characteristic symptoms are rhinorrhea, nasal congestion, cough, sneezing, sore throat, hoarseness, headache, malaise, and myalgia; fever is common in children but rare in adults. Colds are self-limited and usually benign. Persistence or worsening of symptoms suggests development of a secondary bacterial infection.

912

There is no cure for the cold, and hence treatment is purely symptomatic. Because colds are caused by viruses, there is no justification for the routine use of antibiotics. These agents are appropriate only if a bacterial infection arises. There is no evidence that vitamin C can prevent or cure colds. Benefits of zinc lozenges are unclear ([Box 76-1](#)).

913

Because no single drug can relieve all symptoms of a cold, the pharmaceutical industry has formulated a vast number of cold remedies that contain a mixture of ingredients. These combination cold remedies should be reserved for patients with multiple symptoms. In addition, the combination chosen should contain only those agents that are appropriate for the symptoms at hand. Patients who require relief from just a single symptom (eg, rhinitis, cough, or headache) are best treated with a single-entity preparation.

Combination cold remedies frequently contain two or more of the following: (1) a nasal decongestant, (2) an antitussive, (3) an analgesic, (4) an antihistamine, and (5) caffeine. The purpose of the first three agents is self-evident. In contrast, the roles of antihistamines and caffeine require explanation. Since histamine has nothing to do with the symptoms of a cold, antihistamines are not present to block histamine receptors. Rather, because of their anticholinergic actions, antihistamines are included to suppress secretion of mucus. Caffeine is added to offset the sedative effects of the antihistamine.

77.3.1.1 BOX 76-1 Special Interest Topic

77.3.1.1.1 ZINC FOR KIDS WITH COLDS?

In an effort to develop a cure for the common cold, researchers have examined zinc. Results of 10 studies in adults have been mixed: in 5 studies, zinc reduced symptoms; in 5 others,

zinc didn't help. Only one study has been done in children. The result? Zinc had no beneficial effect. However, until more research is done, a final conclusion cannot be drawn.

A theoretical basis for how zinc might work has not been firmly established. The predominant theory suggests that zinc blocks viral binding to cells of the nasal epithelium, and thereby suppresses infection. This theory is based on the observation that zinc can prevent rhinovirus (the most common cause of colds) from binding to epithelial cells grown in culture. However, there is no clear proof that zinc can block the adhesion of other cold viruses (eg, adenoviruses, respiratory syncytial virus, parainfluenza virus). Hence, experimental support for the reduced adhesion theory is limited. Alternative theories posit that zinc may inhibit viral replication, boost immune function, enhance cytoprotection, or suppress cold-related inflammatory responses.

Having shown that zinc can benefit adults with colds, Dr. Michael Macknin of the Cleveland Clinic wanted to see if zinc would also benefit children. Accordingly, he and his team studied responses in 249 students in grades 1 through 12 from two school districts in the eastern suburbs of Cleveland, Ohio. The objective was to determine if zinc could shorten the duration of cold symptoms (cough, headache, hoarseness, muscle ache, nasal congestion, nasal drainage, scratchy throat, sore throat, sneezing). Treatment was begun within 24 hours of the onset of symptoms and consisted of either placebo (cherry-flavored lozenges) or 10-mg zinc gluconate glycine lozenges (also cherry flavored) administered 5 or 6 times a day. The outcome? The time to resolution of symptoms was unaffected by zinc. Not only did zinc fail to accelerate recovery, it produced annoying side effects: bad taste in the mouth (60% vs. 38% for placebo); nausea (29% vs. 16%); diarrhea (11% vs. 4%); and mouth, tongue, or throat discomfort (37% vs. 24%).

Should we conclude from these results that zinc is unable to benefit children with colds? No. Other interpretations are possible:

- Benefits may be related to zinc in the diet. Zinc is a normal micronutrient. If the children in this study had adequate zinc in their diets, it may be that little or no benefit would be seen by giving additional zinc. Conversely, if the study had been done in a region where children are zinc deficient, beneficial effects might have been observed.
- The dosage may have been inadequate. In one successful study in adults, the dosage was 23.7 mg 8 times a day—for a total of 190 mg each day. In the children's study, the daily dosage was only 50 to 60 mg—less than one-third the dosage used in adults.

Since the mechanism by which zinc acts is unknown, it is impossible to predict how much is actually needed. Hence, perhaps a higher dosage would have worked.

- The causative viruses may have been insensitive. We know that zinc can block adhesion of *rhinoviruses* to nasal epithelial cells (at least in culture), but may not block adhesion of other cold viruses. If blockade of viral binding really is the mechanism by which zinc acts, treatment would fail if the causative viruses were not sensitive. Since causative agents may be different in different locales or at different times of the year, perhaps the outcome would have been successful if the study had been done in a different place or at a different time.
- The zinc may have been inactivated. In the successful studies done with adults, zinc was formulated in lemon-lime lozenges—not the cherry-flavored lozenges employed in the children's study. It may be that, somehow, the cherry flavoring inactivated the zinc.

At this time, it would be premature to dismiss zinc as a useful medication. More research is needed. Unanswered questions include

- How does zinc work?
- Which cold viruses are sensitive?
- What dosage is most effective?
- What formulation is most effective?
- Are benefits limited to children who are zinc deficient?

When these questions have been answered, we will be able to draw a more firm conclusion about the utility of zinc as a cold remedy for kids.

913

Although they can be convenient, combination cold remedies do have disadvantages. As with all fixed-dose combinations, there is the chance that a dosage (eg, 1 capsule or 1 tablet) that produces therapeutic levels of one ingredient may produce levels of other ingredients that are either excessive or subtherapeutic. In addition, the combination may contain ingredients for which the patient has no need. Furthermore, under FDA regulations, a brand-name product can be reformulated and then sold under the same name. Hence, without carefully reading the label, the consumer has no assurance that the brand-name product purchased this year contains the same amounts of the same drugs that were present in last year's version of that combination product.

914

77.3.2 Use in Young Children

Many experts believe that over-the-counter (OTC) cold remedies should not be used by young children. Why? Because there is no proof of efficacy or safety in pediatric patients—while there *is* proof of the potential for serious harm. According to the Centers for Disease Control and Prevention, in 2004 and 2005 more than 1500 children under the age of 2 years were taken to emergency departments after receiving cough or cold products. Presenting symptoms included convulsions, tachycardia, hallucinations, and impaired consciousness. Some children died. Accordingly, in early 2008, the FDA recommended that OTC cold remedies no longer be given to children under 2 years of age, owing to the risk of potentially life-threatening events. As of this writing, the FDA is still reviewing the safety of these drugs in children 2 to 11 years old. Nonetheless, in August 2008, manufacturers voluntarily revised the labels of children's cold and cough preparations to indicate they should not be used in children younger than 4 years. In addition, for products that contain an antihistamine, they added a warning against use to sedate children. To minimize harm to pediatric patients, parents should

- Avoid OTC cold remedies in children under 4 years of age.
- Only use products labeled for pediatric use.
- Consult a healthcare professional before giving these drugs to a child.
- Read all product safety information before dosing.
- Use the measuring device provided with the product.
- Discontinue the medicine and seek professional care if the child's condition worsens (or fails to improve).
- Not use antihistamine-containing products to sedate children.

77.3.2.1

KEY POINTS

- Allergic rhinitis is the most common allergic disorder.
- Allergic rhinitis is treated primarily with antihistamines, intranasal glucocorticoids, and sympathomimetic decongestants.
- Antihistamines (H_1 receptor antagonists) are first-line drugs for allergic rhinitis. They relieve rhinorrhea, sneezing, and itching, but not congestion.

- Sedation and anticholinergic effects are common side effects of the first-generation antihistamines but not the second-generation antihistamines.
- Intranasal glucocorticoids are the most effective drugs for allergic rhinitis. These first-line agents relieve rhinorrhea, congestion, itching, and sneezing.
- Sympathomimetics decrease nasal congestion by activating α_1 -adrenergic receptors on blood vessels, which causes vasoconstriction and thereby shrinks swollen nasal membranes.
- *Topical* sympathomimetics decrease nasal congestion rapidly and produce minimal systemic effects, but cause rebound congestion when used more than a few days.
- *Oral* sympathomimetics decrease nasal congestion slowly and produce CNS and cardiovascular stimulation, but do *not* cause rebound congestion, and hence are suited for long-term use.
- Codeine, a member of the opioid family, is the most effective cough suppressant available. Doses are only one-tenth those used for analgesia.
- Dextromethorphan is the most effective nonopioid cough suppressant.
- There is not good evidence that codeine, dextromethorphan, or any other cough medicine can suppress cough associated with the common cold.
- OTC cough and cold remedies should not be given to children under the age of 4 years.

⁷⁸CHAPTER 77 Drugs for Peptic Ulcer Disease

The term *peptic ulcer disease* (PUD) refers to a group of upper GI disorders characterized by varying degrees of erosion of the gut wall. Severe ulcers can be complicated by hemorrhage and perforation. Although peptic ulcers can develop in any region exposed to acid and pepsin, ulceration is most common in the lesser curvature of the stomach and the duodenum. PUD is a very common disorder that affects about 10% of Americans at some time in their lives. About 500,000 Americans get ulcers each year. Prior to the mid-1990s, PUD was considered a chronic, relapsing disorder of unknown cause and with no known cure; therapy promoted healing but did not prevent ulcer recurrence. Today, thanks to the pioneering work of two Australians—Barry J. Marshall and J. Robin Warren—we know that most cases of PUD are caused by infection with *Helicobacter pylori*, and that eradication of this bacterium not only promotes healing, but greatly reduces the chance of recurrence.

Figure 77-1 The relationship of mucosal defenses and aggressive factors to health and peptic ulcer disease. When aggressive factors outweigh mucosal defenses, gastritis and peptic ulcers result. (NSAIDs = nonsteroidal antiinflammatory drugs.)

78.1 PATHOGENESIS OF PEPTIC ULCERS

Peptic ulcers develop when there is an imbalance between mucosal defensive factors and aggressive factors ([Fig. 77-1](#)). The major defensive factors are mucus and bicarbonate. The major aggressive factors are *H. pylori*, nonsteroidal antiinflammatory drugs (NSAIDs), gastric acid, and pepsin.

78.1.1 Defensive Factors

Defensive factors serve the physiologic role of protecting the stomach and duodenum from self-digestion. When defenses are intact, ulcers are unlikely. Conversely, when defenses are compromised, aggressive factors are able to cause injury. Two important agents that can weaken defenses are *H. pylori* and NSAIDs.

78.1.1.1 Mucus.

Mucus is secreted continuously by cells of the GI mucosa, forming a barrier that protects underlying cells from attack by acid and pepsin.

78.1.1.2 Bicarbonate.

Bicarbonate is secreted by epithelial cells of the stomach and duodenum. Most bicarbonate remains trapped in the mucus layer, where it serves to neutralize any hydrogen ions that penetrate the mucus. Bicarbonate produced by the pancreas is secreted into the lumen of the duodenum, where it neutralizes acid delivered from the stomach.

78.1.1.3 Blood Flow.

Sufficient blood flow to cells of the GI mucosa is essential for maintaining mucosal integrity. If submucosal blood flow is reduced, the resultant local ischemia can lead to cell injury, thereby increasing vulnerability to attack by acid and pepsin.

915

78.1.1.4 Prostaglandins.

Prostaglandins play an important role in maintaining defenses. These compounds stimulate secretion of mucus and bicarbonate, and they promote vasodilation, which helps maintain submucosal blood flow. They provide additional protection by suppressing secretion of gastric acid.

916

78.1.2 Aggressive Factors

78.1.2.1 **Helicobacter pylori.**

Helicobacter pylori is a gram-negative bacillus that can colonize the stomach and duodenum. By taking up residence in the space between epithelial cells and the mucus barrier that protects these cells, the bacterium manages to escape destruction by acid and pepsin. Once established, *H. pylori* can remain in the GI tract for decades. Although about half of the world's population is infected with *H. pylori*, most infected people never develop symptomatic PUD.

Why do we think *H. pylori* causes PUD? First, between 60% and 75% of patients with PUD have *H. pylori* infection. (Several years ago, the prevalence was even higher—about 90%.) Second, duodenal ulcers are much more common among people with *H. pylori* infection than among people who are not infected. Third, eradication of the bacterium promotes ulcer healing. And fourth, eradication of the bacterium minimizes ulcer recurrence. (One-year recurrence rates approach 80% when *H. pylori* remains present, compared with only 10% when the organism is gone.)

Although the mechanism by which *H. pylori* promotes ulcers has not been firmly established, likely possibilities are enzymatic degradation of the protective mucus layer, elaboration of a cytotoxin that injures mucosal cells, and infiltration of neutrophils and other inflammatory cells in response to the bacterium's presence. Also, *H. pylori* produces *urease*, an enzyme that forms carbon dioxide and ammonia (from urea in gastric juice); both compounds are potentially toxic to the gastric mucosa.

In addition to its role in PUD, *H. pylori* appears to promote gastric cancer. In fact, the bacterium has been declared a type 1 carcinogen (a definite cause of human cancer) by the International Agency for Research on Cancer. However, there is no definitive proof that eradicating *H. pylori* decreases risk.

78.1.2.2 **Nonsteroidal Anti-inflammatory Drugs.**

NSAIDs are the underlying cause of many gastric ulcers and some duodenal ulcers. As discussed in [Chapter 70](#), aspirin and other NSAIDs inhibit the biosynthesis of prostaglandins. By doing so, they can decrease submucosal blood flow, suppress secretion of mucus and bicarbonate, and promote secretion of gastric acid. Furthermore, NSAIDs can irritate the mucosa directly. NSAID-induced ulcers are most likely with long-term, high-dose therapy.

78.1.2.3 Gastric Acid.

Gastric acid is an absolute requirement for peptic ulcer generation: in the absence of acid, no ulcer will form. Acid causes ulcers directly by injuring cells of the GI mucosa and indirectly by activating pepsin, a proteolytic enzyme. In most cases, acid hypersecretion, by itself, is insufficient to cause ulcers. In fact, in most patients with gastric ulcers, acid secretion is normal or reduced, and among patients with duodenal ulcers, only one-third produce excessive amounts of acid. From these observations, we can conclude that, in the majority of patients with peptic ulcers, factors in addition to acid must be involved.

Zollinger-Ellison syndrome is the primary disorder in which hypersecretion of acid alone causes ulcers. The syndrome is caused by a tumor that secretes gastrin, a hormone that stimulates gastric acid production. The amount of acid produced is so large that it overwhelms mucosal defenses. Zollinger-Ellison syndrome is a rare disorder that accounts for only 0.1% of duodenal ulcers.

78.1.2.4 Pepsin.

Pepsin is a proteolytic enzyme present in gastric juice. Like gastric acid, pepsin can injure unprotected cells of the gastric and duodenal mucosa.

78.1.2.5 Smoking.

Smoking delays ulcer healing and increases the risk of recurrence. Possible mechanisms include reduction of the beneficial effects of antiulcer medications, reduced secretion of bicarbonate, and accelerated gastric emptying, which would deliver more acid to the duodenum.

78.1.3 Summary

Infection with *H. pylori* is the most common cause of gastric and duodenal ulcers. However, among people whose PUD can be ascribed to *H. pylori*, additional factors must be involved. Why? Because more than 50% of the population harbors *H. pylori*, but only 10% develop ulcers. Factors that may increase the risk of PUD in people infected with *H. pylori* include smoking, increased acid secretion, and reduced bicarbonate production. The second most common cause of gastric ulcers is NSAIDs. Hypersecretion of acid underlies a few cases of PUD that are not caused by *H. pylori* or NSAIDs.

78.2 OVERVIEW OF TREATMENT

78.2.1 Drug Therapy

The goal of drug therapy is to (1) alleviate symptoms, (2) promote healing, (3) prevent complications (hemorrhage, perforation, obstruction), and (4) prevent recurrence. With the exception of antibiotics, the drugs employed do not alter the disease process. Rather, they simply create conditions conducive to healing. Since nonantibiotic therapies do not cure ulcers, the relapse rate following their discontinuation is high. In contrast, the relapse rate following antibiotic therapy is low.

78.2.1.1 Classes of Antiulcer Drugs

As shown in [Table 77-1](#), the antiulcer drugs fall into five major groups:

- Antibiotics
- Antisecretory agents (histamine₂ receptor antagonists, proton pump inhibitors, muscarinic antagonists)
- Mucosal protectants
- Antisecretory agents that enhance mucosal defenses
- Antacids

From this classification, we can see that drugs act in three basic ways to promote ulcer healing. Specifically, they can (1) eradicate *H. pylori* (antibiotics do this), (2) reduce gastric acidity (antisecretory agents, misoprostol, and antacids do this), and (3) enhance mucosal defenses (sucralfate and misoprostol do this).

78.2.1.2 Drug Selection

78.2.1.2.1 *Helicobacter pylori*-Associated Ulcers.

In 1997, a National Institutes of Health Consensus Development Conference recommended that all patients with gastric or duodenal ulcers and documented *H. pylori* infection be treated with antibiotics. This recommendation applies to patients with newly diagnosed PUD, recurrent PUD, and PUD in which use of NSAIDs is a contributing factor. To hasten healing and relieve symptoms, an antisecretory agent should be given along with the antibiotics. By eliminating *H. pylori*, antibiotics can cure PUD, and thereby prevent recurrence. Diagnosis of

916

917

H. pylori infection and specific antibiotic regimens are discussed below under *Antibacterial Drugs*.

TABLE 77-1 Classification of Antiulcer Drugs

Class	Drugs	Mechanism of Action
Antibiotics	Amoxicillin [Amoxil]	Eradication of <i>H. pylori</i>
	Bismuth [Pepto-Bismol]	
	Clarithromycin [Biaxin]	
	Metronidazole [Flagyl]	
	Tetracycline [Achromycin V]	
	Tinidazole [Tindamax]	
Antisecretory Agents		
H ₂ receptor antagonists	Cimetidine [Tagamet]	Suppression of acid secretion by blocking H ₂ receptors on parietal cells
	Famotidine [Pepcid]	
	Nizatidine [Axid]	
	Ranitidine [Zantac]	
Proton pump inhibitors	Esomeprazole [Nexium]	Suppression of acid secretion by inhibiting H ⁺ , K ⁺ -ATPase, the enzyme that makes gastric acid
	Lansoprazole [Prevacid]	
	Omeprazole [Prilosec, Zegerid]	
	Pantoprazole [Protonix]	
	Rabeprazole [Aciphex]	
Muscarinic antagonists	Pirenzepine [Gastrozepine]	Suppression of acid secretion by blocking muscarinic cholinergic receptors (on parietal cells?)
Mucosal Protectant	Sucralfate [Carafate]	Forms a barrier over the ulcer crater that protects against acid and pepsin
Antisecretory Agent That Enhances Mucosal Defenses	Misoprostol [Cytotec]	Protects against NSAID-induced ulcers by stimulating secretion of mucus and bicarbonate, maintaining submucosal blood flow, and suppressing secretion of gastric acid
Antacids	Aluminum hydroxide	React with gastric acid to form neutral salts
	Calcium carbonate	
	Magnesium hydroxide	

78.2.1.2.2 NSAID-Induced Ulcers.

78.2.1.2.2.1 Prophylaxis.

For patients with risk factors for ulcer development (eg, age over 60, history of ulcers, high-dose NSAID therapy), prophylactic therapy is indicated. Proton pump inhibitors (eg, omeprazole) are preferred. Misoprostol is also effective, but can cause diarrhea. Antacids, sucralfate, and histamine₂ receptor blockers are not recommended.

78.2.1.2.2.2 Treatment.

NSAID-induced ulcers can be treated with any ulcer medication. However, histamine₂ receptor blockers and proton pump inhibitors are preferred. If possible, the offending NSAID should be discontinued, so as to accelerate healing. If the NSAID cannot be discontinued, a proton pump inhibitor is the best choice to promote healing.

78.2.1.3 Evaluation

We can evaluate ulcer healing by monitoring for relief of pain and by radiologic or endoscopic examination of the ulcer site. Unfortunately, evaluation is seldom straightforward. Why? Because cessation of pain and disappearance of the ulcer rarely coincide: In most cases, pain subsides prior to complete healing. However, the converse may also be true: Pain may persist even though endoscopic or radiologic examination reveals healing is complete.

Eradication of *H. pylori* can be determined with several methods, including breath tests, serologic tests, stool tests, and microscopic observation of a stained biopsy sample. These methods are discussed below under *Tests for Helicobacter pylori*.

78.2.1.4 A Note About the Effects of Drugs on Pepsin

Pepsin is a proteolytic enzyme that can contribute to ulcer formation. The enzyme promotes ulcers by breaking down protein in the gut wall.

Like most enzymes, pepsin is sensitive to pH. As pH rises from 1.3 (the usual pH of the stomach) to 2, peptic activity increases by a factor of 4. As pH goes even higher, peptic activity begins to decline. At a pH of 5, peptic activity drops below baseline rates. When pH exceeds 6 to 7, pepsin undergoes irreversible inactivation.

Because the activity of pepsin is pH dependent, drugs that elevate gastric pH (eg, antacids, histamine₂ antagonists, proton pump inhibitors) can cause peptic activity to increase, thereby

enhancing pepsin's destructive effects. For example, treatment that produces a 99% reduction in gastric acidity will cause pH to rise from a base level of 1.3 up to 3.3. At pH 3.3, peptic activity will be significantly increased. To avoid activation of pepsin, drugs that reduce acidity should be administered in doses sufficient to raise gastric pH above 5.

78.2.2 Nondrug Therapy

Optimal antiulcer therapy requires implementation of nondrug measures in addition to drug therapy.

78.2.2.1 Diet.

Despite commonly held beliefs, diet plays a minor role in ulcer management. The traditional “ulcer diet,” consisting of bland foods together with milk or cream, does not accelerate healing.

917

918

Furthermore, there is no convincing evidence that caffeine-containing beverages (coffee, tea, colas) promote ulcer formation or interfere with recovery. A change in *eating pattern* may be beneficial: Consumption of five or six small meals a day, rather than three larger ones, can reduce fluctuations in intragastric pH, and may thereby facilitate recovery.

78.2.2.2 Other Nondrug Measures.

Smoking is associated with an increased incidence of ulcers and also retards recovery. Accordingly, cigarettes should be avoided. Because of their ulcerogenic actions, *aspirin and other NSAIDs* should be avoided by patients with PUD. The exception to this rule is use of aspirin to prevent cardiovascular disease; in the low doses employed, aspirin is only a small factor in PUD. There are no hard data indicating that *alcohol* contributes to PUD. However, if the patient notes a temporal relationship between alcohol consumption and exacerbation of symptoms, then alcohol use should stop. Many people feel that reduction of *stress and anxiety* may encourage ulcer healing; however, there is no good evidence that this is true.

78.3 ANTIBACTERIAL DRUGS

Antibacterial drugs should be given to all patients with gastric or duodenal ulcers and confirmed infection with *H. pylori*. At this time, antibiotics are not recommended for asymptomatic individuals who test positive for *H. pylori*.

78.3.1 Tests for *Helicobacter pylori*

Several tests for *H. pylori* are available. Some are invasive; some are not. The invasive tests require an endoscopically obtained biopsy sample, which can be evaluated in three ways: (1) staining and viewing under a microscope to see if *H. pylori* is present; (2) assaying for the

presence of urease (a marker enzyme for *H. pylori*); and (3) culturing and then assaying for the presence of *H. pylori*.

In the United States, three types of noninvasive tests are available: breath, serologic, and stool tests. In the breath test, patients are given radiolabeled urea. If *H. pylori* is present, the urea is converted to carbon dioxide and ammonia; radiolabeled carbon dioxide can then be detected in the breath. In the serologic test, blood samples are evaluated for antibodies to *H. pylori*. In the stool test, fecal samples are evaluated for the presence of *H. pylori* antigens.

78.3.2 Antibiotics Employed

The antibiotics employed most often are amoxicillin, clarithromycin, bismuth, metronidazole, and tetracycline. None is effective alone. Furthermore, if these drugs *are* used alone, the risk of developing resistance is increased.

78.3.2.1 Amoxicillin.

Helicobacter pylori is highly sensitive to amoxicillin. The rate of resistance is low, only about 3%. Amoxicillin kills bacteria by disrupting the cell wall. Antibacterial activity is highest at neutral pH, and hence can be enhanced by reducing gastric acidity with an antisecretory agent (eg, omeprazole). The most common side effect is diarrhea. The basic pharmacology of amoxicillin is discussed in [Chapter 83](#).

78.3.2.2 Clarithromycin.

Clarithromycin [Biaxin] suppresses growth of *H. pylori* by inhibiting protein synthesis. Treatment is highly effective. The rate of resistance is about 10%. The most common side effects are nausea, diarrhea, and distortion of taste. The basic pharmacology of clarithromycin is presented in [Chapter 85](#).

78.3.2.3 Bismuth.

Bismuth compounds act topically to disrupt the cell wall of *H. pylori*, thereby causing lysis and death. Bismuth may also inhibit urease activity and may prevent *H. pylori* from adhering to the gastric surface.

Bismuth can impart a harmless black coloration to the tongue and stool. Patients should be forewarned. Stool discoloration may confound interpretation of gastric bleeding. Long-term therapy may carry a risk of neurologic injury.

In the United States, bismuth is available as bismuth subsalicylate [Pepto-Bismol, others]. In Europe, the drug is available as bismuth subcitrate [De-Nol].

78.3.2.4 Tetracycline.

Tetracycline, an inhibitor of bacterial protein synthesis, is highly active against *H. pylori*. Resistance is rare (less than 1%). Because tetracycline can stain developing teeth, it should not be used by pregnant women or young children. The pharmacology of tetracycline is discussed in [Chapter 85](#).

78.3.2.5 Metronidazole.

Metronidazole [Flagyl] is very effective against sensitive strains of *H. pylori*. Unfortunately, over 40% of strains are now resistant. The most common side effects are nausea and headache. A disulfiram-like reaction can occur if metronidazole is used with alcohol, and hence alcohol must be avoided. Metronidazole should not be taken during pregnancy. The basic pharmacology of metronidazole is discussed in [Chapter 98](#).

78.3.2.6 Tinidazole.

Tinidazole [Tindamax] is very similar to metronidazole, and shares that drug's adverse effects and interactions. Like metronidazole, tinidazole can cause a disulfiram-like reaction, and hence must not be combined with alcohol. The basic pharmacology of tinidazole is discussed in [Chapter 98](#).

78.3.3 Antibiotic Regimens

In 2007, the American College of Gastroenterology (ACG) issued updated guidelines for managing *H. pylori* infection. To minimize emergence of resistance, the guidelines recommend using at least two antibiotics, and preferably three. An antisecretory agent (proton pump inhibitor or histamine₂ receptor antagonist) should be included as well. Eradication rates are consistently higher with a 14-day course than with a shorter course. Three ACG-recommended regimens are presented in [Table 77-2](#).

For several reasons, compliance with antibiotic therapy can be difficult. First, antibiotic regimens are complex, requiring the patient to ingest as many as 12 pills a day. Second, side effects—especially nausea and diarrhea—are common. Third, a course of treatment is somewhat expensive (about \$200). However, it costs much less to eradicate *H. pylori* with antibiotics than it does to treat ulcers over and over again with traditional antiulcer drugs, which merely promote healing without eliminating the cause.

78.4 HISTAMINE₂ RECEPTOR ANTAGONISTS

The histamine₂ receptor antagonists (H₂RAs) are first-choice drugs for treating gastric and duodenal ulcers. These agents promote ulcer healing by suppressing secretion of gastric acid. Four H₂RAs are available: cimetidine, ranitidine, famotidine, and nizatidine. All four are equally effective. Serious side effects are uncommon.

TABLE 77-2 Some Regimens for Eradicating *H. pylori* Recommended in the 2007 ACG Treatment Guidelines

Drugs	Duration
Triple Therapy	
Esomeprazole (20 mg twice daily)	14 days
Amoxicillin (1 gm twice daily)	
Clarithromycin (500 mg twice daily)	
Quadruple Therapy	
Esomeprazole (20 mg twice daily)	10 to 14 days
Metronidazole (250 mg 4 times daily)	
Tetracycline (500 mg 4 times daily)	
Bismuth subsalicylate (525 mg 4 times daily)	
Quadruple Therapy	
Ranitidine (150 mg twice daily)	10 or 14 days
Metronidazole (250 mg 4 times daily)	
Tetracycline (500 mg 4 times daily)	
Bismuth subsalicylate (525 mg 4 times daily)	
From Chey WD, Wong BCY, and Practice Parameters Committee of the American College of Gastroenterology: American College of Gastroenterology guideline on the management of <i>Helicobacter pylori</i> infection. Am J Gastronterol 102:1808–1825, 2007.	

78.4.1 Cimetidine

Cimetidine [Tagamet] was the first H₂RA available and will serve as our prototype for the group. At one time, cimetidine was the most frequently prescribed drug in the United States.

78.4.1.1 Mechanism of Action

As discussed in [Chapter 69](#), histamine acts through two types of receptors, named H₁ and H₂. Activation of H₁ receptors produces symptoms of allergy. In contrast, activation of H₂ receptors, which are located on parietal cells of the stomach ([Fig. 77-2](#)), promotes secretion of gastric acid. By blocking H₂ receptors, cimetidine reduces both the volume of gastric juice and its hydrogen ion concentration. Cimetidine suppresses basal acid secretion and secretion stimulated by gastrin and acetylcholine. Because cimetidine produces selective blockade of H₂ receptors, the drug cannot reduce symptoms of allergy.

78.4.1.2 Pharmacokinetics

Cimetidine may be used orally, IM, or IV. Comparable blood levels are achieved with all three routes. When the drug is taken orally, food decreases the rate of absorption but not

Figure 77-2 **A model of the regulation of gastric acid secretion showing the actions of antisecretory drugs and antacids.** Production of gastric acid is stimulated by three endogenous compounds: (1) acetylcholine (ACh) acting at muscarinic (M) receptors; (2) histamine (Hist) acting at histamine₂ (H₂) receptors; and (3) gastrin (Gast) acting at gastrin (G) receptors. As indicated, all three compounds act through intracellular messengers—either calcium (Ca⁺⁺) or cyclic AMP (cAMP)—to increase the activity of H⁺,K⁺-ATPase, the enzyme that actually produces gastric acid. Prostaglandins (PG) decrease acid production, perhaps by suppressing production of intracellular cAMP. The actions of histamine₂ receptor antagonists (H₂RAs), proton pump inhibitors (PPIs), and other drugs are indicated. (P = prostaglandin receptor.)

the extent. Hence, if cimetidine is taken with meals, absorption will be slowed and beneficial effects prolonged. Cimetidine crosses the blood-brain barrier—albeit with difficulty—and central nervous system (CNS) side effects can occur. Although some hepatic metabolism takes place, most of each dose is eliminated intact in the urine. The half-life is relatively short (about 2 hours), but increases in patients with renal impairment. Accordingly, dosage should be reduced in these patients.

78.4.1.3 Therapeutic Uses

78.4.1.3.1 Gastric and Duodenal Ulcers.

Cimetidine promotes healing of gastric and duodenal ulcers. To heal duodenal ulcers, 4 to 6 weeks of therapy are generally required. To heal gastric ulcers, 8 to 12 weeks may be needed. Long-term therapy with low doses may be given as prophylaxis against recurrence of gastric and duodenal ulcers.

78.4.1.3.2 Gastroesophageal Reflux Disease (GERD).

Reflux esophagitis is an inflammatory condition caused by reflux of gastric contents back into the esophagus. Cimetidine is a drug of choice for relieving symptoms. However, cimetidine does little to hasten healing.

78.4.1.3.3 Zollinger-Ellison Syndrome.

This syndrome is characterized by hypersecretion of gastric acid and development of peptic ulcers. The underlying cause is secretion of gastrin from a gastrin-producing tumor. Cimetidine can promote healing of ulcers in patients with Zollinger-Ellison syndrome, but only if high doses are employed. At these doses, significant adverse effects can occur.

78.4.1.3.4 Aspiration Pneumonitis.

Anesthesia suppresses the glottal reflex, permitting aspiration of gastric acid. When acid is aspirated, pulmonary injury develops within seconds and can be fatal. Surgical patients at high risk for this disorder include obese patients and women undergoing obstetric procedures. Cimetidine is a drug of choice for preventing aspiration pneumonitis. Gastric acidity can be reduced substantially by administering cimetidine 60 to 90 minutes prior to anesthesia.

78.4.1.3.5 Heartburn, Acid Indigestion, and Sour Stomach.

Cimetidine is now available over the counter to treat these common acid-related symptoms.

78.4.1.4 Adverse Effects

The incidence of side effects is low—and those that do occur are usually benign.

78.4.1.4.1 Antiandrogenic Effects.

Cimetidine binds to androgen receptors, producing receptor blockade. This causes gynecomastia, reduced libido, and impotence—all of which reverse when dosing stops.

78.4.1.4.2 CNS Effects.

Effects on the CNS are most likely in elderly patients who have renal or hepatic impairment. Possible reactions include confusion, hallucinations, CNS depression (lethargy, somnolence), and CNS excitation (restlessness, seizures).

78.4.1.4.3 Pneumonia.

A recent study has shown that elevation of gastric pH with an antisecretory agent increases the risk of pneumonia. Why? Because, when gastric acidity is reduced, bacterial colonization of the stomach increases, resulting in a secondary increase in colonization of the respiratory tract. Among people using an H₂RA, the *relative* risk of acquiring pneumonia is doubled. However, the *absolute* risk is still low (about 1 extra case for every 500 people using the drug).

78.4.1.4.4 Other Adverse Effects.

When administered by IV bolus, cimetidine can cause hypotension and dysrhythmias. These reactions are rare and do not occur with oral therapy. By reducing gastric acidity, cimetidine may permit growth of *Candida* in the stomach. Hematologic effects (neutropenia, leukopenia, thrombocytopenia) occur rarely. Minor side effects include headache, dizziness, myalgia, nausea, diarrhea, constipation, rash, and pruritus.

78.4.1.5 Drug Interactions

78.4.1.5.1 Interactions Related to Inhibition of Drug Metabolism.

Cimetidine inhibits hepatic drug-metabolizing enzymes, and hence can cause levels of many other drugs to rise. Agents of particular concern are *warfarin*, *phenytoin*, *theophylline*, and *lidocaine*, all of which have a narrow margin of safety. If these agents are used with cimetidine, their dosages should be reduced.

78.4.1.5.2 Antacids.

Antacids can decrease absorption of cimetidine. Accordingly, cimetidine and antacids should be administered at least 1 hour apart.

78.4.1.6 Preparations, Dosage, and Administration

78.4.1.6.1 Oral.

Cimetidine [Tagamet] is available in tablets (200, 300, 400, and 800 mg) and an oral solution (300 mg/5 mL). For treatment of duodenal and gastric ulcers, dosing may be done once daily (800 mg at bedtime), twice daily (400 mg each dose), or 4 times a day (300 mg with meals and at bedtime). In patients with renal impairment, dosage should be lowered to 300 mg every 12 hours. For prophylaxis against ulcer recurrence, a single 400-mg dose at bedtime may be employed. Patients with Zollinger-Ellison syndrome require high doses, but not more than 2.4 gm/day.

78.4.1.6.2 Parenteral.

Parenteral cimetidine is reserved for patients with hypersecretory conditions (eg, Zollinger-Ellison syndrome) and ulcers that have failed to respond to oral therapy. The usual dosage (IM or IV) is 300 mg every 6 to 8 hours. Intramuscular injections are made with a concentrated solution (300 mg/2 mL). For IV administration, two concentrations may be employed: (1) 300 mg may be diluted in 20 mL of 0.9% sodium chloride and injected slowly (over 2 minutes), or (2) 300 mg may be diluted in 100 mL of 0.9% sodium chloride and infused over 15 minutes.

78.4.2 Ranitidine

Ranitidine [Zantac, Zantac EFFERdose] shares many of the properties of cimetidine. However, although similar to cimetidine, the drug differs in three important respects: ranitidine is more potent, produces fewer adverse effects, and causes fewer drug interactions.

78.4.2.1 Actions.

Like cimetidine, ranitidine suppresses secretion of gastric acid by blocking H_2 receptors on gastric parietal cells. It does not block H_1 receptors, and hence does not reduce symptoms of allergy.

78.4.2.2 Pharmacokinetics.

Ranitidine can be administered PO, IM, or IV. Oral bioavailability is about 50%. In contrast to cimetidine, ranitidine is absorbed at the same rate in the presence or absence of food.

Ranitidine's ability to enter the CNS is even less than that of cimetidine. Elimination is by hepatic metabolism and renal excretion. Accumulation will occur in patients with renal impairment unless the dosage is reduced. The half-life is 2 to 3 hours.

78.4.2.3 Adverse Effects.

Significant side effects are uncommon. Because ranitidine penetrates the blood-brain barrier poorly, CNS effects are rare. In contrast to cimetidine, ranitidine does not bind to androgen receptors, and hence does not cause antiandrogenic effects (eg, gynecomastia, impotence). Elevation of gastric pH may increase the risk of pneumonia.

78.4.2.4 Drug Interactions.

Ranitidine has few drug interactions. In contrast to cimetidine, ranitidine is a weak inhibitor of hepatic drug-metabolizing enzymes, and therefore does not greatly depress metabolism of other drugs. Antacids have a small effect on ranitidine absorption.

920

921

78.4.2.5 Therapeutic Uses.

Ranitidine has the same indications as cimetidine: (1) short-term treatment of gastric and duodenal ulcers, (2) prophylaxis of recurrent duodenal ulcers, (3) treatment of Zollinger-Ellison syndrome and other hypersecretory states, and (4) treatment of GERD. Because it produces fewer side effects than cimetidine, and because of its greater potency, ranitidine is preferred to cimetidine for treating hypersecretory states (eg, Zollinger-Ellison syndrome).

78.4.2.6 Preparations, Dosage, and Administration.

78.4.2.6.1 Preparations.

Ranitidine [Zantac, Zantac EFFERdose] is available in standard tablets (75, 150, and 300 mg), effervescent tablets (25 and 150 mg), capsules (150 and 300 mg), and a syrup (15 mg/mL) for oral use, and in solution (1 and 25 mg/mL) for parenteral use.

78.4.2.6.2 Oral Dosage.

The usual adult dosage for gastric or duodenal ulcers is 150 mg twice a day. (Note that this dosage is considerably lower than that for cimetidine.) Alternatively, a 300-mg dose can be

given once daily at bedtime. For patients with Zollinger-Ellison syndrome, higher doses may be required. The dosage for preventing recurrence of duodenal ulcers is 150 mg once daily at bedtime. Ranitidine can be administered without regard to meals.

78.4.2.6.3 Parenteral Dosage.

The usual parenteral dosage (IM or IV) is 50 mg every 6 to 8 hours. Intramuscular doses can be injected without dilution. For *IV injection*, the preparation should be diluted to a volume of 20 mL in 0.9% sodium chloride injection and administered slowly (over 5 or more minutes). For *IV infusion*, the drug should be diluted in 100 mL of 0.9% sodium chloride injection and administered over 15 to 20 minutes.

78.4.3 Famotidine

78.4.3.1 Basic and Clinical Pharmacology.

Famotidine [Pepcid, Pepcid AC, Pepcid RPD] is much like ranitidine. The drug is approved for treatment and prevention of duodenal ulcers, and treatment of gastric ulcers, GERD, and hypersecretory states (eg, Zollinger-Ellison syndrome). An over-the-counter formulation is approved for heartburn, acid indigestion, and sour stomach. Like ranitidine, famotidine does not bind to androgen receptors, and hence does not have antiandrogenic effects. Elevation of gastric pH may increase the risk of pneumonia. Famotidine does not inhibit hepatic drug-metabolizing enzymes, and hence does not suppress the metabolism of other drugs.

78.4.3.2 Preparations, Dosage, and Administration.

Prescription-strength famotidine [Pepcid, Pepcid RPD] is available in standard tablets (20 and 40 mg), orally disintegrating tablets (20 and 40 mg), powder for oral suspension (40 mg/5 mL when reconstituted), and solution (0.4 and 10 mg/mL) for IV use. For treatment of duodenal and gastric ulcers, the dosage is 20 mg twice daily or 40 mg once daily at bedtime. For preventing recurrence of duodenal ulcers, the dosage is 20 mg once daily at bedtime. For treatment of GERD, the dosage is 20 to 40 mg twice daily. For treatment of hypersecretory states, the initial dosage is 20 mg every 6 hours; severe cases may require up to 160 mg every 6 hours. All doses should be reduced in patients with moderate to severe renal impairment.

Over-the-counter famotidine is available in 20-mg standard tablets marked as Pepcid AC Maximum Strength, and in three 10-mg formulations—standard tablets, chewable tablets, and gelcaps—marketed as Pepcid AC. Indications are prevention and relief of heartburn, acid indigestion, and sour stomach. For prevention of symptoms, the drug is taken 1 hour before eating. The dosage for prevention or relief is 10 mg, taken with a glass of water. As with

prescription-strength famotidine, dosages should be reduced in patients with moderate to severe renal impairment.

78.4.4 Nizatidine

78.4.4.1 Basic and Clinical Pharmacology.

Nizatidine [Axid, Axid AR, Axid Pulvules] is much like ranitidine and famotidine. The drug is used to treat and prevent duodenal ulcers and to treat gastric ulcers, GERD, heartburn, acid indigestion, and sour stomach. Like ranitidine and famotidine, nizatidine does not have antiandrogenic effects and does not inhibit the metabolism of other drugs. Elevation of gastric pH may increase the risk of pneumonia.

78.4.4.2 Preparations, Dosage, and Administration.

Prescription-strength nizatidine is available in capsules (150 and 300 mg) marketed as Axid Pulvules, and in a generic oral solution (15 mg/mL). The dosage for treatment of active gastric and duodenal ulcers is 150 mg twice daily or 300 mg once daily at bedtime. For preventing the recurrence of duodenal ulcers, the dosage is 150 mg once daily at bedtime. For treatment of GERD, the dosage is 150 mg twice daily.

Over-the-counter nizatidine [Axid AR] is available in 75-mg capsules. The dosage for preventing heartburn is 75 mg, taken any time in the 30-minute interval preceding a meal.

78.5 PROTON PUMP INHIBITORS

The proton pump inhibitors (PPIs) are the most effective drugs for suppressing secretion of gastric acid. Indications include gastric and duodenal ulcers and GERD. All PPIs are well tolerated. Similarities among them are more profound than the differences. Hence, selecting a PPI is based largely on cost and prescriber preference.

78.5.1 Omeprazole

Omeprazole [Prilosec, Prilosec OTC, Zegerid] was the first PPI available and will serve as our prototype for the group. The drug is a powerful suppressant of acid secretion. Effects are superior to those of the H₂RAs. Side effects from short-term therapy are minimal.

78.5.1.1 Mechanism of Action.

Omeprazole, a prodrug, is converted to its active form inside parietal cells of the stomach. The active drug then causes irreversible inhibition of H⁺,K⁺-ATPase (proton pump), the enzyme that

generates gastric acid (see [Fig. 77-2](#)). Because it blocks the final common pathway of gastric acid production, omeprazole can inhibit basal and stimulated acid release. A single 30-mg oral dose reduces acid production by 97% within 2 hours. Because inhibition of the ATPase is not reversible, effects persist until new enzyme is synthesized. Partial recovery occurs 3 to 5 days after stopping treatment. Full recovery may take weeks.

78.5.1.2 Pharmacokinetics.

After oral dosing, about 50% of the drug reaches the systemic circulation. Omeprazole undergoes hepatic metabolism followed by renal excretion. The plasma half-life is short—about 1 hour. However, because omeprazole acts by irreversible enzyme inhibition, effects persist long after the drug has been cleared from the body.

Omeprazole is acid labile, and hence must be protected from stomach acid. To accomplish this, the drug is formulated in a capsule that contains protective enteric-coated granules. The capsule dissolves in the stomach, but the granules remain intact until they reach the relatively alkaline environment of the duodenum.

78.5.1.3 Therapeutic Use.

Omeprazole is approved for short-term therapy of duodenal ulcers, gastric ulcers, erosive esophagitis, and GERD, and for long-term therapy of hypersecretory conditions (eg, Zollinger-Ellison syndrome). Except for therapy of hypersecretory states, treatment should be limited to 4 to 8 weeks.

In clinical trials, duodenal ulcers healed faster with omeprazole (40 mg/day) than with conventional doses of H₂RAs. However, by the end of 8 weeks, the success rate was the same with both treatments. Patients who fail to respond to H₂RAs can often benefit from omeprazole. The 6-month relapse rate following discontinuation of omeprazole is like that seen with H₂RAs.

Use of omeprazole and other PPIs for GERD is discussed in [Box 77-1](#).

78.5.1.4 Adverse Effects.

78.5.1.4.1 Minor Effects.

Effects seen with short-term therapy are generally inconsequential. Like the H₂RAs, omeprazole can cause headache, diarrhea, nausea, and vomiting. The incidence of these effects is less than 1%. As with H₂RAs, elevation of gastric pH increases the risk of pneumonia (about 1 extra case for every 220 people using a PPI).

921

922

78.5.1.4.1.1

BOX 77-1 Special Interest Topic

78.5.1.4.1.1.1

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) is a common disorder characterized by heartburn and acid regurgitation. The disease is formally defined by the presence of troublesome symptoms or complications caused by passage of gastric contents into the esophagus. How common is GERD? Among American adults, heartburn develops in 44% at least once a month, in 14% at least once a week, and in up to 7% every day. GERD is also common among children.

GERD is associated with a wide range of symptoms and complications. On the basis of endoscopic examination, patients fall into two major groups: those with *erosive esophagitis* and those with *nonerosive reflux disease* (NERD). Erosive esophagitis is characterized by breaks in the esophageal mucosa. In contrast, mucosal breaks are absent in people with NERD. Less than 50% of patients with GERD have the erosive form. Complications of erosive GERD include difficulty swallowing, painful swallowing, esophageal stricture, ulcers, GI bleeding, anemia, and persistent vomiting. Erosive GERD can also lead to esophageal adenocarcinoma and to Barrett's esophagus, a premalignant condition that can evolve into adenocarcinoma.

Why does GERD occur? The primary problem is inappropriate relaxation of the lower esophageal sphincter (LES), a ring of smooth muscle that normally prevents reflux of gastric acid. In people with GERD, the LES undergoes frequent, transient relaxation, thereby allowing pressure in the stomach to force gastric contents up into the esophagus. Other factors that can contribute to GERD include obesity, hiatal hernia, delayed gastric emptying, and impaired clearance of acid from the esophagus. Of note, *Helicobacter pylori*, the bacterium that causes most gastric and duodenal ulcers, appears to play little or no role in GERD.

We can treat GERD with drugs or with surgery. For most patients, drugs are preferred. As a rule, surgery should be reserved for young, healthy patients who either cannot or will not take drugs chronically. With either drug therapy or surgery, treatment has three goals: relief of symptoms, promotion of healing, and prevention of complications.

For drug therapy, the principal options are proton pump inhibitors (PPIs) and histamine₂ receptor antagonists (H₂RAs). However, since PPIs are much better than H₂RAs at healing esophagitis and maintaining remission, PPIs are considered the clear drugs of choice. For patients with NERD, PPIs may be taken PRN. For patients with

erosive GERD, PPIs should be taken continuously until symptoms resolve (typically 4 to 8 weeks). Unfortunately, when PPIs are discontinued, the relapse rate is high, occurring in 80% to 90% of patients within 6 to 12 months. Accordingly, for patients with severe GERD, long-term maintenance therapy is recommended.

Several lifestyle changes can complement drug therapy—but should not be substituted for drugs. Recommended measures include smoking cessation, weight loss, avoidance of alcohol and late-night meals, and sleeping with the head elevated.

78.5.1.4.2 Gastric Cancer.

Long-term therapy may pose a risk of cancer. Gastric carcinoid tumors have developed in rats given omeprazole daily for 2 years. Tumor generation is related to hypersecretion of gastrin, which occurs in response to omeprazole-induced suppression of gastric acidity. Gastrin stimulates hyperplasia of gastric epithelial cells, whose growth may ultimately result in a gastric carcinoid tumor.

78.5.1.4.3 Hip Fracture.

Long-term therapy, especially in high doses, may increase the risk of osteoporosis and fractures. How? By reducing acid secretion, omeprazole may decrease absorption of calcium, and may thereby promote osteoporosis. However, the risk appears to low: only 1 extra hip fracture would be expected for each 1200 patients. To minimize fracture risk, treatment should use the lowest dose needed for the shortest duration possible. Also, patients should be encouraged to maintain adequate intake of calcium and vitamin D.

78.5.1.5 Drug Interactions.

By elevating gastric pH, PPIs can significantly reduce absorption of *atazanavir* (used for HIV/AIDS) and two antifungal drugs: *ketoconazole* and *itraconazole*. Concurrent use of atazanavir with omeprazole is not recommended.

78.5.1.6 Preparations, Dosage, and Administration.

Prescription-strength omeprazole [Prilosec, Zegerid] is available in two formulations: (1) delayed-release capsules (10, 20, and 40 mg) marketed as *Prilosec*, and (2) a powder (20 and 40 mg), marketed as *Zegerid*, used to make an immediate-release oral suspension. (The powder contains sodium bicarbonate, which elevates gastric pH and thereby protects omeprazole from acid destruction. Each dose contains 460 mg of sodium, making the product unsuitable for people who must restrict sodium intake.) To treat active duodenal ulcer and GERD, the usual

dosage is 20 mg once a day, taken before a meal, for 4 to 8 weeks. To treat Zollinger-Ellison syndrome and other hypersecretory states, doses up to 120 mg 3 times a day may be needed.

Over-the-counter omeprazole is available in 20-mg delayed-release tablets, marketed as Prilosec OTC. The product is indicated for adults with frequent heartburn (2 or more episodes a week). The dosage is 20 mg once daily for 14 days, taken before the first meal of the day.

78.5.2 Esomeprazole

Esomeprazole [Nexium, Nexium I.V.] is nearly identical to omeprazole [Prilosec]. Structurally, esomeprazole is the *S*-isomer of omeprazole (which is a mixture of *S*- and *R*-isomers). The *S*-isomer (esomeprazole) is metabolized more slowly than the *R*-isomer, and hence esomeprazole achieves higher blood levels than omeprazole, and its effects last somewhat longer. Otherwise the two drugs are essentially the same. The most common adverse effects are headache and diarrhea. In addition, esomeprazole may cause nausea, flatulence, abdominal pain, and dry mouth. Elevation of gastric pH may increase the risk of pneumonia. As with omeprazole, long-term therapy may pose a risk of osteoporosis and fractures. Approved indications are erosive esophagitis, GERD, and duodenal ulcers associated with *H. pylori* infection. In addition, the drug may be used for prophylaxis of NSAID-induced ulcers.

For oral therapy, esomeprazole is available in two formulations: (1) delayed-release capsules (20 and 40 mg) and (2) enteric-coated granules (10, 20, and 40 mg) that form a delayed-release suspension when mixed with water (1 tablespoon). To treat erosive gastritis, the usual dosage is 20 or 40 mg once daily, taken at least 1 hour before a meal, for 4 to 8 weeks. To treat GERD, the usual dosage is 20 mg once daily for 4 to 8 weeks. To treat duodenal ulcers associated with *H. pylori*, one ACG-recommended regimen consists of triple therapy—esomeprazole (20 mg twice daily), amoxicillin (1000 mg twice daily), and clarithromycin (500 mg twice daily)—administered for 14 days. The goal is to eradicate *H. pylori*.

922

923

For intravenous therapy, esomeprazole is supplied as a powder (20 and 40 mg) to be reconstituted with 0.9% sodium chloride for injection. Administration is by injection (over 3 minutes or longer) or infusion (over 10 to 30 minutes). Intravenous therapy is indicated only for GERD with a history of erosive gastritis. The dosage is 20 or 40 mg once a day for up to 10 days.

78.5.3 Lansoprazole

Lansoprazole [Prevacid, Prevacid IV] is very similar to omeprazole. Both drugs cause prolonged inhibition of H^+, K^+ -ATPase. Hence, suppression of acid secretion is sustained. Like omeprazole, lansoprazole is well tolerated. The most common adverse effects are diarrhea, abdominal pain,

and nausea. Elevation of gastric pH may increase the risk of pneumonia. Prolonged, high-dose therapy may pose a risk of osteoporosis and fracture.

Lansoprazole may be administered PO or IV. Three oral formulations are available: (1) delayed-release capsules (15 and 30 mg); (2) orally disintegrating, delayed-release tablets (15 and 30 mg); and (3) enteric-coated granules (15 and 30 mg/packet) that form a suspension when mixed with water (2 tablespoons). All three formulations should be taken immediately before a meal. The dosage for duodenal ulcers (prevention and treatment) and GERD is 15 mg once daily. The dosage for erosive gastritis and active gastric ulcers is 30 mg once daily. For hypersecretory states, the initial dosage is 60 mg/day; for severe cases, up to 90 mg twice daily may be needed.

For IV therapy, lansoprazole is available as a powder (30 mg/vial) to be reconstituted with 5 mL of sterile water, and then diluted with 50 mL of either 0.9% sodium chloride injection, lactated Ringer's injection, or 5% dextrose in water. Infusions are done over 30 minutes. An in-line filter *must* be used to trap particulate matter. Dosages are the same as for oral therapy.

78.5.4 Rabeprazole

Rabeprazole [Aciphex] is much like omeprazole and lansoprazole in actions, uses, and adverse effects. The drug is approved for duodenal ulcers, GERD, and hypersecretory states, such as Zollinger-Ellison syndrome. Like other PPIs, rabeprazole suppresses acid secretion by inhibiting H^+,K^+ -ATPase in parietal cells. However, in contrast to omeprazole, the drug causes *reversible* inhibition of H^+,K^+ -ATPase, and hence its effects are less durable. In addition to suppressing acid secretion, rabeprazole has antibacterial activity. As a result, it may help other antibacterial drugs eradicate *H. pylori*. The most common adverse effects are diarrhea, headache, dizziness, malaise, nausea, and rash. Elevation of gastric pH may increase the risk of pneumonia. Although rabeprazole is metabolized by cytochrome P450 enzymes, it does not appear to influence the metabolism of other drugs. However, it *can* increase digoxin levels by 20%. Accordingly, levels of digoxin should be monitored. Rabeprazole is available in 20-mg delayed-release, enteric-coated tablets. The dosage for GERD and duodenal ulcers is 20 mg once daily, taken with or without food. The initial dosage for hypersecretory states is 60 mg once daily; for severe cases, 60 mg twice daily may be needed. Although rabeprazole is not approved for treating gastric ulcers, 20 to 40 mg once daily has been effective.

78.5.5 Pantoprazole

Pantoprazole [Protonix, Protonix I.V.] is similar to omeprazole and the other PPIs. Indications are duodenal ulcers, gastric ulcers, GERD, and hypersecretory states. Like other PPIs, pantoprazole is well tolerated. Like lansoprazole, pantoprazole may be administered PO or IV. With oral therapy,

the most common adverse effects are diarrhea (1.5%), headache (1.3%), and dizziness (0.7%). With IV therapy, the most common adverse effects are diarrhea, headache, nausea, dyspepsia, and injection-site reactions, including thrombophlebitis and abscess. With both routes, elevation of gastric pH may increase the risk of pneumonia. Pantoprazole does not affect cytochrome P450 enzymes, and hence does not affect the metabolism of other drugs. Pantoprazole is available in three formulations:

- Delayed-release tablets (20 and 40 mg)
- Enteric-coated granules (40 mg) that can be sprinkled on applesauce or mixed with 5 mL of apple juice for oral administration, or mixed with 10 mL of apple juice for administration by nasogastric tube
- Powder (40 mg/vial) to be reconstituted for IV use

Oral doses may be taken with or without food. Infusions are done over 15 minutes, and a filter *must* be used to remove precipitates. The usual dosage, either PO or IV, is 40 mg/day.

78.6 OTHER ANTIULCER DRUGS

78.6.1 Sucralfate

Sucralfate [Carafate] is an effective antiulcer medication notable for minimal side effects and lack of significant drug interactions. The drug promotes ulcer healing by creating a protective barrier against acid and pepsin. Sucralfate has no acid-neutralizing capacity and does not decrease acid secretion.

78.6.1.1 Mechanism of Antiulcer Action.

Sucralfate is a complex substance composed of sulfated sucrose and aluminum hydroxide. Under mildly acidic conditions (pH less than 4), sucralfate undergoes polymerization and cross-linking reactions. The resultant product is a viscid and very sticky gel that adheres to the ulcer crater, creating a barrier to back-diffusion of hydrogen ions, pepsin, and bile salts. Attachment to the ulcer appears to last up to 6 hours.

78.6.1.2 Pharmacokinetics.

Sucralfate is administered orally, and systemic absorption is minimal (3% to 5%). About 90% of each dose is eliminated in the feces.

78.6.1.3 Therapeutic Uses.

Sucralfate is approved for acute and maintenance therapy of duodenal ulcers. Rates of healing are comparable to those achieved with cimetidine. Controlled trials indicate that sucralfate can also promote healing of gastric ulcers.

78.6.1.4 Adverse Effects.

Sucralfate has no known serious adverse effects. The most significant side effect is constipation, which occurs in only 2% of patients. Because sucralfate is not absorbed, systemic effects are absent.

78.6.1.5 Drug Interactions.

Interactions with other drugs are minimal. By raising gastric pH above 4, antacids may interfere with sucralfate's effects. This interaction can be minimized by administering these drugs at least 30 minutes apart.

Sucralfate may impede the absorption of some drugs, including phenytoin, theophylline, digoxin, warfarin, and fluoroquinolone antibiotics (eg, ciprofloxacin, norfloxacin). These interactions can be minimized by administering sucralfate at least 2 hours apart from these other drugs.

78.6.1.6 Preparations, Dosage, and Administration.

Sucralfate [Carafate] is available in 1-gm tablets and a suspension (1 gm/10 mL) for oral administration. Administer on an empty stomach. The recommended adult dosage is 1 gm 4 times a day, taken 1 hour before meals and at bedtime. However, a dosing schedule of 2 gm twice a day appears equally effective. Treatment should continue for 4 to 8 weeks. Sucralfate tablets are large and difficult to swallow, especially by the elderly. The oral suspension is much easier to ingest.

78.6.2 Misoprostol

78.6.2.1 Therapeutic Use.

Misoprostol [Cytotec] is an analog of prostaglandin E₁. In the United States, the drug's only approved GI indication is prevention of gastric ulcers caused by long-term therapy with NSAIDs. In other countries, misoprostol is also used to treat peptic ulcers unrelated to NSAIDs.

In addition to its use in PUD, misoprostol is used to promote cervical ripening (see [Chapter 63](#)), and, in combination with mifepristone (RU 486), to induce abortion (see [Chapter 61](#)).

78.6.2.2 Mechanism of Action.

In normal individuals, prostaglandins help protect the stomach by suppressing secretion of gastric acid, promoting secretion of bicarbonate and cytoprotective mucus, and maintaining submucosal blood flow (by promoting vasodilation). As discussed in [Chapter 70](#), aspirin and other NSAIDs cause gastric ulcers in part by inhibiting prostaglandin biosynthesis. Misoprostol prevents NSAID-induced ulcers by serving as a replacement for endogenous prostaglandins.

923

78.6.2.3 Adverse Effects.

924

The most common reactions are dose-related diarrhea (13% to 40%) and abdominal pain (7% to 20%). Some women experience spotting and dysmenorrhea.

78.6.2.3.1 Misoprostol is contraindicated during pregnancy.

The drug is classified in Food and Drug Administration Pregnancy Risk Category X: the risk of use by pregnant women clearly outweighs any possible benefits. Prostaglandins stimulate uterine contractions. Use during pregnancy has caused partial or complete expulsion of the developing fetus. If women of child-bearing age are to use misoprostol, they must (1) be able to comply with birth control measures, (2) be given oral and written warnings about the dangers of misoprostol, (3) have a negative serum pregnancy test result within 2 weeks prior to beginning therapy, and (4) begin therapy only on the second or third day of the next normal menstrual cycle.

78.6.2.4 Preparations, Dosage, and Administration.

Misoprostol [Cytotec] is supplied in 100- and 200-mcg tablets for oral administration. The usual dosage is 200 mcg 4 times a day administered with meals and at bedtime. Patients who cannot tolerate this dosage may try 100 mcg 4 times a day.

78.6.3 Antacids

Antacids are alkaline compounds that neutralize stomach acid. Their principal indications are PUD and GERD.

78.6.3.1 Beneficial Actions

Antacids react with gastric acid to produce neutral salts or salts of low acidity. By neutralizing acid, these drugs decrease destruction of the gut wall. In addition, if treatment raises gastric pH above 5, these drugs will reduce pepsin activity as well. Antacids may also enhance mucosal protection by stimulating production of prostaglandins. These drugs do not coat the ulcer crater to protect it from acid and pepsin. With the exception of sodium bicarbonate, antacids are poorly absorbed, and therefore do not alter systemic pH.

78.6.3.2 Therapeutic Uses

78.6.3.2.1 Peptic Ulcer Disease.

The primary indication for antacids is PUD. Rates of healing are equivalent to those achieved with H₂RAs. At one time, antacids were the mainstay of antiulcer therapy. However, these drugs have been largely replaced by newer options (H₂RAs, PPIs, sucralfate) that are equally effective and more convenient to administer, and cause fewer side effects.

78.6.3.2.2 Other Uses.

Antacids are administered prior to anesthesia to prevent aspiration pneumonitis. In addition, they can provide prophylaxis against stress-induced ulcers. For patients with GERD, antacids can produce symptomatic relief, but they do not accelerate healing. Although these drugs are used widely by the general public to relieve functional symptoms (dyspepsia, heartburn, acid indigestion), there are no controlled studies that demonstrate efficacy in these conditions.

78.6.3.3 Potency, Dosage, and Formulations

78.6.3.3.1 Potency.

Antacid potency is expressed as acid-neutralizing capacity (ANC). ANC is defined as the number of milliequivalents of hydrochloric acid that can be neutralized by a given weight or volume of antacid. Individual antacids differ widely in ANC. The ANCs of commonly used proprietary preparations are listed in [Table 77-3](#).

78.6.3.3.2 Dosage.

The objective of peptic ulcer therapy is to promote healing, and not simply to relieve pain. Consequently, antacids should be taken on a regular schedule, not just in response to

discomfort. In the usual dosing schedule, antacids are administered 7 times a day: 1 and 3 hours after each meal and at bedtime.

Dosage recommendations should be based on ANC and not on weight or volume of antacid. The ANC of a single dose usually ranges from 20 to 80 mEq. Single doses for gastric ulcers are relatively low (20 to 40 mEq), whereas single doses for duodenal ulcers are higher (40 to 80 mEq). Frequent administration of even larger doses (120 mEq) may be required if ulceration is especially severe.

To provide maximum benefits, treatment should elevate gastric pH above 5. At this pH there is inhibition of pepsin's activity in addition to nearly complete (greater than 99.9%) neutralization of acid.

Antacids are inconvenient and unpleasant to ingest, making adherence difficult to achieve—especially in the absence of pain. Patients should be encouraged to take their medication as prescribed, even after symptoms are gone.

78.6.3.3.3 Formulations.

Antacids are available in tablet and liquid formulations. Antacid tablets should be chewed thoroughly and followed with a glass of water or milk. Liquid preparations should be shaken before dispensing. As a rule, liquids (suspensions) are more effective than tablets.

78.6.3.4 Adverse Effects

78.6.3.4.1 Constipation and Diarrhea.

Most antacids affect the bowel. Some (eg, aluminum hydroxide) promote constipation, whereas others (eg, magnesium hydroxide) promote diarrhea. Effects on the bowel can be minimized by combining an antacid that promotes constipation with one that promotes diarrhea. Patients should be taught to adjust the dosage of one agent or the other to normalize bowel function.

78.6.3.4.2 Sodium Loading.

Some antacid preparations contain substantial amounts of sodium (see [Table 77-3](#)). Because sodium excess can exacerbate hypertension and heart failure, patients with these disorders should avoid preparations that have a high sodium content.

924

925

TABLE 77-3 Composition and Acid-Neutralizing Capacity of Commonly Used Over-the-Counter Antacid Suspensions

Product	Acid- Neutralizing Capacity (mEq/5 mL)	Active Ingredients (mg/5 mL)				Sodium (mg/5 mL)
		Al(OH) ₃	Mg(OH) ₂	Simethicone	Magaldrate	
AlternaGEL	16	600				<2.5
Aludrox Suspension	12	307	103			2.3
Amphojel	10	300				2.3
Maalox Regular Strength	13	200	200			1.4
Milk of Magnesia	14		390			0.1
Mylagen II Liquid	24	400	400	40		1.3
Mylanta Maximum Liquid	25	400	400	40		1.1
Riopan	15				540	<0.1
Riopan Plus Suspension	15			40	540	<0.1
Riopan Plus DS Suspension	30			40	1080	0.3
DS = double strength.						

78.6.3.5 Drug Interactions

By raising gastric pH, antacids can influence the dissolution and absorption of many other drugs, including *cimetidine* and *ranitidine*. These interactions can be minimized by allowing 1 hour between taking antacids and these other drugs.

Antacids can interfere with the actions of sucralfate. To minimize this interaction, administer these drugs at least 1 hour apart.

If absorbed in substantial amounts, antacids can alkalinize the urine. Elevation of urinary pH can accelerate excretion of acidic drugs and delay excretion of basic drugs.

78.6.3.6 Antacid Families

There are four major groups of antacids: (1) aluminum compounds, (2) magnesium compounds, (3) calcium compounds, and (4) sodium compounds. Individual agents that belong to each group are listed in [Table 77-4](#). Representative members of these groups are discussed below.

78.6.3.7 Representative Antacids

Antacids differ from one another with respect to ANC, onset and duration of action, effects on the bowel, systemic effects, and special applications. In this section, we discuss the two most commonly used antacids—magnesium hydroxide and aluminum hydroxide—and two less commonly used drugs—calcium carbonate and sodium bicarbonate. The distinguishing properties of these agents are summarized in [Table 77-5](#).

78.6.3.7.1 Magnesium Hydroxide.

This antacid is rapid acting, has high ANC, and produces effects of long duration. These properties make magnesium hydroxide an antacid of choice. The liquid formulation of magnesium hydroxide is often referred to as milk of magnesia.

TABLE 77-4 Classification of Antacids

Aluminum Compounds
Aluminum hydroxide
Aluminum carbonate
Aluminum phosphate
Dihydroxyaluminum sodium carbonate
Magnesium Compounds
Magnesium hydroxide (milk of magnesia)
Magnesium oxide
Calcium Compounds
Calcium carbonate
Sodium Compounds
Sodium bicarbonate
Other
Magaldrate (a complex of magnesium and aluminum compounds)

The most prominent adverse effect is diarrhea, which results from retention of water in the intestinal lumen. To compensate for this effect, magnesium hydroxide is usually administered in combination with aluminum hydroxide, an antacid that promotes constipation. However, if the dose of magnesium hydroxide is sufficiently high, no amount of aluminum hydroxide will prevent diarrhea. Since stimulation of the bowel can be hazardous for patients with intestinal obstruction or appendicitis, magnesium hydroxide should be avoided in those with undiagnosed abdominal pain. Because of its effect on the bowel, magnesium hydroxide is frequently employed as a laxative (see [Chapter 78](#)). In patients with renal impairment, magnesium may accumulate to high levels, causing signs of toxicity (eg, CNS depression).

78.6.3.7.2

Aluminum Hydroxide.

This drug has relatively low ANC and is slow acting, but produces effects of long duration. Although rarely used alone, this compound is widely used in combination with magnesium hydroxide (see [Table 77-3](#)). Aluminum hydroxide preparations contain significant amounts of

sodium; appropriate caution should be exercised. The most common adverse effect is constipation.

Aluminum hydroxide adsorbs a variety of compounds. Binding of certain drugs (eg, tetracyclines, warfarin, digoxin) may reduce their effects. Aluminum hydroxide has a high affinity for phosphate. By binding with phosphate, the drug can reduce phosphate absorption, and can thereby cause hypophosphatemia. Aluminum hydroxide can also bind to pepsin, which may facilitate ulcer healing.

78.6.3.7.3

Calcium Carbonate.

Calcium carbonate, like magnesium hydroxide, is rapid acting, has high ANC, and produces effects of long duration. Because of these properties, calcium carbonate was once considered the ideal antacid. However, because of concerns about acid rebound (stimulation of acid secretion), use of calcium carbonate has declined. The principal adverse effect is constipation, which can be overcome by combining calcium carbonate with a magnesium-containing antacid (eg, magnesium hydroxide). Calcium carbonate releases carbon dioxide in the stomach, and can thereby cause eructation (belching) and flatulence. Rarely, systemic absorption is sufficient to produce the milk-alkali syndrome, a condition characterized by hypercalcemia, metabolic alkalosis, soft tissue calcification, and impaired renal function. The palatability of calcium carbonate is low, and hence can detract from adherence.

78.6.3.7.4

Sodium Bicarbonate.

Although capable of neutralizing gastric acid, sodium bicarbonate is unfit for treating ulcers. This agent has a rapid onset but its effects are short lasting. Like calcium carbonate, sodium bicarbonate liberates carbon dioxide, thereby increasing intra-abdominal pressure and promoting eructation and flatulence. Absorption of sodium can exacerbate hypertension and heart failure. In patients with renal impairment, sodium bicarbonate can cause systemic alkalosis. (Other antacids rarely alter systemic pH.) Because of its brief duration, high sodium content, and ability to cause alkalosis, sodium bicarbonate is inappropriate for treating PUD. The drug *is* useful, however, for treating acidosis and elevating urinary pH to promote excretion of acidic drugs following overdose.

TABLE 77-5 Representative Antacids: Summary of Distinguishing Properties

Antacid	Effect on the Bowel		Effect on Systemic pH	Comments
	Constipation	Diarrhea		
Aluminum hydroxide	Yes	No	None	Can cause hypophosphatemia; can treat hyperphosphatemia
Magnesium hydroxide	No	Yes	None	Can cause magnesium toxicity (CNS depression) in patients with renal impairment
Calcium carbonate	Yes	No	None	May cause acid rebound or milk-alkali syndrome; releases CO ₂
Sodium bicarbonate	No	No	Increase	Not used routinely to treat ulcers; used to treat acidosis and to alkalinize urine; high risk of sodium loading; releases CO ₂

925

926

78.6.4 Anticholinergics

Atropine and other classic muscarinic antagonists have a very limited role in treating PUD. Why? Because the doses required to inhibit acid secretion are so high that they produce muscarinic blockade throughout the body. Hence, when used to treat ulcers, these drugs cause a high incidence of anticholinergic side effects, such as dry mouth, constipation, urinary retention, and visual disturbances.

78.6.4.1 Pirenzepine.

Pirenzepine [Gastrozepine] is a unique muscarinic antagonist available for treating PUD. In contrast to the classic anticholinergic drugs, pirenzepine produces “selective” blockade of the muscarinic receptors that regulate gastric acid secretion (see [Fig. 77-2](#)). As a result, the drug can inhibit acid secretion without causing pronounced anticholinergic side effects. For treatment of duodenal ulcers, pirenzepine (50 mg 2 to 3 times/day) is about equal to cimetidine (1 gm/day).

Following oral administration, about 20% to 30% of the drug is absorbed. Very little crosses the blood-brain barrier. About 80% is excreted unchanged in the urine. The half-life is approximately 10 hours.

The most common side effect is dry mouth. In addition, pirenzepine can cause constipation, visual disturbances, nausea, vomiting, and diarrhea.

78.6.5 Combination Packs

Three combination packs—Helidac, Pylera, and Prevpac—are available for treating *H. pylori*–associated ulcers. The purpose of these packs is to simplify the purchase and administration of drugs for triple and quadruple therapy of PUD.

78.6.5.1 Helidac.

The Helidac pack contains bismuth subsalicylate tablets (262.4 mg), metronidazole tablets (250 mg), and tetracycline capsules (500 mg). One dose consists of 2 bismuth tablets, 1 metronidazole tablet, and 1 tetracycline capsule. Patients take four such doses a day, along with two daily doses of a PPI or H₂RA.

78.6.5.2 Pylera.

The Pylera pack consists of capsules each of which contains three drugs: bismuth subcitrate potassium (140 mg), metronidazole (125 mg), and tetracycline (125 mg). One dose consists of 3 capsules. Patients take four such doses a day, along with two daily doses of a PPI or H₂RA.

78.6.5.3 Prevpac.

The Prevpac pack contains lansoprazole [Prevacid] capsules (30 mg), amoxicillin capsules (500 mg), and clarithromycin tablets (500 mg). One dose consists of 1 lansoprazole capsule, 2 amoxicillin capsules, and 1 clarithromycin tablet. Patients take two of these doses a day.

78.6.5.3.1

KEY POINTS

- The term *peptic ulcer disease* (PUD) refers to a group of upper GI disorders characterized by varying degrees of erosion of the gut wall.
- PUD develops when aggressive factors (*H. pylori*, NSAIDs, acid, pepsin) outweigh defensive factors (mucus, bicarbonate, submucosal blood flow, prostaglandins).
- Gastric acid is an absolute requirement for ulcer formation. In the absence of acid, no ulcer will form.
- The most common cause of PUD is infection with *H. pylori*. The next most common cause is use of NSAIDs.
- The goal of PUD therapy is to alleviate symptoms, promote healing, prevent complications (hemorrhage, perforation, obstruction), and prevent recurrence.

- The major drugs used to treat PUD are antibiotics, antisecretory agents (H₂RAs, PPIs), and sucralfate, a mucosal protectant.
- With the exception of antibiotics, antiulcer drugs do not alter the disease process; rather, they simply create conditions conducive to healing. Because nonantibiotic therapies do not cure ulcers, the relapse rate is high. In contrast, the relapse rate following successful antibiotic therapy is low.
- All patients with gastric or duodenal ulcers and confirmed infection with *H. pylori* should be treated with antibiotics in combination with an antisecretory agent.
- The antibiotics employed most often are amoxicillin, clarithromycin, bismuth, tetracycline, and metronidazole.
- To avoid resistance and increase efficacy, at least two antibiotics should be used.
- Cimetidine and other H₂RAs suppress secretion of gastric acid by blocking histamine₂ receptors on parietal cells of the stomach.
- Cimetidine inhibits hepatic drug-metabolizing enzymes, and can thereby cause levels of other drugs to rise.
- In contrast to cimetidine, ranitidine has little effect on drug metabolism.
- Proton pump inhibitors (eg, omeprazole, lansoprazole) suppress acid secretion by inhibiting gastric H⁺, K⁺-ATPase, the enzyme that makes gastric acid. PPIs are the most effective inhibitors of acid secretion available.
- Sucralfate promotes ulcer healing by creating a protective barrier against acid and pepsin.
- Misoprostol, an analog of prostaglandin E₁, is used to prevent gastric ulcers caused by NSAIDs.
- Misoprostol stimulates uterine contraction and hence is contraindicated during pregnancy.

78.6.5.3.2

Summary of Major Nursing Implications*

78.6.5.3.2.1

H₂ RECEPTOR ANTAGONISTS

- Cimetidine
- Famotidine
- Nizatidine
- Ranitidine

78.6.5.3.2....

Preadministration Assessment

78.6.5.3.2....

Therapeutic Goal

H₂RAs are used primarily to treat PUD. The objective is to relieve pain, promote healing, prevent ulcer recurrence, and prevent complications.

78.6.5.3.2....

Baseline Data

Definitive diagnosis of PUD requires radiographic or endoscopic visualization of the ulcer and testing for *H. pylori* infection, either by a noninvasive method (urea breath test, stool antigen test, or serologic antibody test) or by an invasive method involving evaluation of a biopsy sample by either (1) staining and viewing under a microscope to see if *H. pylori* is present, (2) assaying for the presence of urease, or (3) culturing and then assaying for the presence of *H. pylori*.

78.6.5.3.2....

Identifying High-Risk Patients

Use H₂RAs with *caution* in patients with renal or hepatic dysfunction.

78.6.5.3.2....

Implementation: Administration

78.6.5.3.2....

Routes

78.6.5.3.2....

Cimetidine and Ranitidine.

Oral, IM, and IV.

78.6.5.3.2....

Famotidine.

Oral and IV.

78.6.5.3.2....

Nizatidine.

Oral only.

78.6.5.3.2....

Administration

78.6.5.3.2....

Oral.

Inform patients that H₂RAs may be taken without regard to meals.

With all H₂RAs, dosing may be done twice daily or once daily at bedtime. With ranitidine, dosing may also be done 4 times a day (with meals and at bedtime).

Make sure the patient knows which dosing schedule has been prescribed.

78.6.5.3.2....

Intramuscular.

Cimetidine and Ranitidine.

Use concentrated solutions for IM injections.

78.6.5.3.2....

Intravenous.

Cimetidine, Famotidine, and Ranitidine.

For IV injection, dilute in a small volume (eg, 20 mL) of 0.9% sodium chloride and inject slowly (over 5 or more minutes). For IV infusion, dilute in a large volume (100 mL) of 0.9% sodium chloride and infuse over 15 to 20 minutes.

78.6.5.3.2....

Implementation: Measures to Enhance Therapeutic Effects

Advise patients to avoid cigarettes and ulcerogenic over-the-counter drugs (aspirin and other NSAIDs). Advise patients to stop drinking alcohol if drinking exacerbates ulcer symptoms. Inform patients that five or six small meals per day may be preferable to three larger ones.

78.6.5.3.2.... Ongoing Evaluation and Interventions

78.6.5.3.2.... Evaluating Therapeutic Effects

78.6.5.3.2.... Ulcer Healing.

Monitor for relief of pain. Radiologic or endoscopic examination of the ulcer site may also be employed. Monitor gastric pH; treatment should increase pH to 5 or above. **Educate patients about signs of GI bleeding (eg, black, tarry stools; “coffee-grounds” vomitus), and instruct them to notify the prescriber if these occur.**

78.6.5.3.2.... *Helicobacter pylori*.

If *H. pylori* was present at the onset of treatment, it may be useful to determine if the infection was eradicated.

78.6.5.3.2.... Minimizing Adverse Effects

78.6.5.3.2.... Antiandrogenic Effects.

Cimetidine can cause gynecomastia, reduced libido, and impotence. These effects reverse after drug withdrawal.

78.6.5.3.2.... CNS Effects.

Cimetidine can cause confusion, hallucinations, lethargy, somnolence, restlessness, and seizures. These responses are most likely in elderly patients who have renal or hepatic impairment. **Inform patients about possible CNS effects and instruct them to notify the prescriber if these occur.** CNS effects are less likely with ranitidine, famotidine, and nizatidine.

78.6.5.3.2.... Pneumonia.

Elevation of gastric pH increases the risk of pneumonia. **Inform patients about signs of respiratory infection and instruct them to inform the prescriber if they occur.**

78.6.5.3.2....	Minimizing Adverse Interactions	
78.6.5.3.2....	Interactions Secondary to Inhibition of Drug Metabolism. <i>Cimetidine</i> inhibits hepatic drug-metabolizing enzymes and can thereby increase levels of other drugs. Drugs of particular concern are <i>warfarin</i>, <i>phenytoin</i>, <i>theophylline</i>, and <i>lidocaine</i>. Dosages of these drugs may need to be reduced. <i>Ranitidine</i> inhibits drug metabolism, but to a lesser degree than <i>cimetidine</i>. <i>Famotidine</i> and <i>nizatidine</i> do not inhibit drug metabolism.	
78.6.5.3.2....	Antacids. Antacids can decrease absorption of <i>cimetidine</i> and <i>ranitidine</i>. At least 1 hour should separate administration of antacids and these drugs.	
78.6.5.3.2.2	PROTON PUMP INHIBITORS Esomeprazole Lansoprazole Omeprazole Pantoprazole Rabeprazole	
78.6.5.3.2....	Preadministration Assessment	
78.6.5.3.2....	Therapeutic Goal PPIs are used primarily to treat PUD. The objective is to relieve pain, promote healing, prevent ulcer recurrence, and prevent complications.	927
78.6.5.3.2....	Baseline Data See <i>Baseline Data</i> for H₂RAs.	928

78.6.5.3.2....

Identifying High-Risk Patients

PPIs are remarkably safe. Their only *contraindication* is hypersensitivity to the drug itself or to a component of the formulation.

78.6.5.3.2....

Implementation: Administration

78.6.5.3.2....

Routes

78.6.5.3.2....

Esomeprazole, Omeprazole, and Rabeprazole.

Oral only.

78.6.5.3.2....

Pantoprazole and Lansoprazole.

Oral and IV.

78.6.5.3.2....

Administration

78.6.5.3.2....

Oral.

Inform patients that capsules and tablets should be swallowed intact—not opened, split, crushed, or chewed.

Instruct patients to take esomeprazole at least 1 hour before a meal, and to take omeprazole or lansoprazole just before eating. Inform patients that pantoprazole and rabeprazole may be taken without regard to food.

78.6.5.3.2....

Intravenous.

For IV therapy (with pantoprazole or lansoprazole), an in-line filter *must* be used to remove any precipitate.

78.6.5.3.2....

Implementation: Measures to Enhance Therapeutic Effects

See nursing implications for H_2 Receptor Antagonists.

78.6.5.3.2....

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

See nursing implications for H_2 Receptor Antagonists.

78.6.5.3.2....

Minimizing Adverse Effects

78.6.5.3.2....

In General.

Adverse effects are uncommon and generally inconsequential.

78.6.5.3.2....

Pneumonia.

Elevation of gastric pH increases the risk of pneumonia. **Inform patients about signs of respiratory infection and instruct them to inform the prescriber if they occur.**

78.6.5.3.2....

Osteoporosis and Fractures.

Long-term, high-dose therapy may pose a risk of osteoporosis and hip fracture. To minimize fracture risk, use the lowest dose needed for the shortest time possible.

Encourage patients to maintain adequate intake of calcium and vitamin D.

78.6.5.3.2....

Minimizing Adverse Interactions

78.6.5.3.2....

Atazanavir, Ketoconazole, and Itraconazole.

PPIs significantly reduce absorption of these three drugs (by elevating gastric pH). Taking atazanavir with PPIs is not recommended.

* Patient education information is highlighted as blue text.

⁷⁹CHAPTER 78 Laxatives

Laxatives are used to ease or stimulate defecation. These agents can soften the stool, increase stool volume, hasten fecal passage through the intestine, and facilitate evacuation from the rectum. When properly employed, laxatives are valuable medications. However, these agents are also subject to abuse. Misuse of laxatives is largely the result of misconceptions about what constitutes normal bowel function.

Before we talk about laxatives, we need to distinguish between two terms: *laxative effect* and *catharsis*. The term *laxative effect* refers to production of a soft, formed stool over a period of 1 or more days. In contrast, the term *catharsis* refers to a prompt, fluid evacuation of the bowel. Hence, a laxative effect is leisurely and relatively mild, whereas catharsis is relatively fast and intense.

^{79.1}GENERAL CONSIDERATIONS

^{79.1.1}Function of the Colon

The principal function of the colon is to absorb water and electrolytes. Absorption of nutrients is minimal. Normally, about 1500 mL of fluid enters the colon each day, and approximately 90% gets absorbed. When the colon is working correctly, the extent of fluid absorption is such that the resulting stool is soft (but formed) and capable of elimination without strain. However, when fluid absorption is excessive, as can happen when transport through the intestine is delayed, the resultant stool is dehydrated and hard. Conversely, if insufficient fluid is absorbed, watery stools result.

Frequency of bowel evacuation varies widely among individuals. For some people, bowel movements occur 2 or 3 times a day. For others, elimination may occur only 2 times a week. Because of this wide individual variation, we can't define a normal frequency for bowel movements. That is, although a daily bowel movement may be normal for many people, it may be abnormal for many others.

^{79.1.2}Dietary Fiber

Proper function of the bowel is highly dependent on dietary fiber—the component of vegetable matter that escapes digestion in the stomach and small intestine. Fiber facilitates colonic function in two ways: (1) it can absorb water, thereby softening the feces and increasing their mass; and (2) it can be digested by colonic bacteria, whose subsequent growth increases fecal mass. The best source of fiber is bran. Fiber can also be obtained from fruits and vegetables. Ingestion of 20 to 60 gm of fiber a day should optimize intestinal function.

TABLE 78-1 Rome II Criteria for Constipation

Adults
Two or more of the following for at least 12 weeks (not necessarily consecutive) in the preceding 12 months:
• Straining during more than 25% of bowel movements • Lumpy or hard stools for more than 25% of bowel movements • Sensation of incomplete evacuation for more than 25% of bowel movements • Sensation of anorectal blockage for more than 25% of bowel movements • Manual maneuvers (eg, digital evacuation; support of the pelvic floor) to facilitate more than 25% of bowel movements • Fewer than three bowel movements per week • Loose stools not present, and insufficient criteria to permit diagnosis of irritable bowel syndrome
Infants and Children
• Pebble-like, hard stools for a majority of bowel movements for at least 2 weeks • Firm stools twice a week or less for at least 2 weeks • No evidence of structural, endocrine, or metabolic disease

79.1.3 Constipation

Constipation is one of the most common GI disorders. In the United States, people seek medical help for constipation at least 2.5 million times a year, and spend hundreds of millions of dollars on laxatives.

Constipation is defined in terms of symptoms, which include hard stools, infrequent stools, excessive straining, prolonged effort, a sense of incomplete evacuation, and unsuccessful defecation. People who do research on constipation usually define it using the Rome II criteria, which are summarized in [Table 78-1](#).

As [Table 78-1](#) indicates, constipation is determined more by stool *consistency* (degree of hardness) than by *how often* bowel movements occur. Hence, if the interval between bowel movements becomes prolonged, but the stool remains soft and hydrated, a diagnosis of constipation would be improper. Conversely, if bowel movements occur with regularity, but the feces are hard and dry, we would consider constipation to be present—despite the regular and frequent passage of stool.

A common cause of constipation is poor diet—specifically, a diet deficient in fiber and fluid. 929

Other causes include dysfunction of the pelvic floor and anal sphincter, slow intestinal transit, and 930
use of certain drugs (eg, opioids, anticholinergics, some antacids).

TABLE 78-2 Classification of Laxatives by Pharmacologic Category

Class and Agent	Site of Action	Mechanism of Action
Bulk-Forming Laxatives		
Methylcellulose	Small intestine and colon	Absorb water, thereby softening and enlarging the fecal mass; fecal swelling promotes peristalsis
Psyllium		
Polycarbophil		
Surfactant Laxatives		
Docusate sodium	Small intestine and colon	Surfactant action softens stool by facilitating penetration of water; also cause secretion of water and electrolytes into intestine
Docusate calcium		
Stimulant Laxatives		
Bisacodyl	Colon	(1) Stimulate peristalsis and (2) soften feces by increasing secretion of water and electrolytes into the intestine and decreasing water and electrolyte absorption
Senna	Colon	
Castor oil	Small intestine	
Osmotic Laxatives		
Magnesium hydroxide	Small intestine and colon	Osmotic action retains water and thereby softens the feces; fecal swelling promotes peristalsis
Magnesium sulfate		
Magnesium citrate		
Sodium phosphate		
Polyethylene glycol		
Miscellaneous Laxatives		
Lubiprostone	Small intestine and colon	Opens chloride channels in the intestinal epithelium and thereby increases intestinal motility and secretion of fluid into the lumen
Mineral oil	Colon	Lubricates and reduces water absorption
Glycerin suppository	Colon	Lubricates and causes reflex rectal contraction
Lactulose	Colon	Similar to osmotic laxatives
Polyethylene glycol–electrolyte solution	Small intestine and colon	Similar to osmotic laxatives

In most cases, constipation can be readily corrected. Stools will become softer and more easily passed within days of increasing fiber and fluid in the diet. Mild exercise, especially after meals, also helps improve bowel function. If necessary, a laxative may be employed—but only briefly and only as an adjunct to diet and exercise.

79.1.4 Indications for Laxative Use

Laxatives can be highly beneficial when employed for valid indications. By softening the stool, laxatives can reduce the painful elimination that can be associated with episiotomy and with hemorrhoids and other anorectal lesions. In patients with cardiovascular diseases (eg, aneurysm, myocardial infarction, disease of the cerebral or cardiac vasculature), softening the stool decreases the amount of strain needed to defecate, thereby avoiding dangerous elevation of blood pressure. In elderly patients, laxatives can help compensate for loss of tone in abdominal and perineal muscles. As an adjunct to anthelmintic therapy, laxatives can be used for (1) obtaining a fresh stool sample for diagnosis; (2) emptying the bowel prior to treatment (so as to increase parasitic exposure to anthelmintic medication); and (3) facilitating export of dead parasites following anthelmintic use. Additional applications include (1) emptying of the bowel prior to surgery and diagnostic procedures (eg, radiologic examination, sigmoidoscopy); (2) modifying the effluent from an ileostomy or colostomy; (3) preventing fecal impaction in bedridden patients; (4) removing ingested poisons; and (5) correcting constipation associated with pregnancy and certain drugs (eg, opioid analgesics).

79.1.5 Precautions and Contraindications to Laxative Use

Laxatives are contraindicated for individuals with certain disorders of the bowel. Specifically, laxatives must be avoided by individuals experiencing abdominal pain, nausea, cramps, or other symptoms of appendicitis, regional enteritis, diverticulitis, and ulcerative colitis. Laxatives are also contraindicated for patients with acute surgical abdomen. In addition, laxatives should not be used in patients with fecal impaction or obstruction of the bowel, because increased peristalsis could cause bowel perforation. Lastly, laxatives should not be employed habitually for the treatment of constipation. Reasons why are discussed below under *Laxative Abuse*.

Laxatives should be used with caution during pregnancy (because GI stimulation might induce labor) and during lactation (because the laxative may be excreted in breast milk).

930

TABLE 78-3 Classification of Laxatives by Therapeutic Response

Group I: Produce Watery Stool in 2–6 Hr	Group II: Produce Semifluid Stool in 6–12 Hr	Group III: Produce Soft Stool in 1–3 Days
Osmotic Laxatives (in High Doses)	Osmotic Laxatives (in Low Doses)	Bulk-Forming Laxatives
Magnesium salts	Magnesium salts	Methylcellulose
Sodium salts	Sodium salts	Psyllium
	Polyethylene glycol	Polycarbophil
Others	Stimulant Laxatives (Except Castor Oil)	Surfactant Laxatives
Castor oil	Bisacodyl, oral*	Docusate sodium
Polyethylene glycol–electrolyte solution	Senna	Docusate calcium
		Others
		Lactulose
		Lubiprostone

* Bisacodyl suppositories act in 15 minutes.

79.1.6 Laxative Classification Schemes

Traditionally, laxatives have been classified according to general *mechanism of action*. This scheme has four major categories: (1) bulk-forming laxatives, (2) surfactant laxatives, (3) stimulant laxatives, and (4) osmotic laxatives. Drugs representing these classes are listed in [Table 78-2](#).

From a clinical perspective, it can be helpful to classify laxatives according to *therapeutic effect* (time of onset and impact on stool consistency). When these properties are considered, most laxatives fall into one of three groups (labeled I, II, and III in this chapter). Group I agents act rapidly (within 2 to 6 hours) and give a watery consistency to the stool. Laxatives in group I are especially useful when preparing the bowel for diagnostic procedures or surgery. Group II agents have an intermediate latency (6 to 12 hours) and produce a stool that is semifluid. Group II agents are the ones most frequently abused by the general public. Group III laxatives act slowly (in 1 to 3 days) to produce a soft but formed stool. Uses for this group include treating constipation and preventing straining at stool. Representative members of groups I, II, and III are listed in [Table 78-3](#).

79.2 BASIC PHARMACOLOGY OF LAXATIVES

79.2.1 Bulk-Forming Laxatives

The bulk-forming laxatives (eg, methylcellulose, psyllium, polycarbophil) have actions and effects much like those of dietary fiber. These agents consist of natural or semisynthetic polysaccharides and celluloses derived from grains and other plant material. With regard to clinical response, the bulk-forming agents belong to group III: They produce a soft, formed stool 1 to 3 days after the onset of treatment.

79.2.1.1 Mechanism of Action.

Bulk-forming agents have the same impact on bowel function as dietary fiber. Following ingestion, these agents, which are nondigestible and nonabsorbable, swell in water to form a viscous solution or gel, thereby softening the fecal mass and increasing its bulk. Fecal volume may be further enlarged by growth of colonic bacteria, which can utilize these materials as nutrients. Transit through the intestine is hastened because swelling of the fecal mass stretches the intestinal wall, thereby stimulating peristalsis.

79.2.1.2 Indications.

Bulk-forming laxatives are preferred agents for temporary treatment of constipation. Also, they are widely used in patients with diverticulosis and irritable bowel syndrome. In addition, by altering fecal consistency, they can provide symptomatic relief of diarrhea and can reduce discomfort and inconvenience for patients with an ileostomy or colostomy.

79.2.1.3 Adverse Effects.

Untoward effects are minimal. Because the bulk-forming agents are not absorbed, systemic reactions are rare. *Esophageal obstruction* can occur if they are swallowed in the absence of sufficient fluid. Accordingly, bulk-forming laxatives should be administered with a full glass of water or juice. If their passage through the intestine is arrested, they may produce *intestinal obstruction* or *impaction*. Accordingly, they should be avoided if there is narrowing of the intestinal lumen.

79.2.1.4 Preparations, Dosage, and Administration.

Psyllium (prepared from *Plantago* seed), *methylcellulose*, and *polycarbophil* are the principal bulk-forming laxatives. All three preparations should be administered with a full glass of water or juice. Dosages and trade names are presented in [Table 78-4](#).

79.2.2 Surfactant Laxatives

79.2.2.1 Actions.

The surfactants (eg, docusate sodium) are group III laxatives: They produce a soft stool several days after the onset of treatment. Surfactants alter stool consistency by lowering surface tension, which facilitates penetration of water into the feces. The surfactants may also act on the intestinal wall to (1) inhibit fluid absorption and (2) stimulate secretion of water and electrolytes into the intestinal lumen. In this respect, surfactants resemble the stimulant laxatives (see below).

79.2.2.2 Preparations, Dosage, and Administration.

The surfactant family consists of two *docusate salts*: docusate sodium and docusate calcium. The dosage for docusate sodium [Colace, others], the prototype surfactant, is presented in [Table 78-4](#). Administration should be accompanied by a full glass of water.

931

TABLE 78-4 Representative Laxatives: Trade Names, Dosage Forms, and Dosages

Drug Class and Generic Name	Trade Name	Dosage Forms	Dosage and Administration
Bulk-Forming			
Methylcellulose	Citrucel	Powder	<i>Powder:</i> 1 heaping tbsp in 8 oz cold water 1–3 times a day
Psyllium	Metamucil, others	Powder, wafer	<i>Adults:</i> 1 rounded tsp (or 1 packet) mixed with water or other fluid, taken 1–3 times daily <i>Children over 6 yr:</i> one-third to one-half adult dose
Polycarbophil	FiberCon	Tablets	<i>Adults:</i> 1 gm 1–4 times a day <i>Children 6–12 yr:</i> 500 mg 1–4 times a day
Surfactant			
Docusate sodium	Colace, others	Capsules, tablets, syrup, liquid	<i>Adults and children over 12 yr:</i> 50–500 mg/day <i>Children 6–12 yr:</i> 40–150 mg/day (All doses taken with a full glass of water)
Stimulant			
Bisacodyl	Correctol, Dulcolax, Feen-a-mint, Fleet Laxative, others	Tablets, suppositories	<i>Adults:</i> 10–15 mg (tablets) or 10-mg suppository once daily <i>Children:</i> 5-mg tablet or 5-mg suppository once daily
Senna	Senokot, ex-lax, others	Tablets	<i>Adults:</i> 2 tablets once or twice a day <i>Children 6–12 yr:</i> 1 tablet once or twice a day
Osmotic			
Magnesium hydroxide (milk of magnesia)	Phillips' Milk of Magnesia, others	Liquid	<i>Low dose:</i> 15–30 mL <i>High dose:</i> 30–60 mL
Polyethylene glycol	MiraLax	Powder	<i>Adults:</i> 17 gm (dissolved in 4 to 8 oz of water, juice, soda, coffee, or tea) once a day
Sodium phosphate	Fleet Phospho-Soda	Liquid	<i>Adults:</i> 20–45 mL/day <i>Children 10–11 yr:</i> 10–20 mL/day <i>Children 5–9 yr:</i> 5–10 mL/day

Other			
Lubiprostone	Amitiza generic only	Capsule	<i>Adults:</i> 24 mcg twice a day with food
Mineral oil		Liquid	<i>Adults:</i> 45 mL PO twice a day <i>Children:</i> 5–20 mL PO at bedtime

79.2.3 Stimulant Laxatives

The stimulant laxatives (eg, bisacodyl, castor oil) have two effects on the bowel. First, they stimulate intestinal motility—hence their name. Second, they increase the amount of water and electrolytes within the intestinal lumen. How? By increasing secretion of water and ions into the intestine, and by reducing water and electrolyte absorption. Most stimulant laxatives are group II agents: They act on the colon, producing a semifluid stool within 6 to 12 hours.

Stimulant laxatives are widely used—and abused—by the general public, and are of concern for this reason. They have few legitimate applications. Two applications that *are* legitimate are (1) treatment of opioid-induced constipation and (2) treatment of constipation resulting from slow intestinal transit. Properties of individual agents are discussed below.

79.2.3.1 Bisacodyl.

Bisacodyl [Correctol, Dulcolax, Feen-a-mint, others] is unique among the stimulant laxatives in that it can be administered by rectal suppository as well as by mouth. *Oral* bisacodyl acts within 6 to 12 hours. Hence, tablets may be given at bedtime to produce a response the following morning. Bisacodyl *suppositories* act rapidly (in 15 to 60 minutes). Dosages for bisacodyl are presented in [Table 78-4](#).

Bisacodyl tablets are enteric coated to prevent gastric irritation. Accordingly, patients should be advised to swallow them intact, without chewing or crushing. Because milk and antacids accelerate dissolution of the enteric coating, the tablets should be administered no sooner than 1 hour after ingesting these substances. 932
933

Bisacodyl suppositories may cause a burning sensation and, with continued use, proctitis may develop. Accordingly, long-term use should be discouraged.

79.2.3.2 Senna.

Senna [Senokot, ex-lax, others] is a plant-derived laxative that contains *anthraquinones* as active ingredients. The actions and applications of senna are similar to those of bisacodyl. Anthraquinones act on the colon to produce a soft or semifluid stool in 6 to 12 hours. Systemic

absorption followed by renal secretion may impart a harmless yellowish-brown or pink color to the urine. Dosages for senna are presented in [Table 78-4](#).

79.2.3.3 Castor Oil.

Castor oil is the only stimulant laxative that acts on the *small intestine*. As a result, the drug acts quickly (in 2 to 6 hours) to produce a watery stool. Hence, unlike other stimulant laxatives, which are all group II agents, castor oil belongs to group I. Use of castor oil is limited to situations in which rapid and thorough evacuation of the bowel is desired (eg, preparation for radiologic procedures). The drug is far too powerful for routine treatment of constipation. Because of its relatively prompt action, castor oil should not be administered at bedtime. The drug has an unpleasant taste that can be improved by chilling and mixing with fruit juice.

79.2.3.4 Phenolphthalein.

Phenolphthalein is similar in structure and actions to bisacodyl. This agent acts on the colon to produce a semifluid stool in 6 to 8 hours. Because phenolphthalein undergoes enterohepatic recirculation, effects may persist for 3 to 4 days. The drug can impart a harmless pink tint to the urine.

Phenolphthalein can cause *cancer*. Mice given 30 to 100 times the daily human dose for 6 months to 2 years developed a variety of tumors. Genetic damage was also observed. Although there is no evidence that phenolphthalein causes cancer in humans, a Food and Drug Administration (FDA) advisory panel has recommended banning the drug from over-the-counter (OTC) sales. In response to this recommendation, makers of brand-name laxatives that once contained phenolphthalein have replaced the compound with other stimulant agents. For example, Ex-Lax now contains senna, while Feen-a-mint and Correctol now contain bisacodyl.

79.2.4 Osmotic Laxatives

79.2.4.1 Laxative Salts

79.2.4.1.1 Actions and Uses.

The laxative salts (eg, magnesium hydroxide, sodium phosphate) are poorly absorbed salts whose osmotic action draws water into the intestinal lumen. Accumulation of water causes the fecal mass to soften and swell, thereby stretching the intestinal wall, which stimulates peristalsis. When administered in low doses, the osmotic laxatives produce a soft or semifluid stool in 6 to 12 hours. In high doses, these agents act rapidly (in 2 to 6 hours) to cause a fluid evacuation of the bowel. High-dose therapy is employed to empty the bowel in preparation for

diagnostic and surgical procedures. High doses are also employed to purge the bowel of ingested poisons, and to evacuate dead parasites following anthelmintic therapy.

79.2.4.1.2 Preparations.

We have two groups of laxative salts: (1) *magnesium salts* (magnesium hydroxide, magnesium citrate, and magnesium sulfate), and (2) one *sodium salt* (sodium phosphate). Dosages for magnesium hydroxide solution (also known as milk of magnesia) and sodium phosphate are presented in [Table 78-4](#).

79.2.4.1.3 Adverse Effects.

Osmotic laxatives can cause substantial *loss of water*. To avoid dehydration, patients should increase fluid intake. Although the osmotic laxatives are poorly and slowly absorbed, some absorption does take place. In patients with renal dysfunction, *magnesium can accumulate to toxic levels*. Accordingly, magnesium salts are contraindicated in patients with kidney disease. Sodium absorption (from sodium phosphate) can cause *fluid retention*, which in turn can exacerbate heart failure, hypertension, and edema. Accordingly, sodium phosphate is contraindicated for patients with these disorders. Sodium phosphate can also cause *acute renal failure* in vulnerable patients, especially those with kidney disease and those taking drugs that alter renal function (eg, diuretics, angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs]). The mechanism involves dehydration and precipitation of calcium and phosphate in renal tubules. Accordingly, sodium phosphate should be avoided in this vulnerable group.

79.2.4.2 Polyethylene Glycol

Polyethylene glycol [MiraLax] is an osmotic laxative indicated for occasional constipation. Like the laxative salts, this nonabsorbable compound retains water in the intestinal lumen, causing the fecal mass to soften and swell. The most common adverse effects are nausea, abdominal bloating, cramping, and flatulence. High doses may cause diarrhea. The recommended dosage is 17 gm once a day, dissolved in 4 to 8 ounces of water, juice, soda, coffee, or tea. Bowel movement may not occur for another 2 to 4 days.

79.2.5 Miscellaneous Laxatives

79.2.5.1 Lubiprostone.

Lubiprostone [Amitiza] is the first representative of a new class of drugs: the selective *chloride channel activators*. By activating (opening) chloride channels in epithelial cells lining the

intestine, lubiprostone (1) promotes secretion of chloride-rich fluid into the intestine and (2) enhances motility in the small intestine and colon. The result is spontaneous evacuation of a semisoft stool, usually within 24 hours. Lubiprostone has two indications: (1) chronic idiopathic constipation in adults and (2) irritable bowel syndrome with constipation (IBS-C) in women at least 18 years old. In clinical trials, the drug reduced constipation severity, abdominal bloating, and discomfort. Lubiprostone is taken orally, and very little is absorbed. Nausea is the most common side effect (30%) and can be reduced by taking lubiprostone with food and water. Other GI effects include diarrhea (13.2%), abdominal distention (7.1%), abdominal pain (6.7%), gas (6.1%), vomiting (4.6%), and loose stools (3.4%). Headache (13.2%) is the major non-GI effect. About 2.4% of patients experience difficulty breathing in association with a sense of tightness in the chest, starting 30 to 60 minutes after the first dose and resolving in a few hours. Lubiprostone is categorized in FDA Pregnancy Category C, and hence should be used only if benefits are deemed to outweigh potential risks to the fetus. (In animal studies, lubiprostone was not teratogenic. However, when given to guinea pigs in doses more than 100 times the human dose, lubiprostone did cause fetal loss.) Interactions with other drugs have not been studied, but seem unlikely. Why? Because lubiprostone is poorly absorbed and does not alter the activity of cytochrome P450 drug-metabolizing enzymes. Lubiprostone is available in 8- and 24-mcg soft-gelatin capsules that should be taken with food and water. The recommended dosage is 24 mcg twice daily for constipation and 8 mcg twice daily for IBS-C.

933

934

79.2.5.2 Mineral Oil.

Mineral oil is a mixture of indigestible and poorly absorbed hydrocarbons. Laxative action is produced by lubrication. Mineral oil is especially useful when administered by enema to treat fecal impaction.

Mineral oil can produce a variety of adverse effects. Aspiration of oil droplets can cause lipid pneumonia. Anal leakage can cause pruritus and soiling. Systemic absorption can produce deposition of mineral oil in the liver. Excessive dosing can decrease absorption of fat-soluble vitamins. Dosages for adults and children are presented in [Table 78-4](#).

79.2.5.3 Lactulose.

Lactulose is a semisynthetic disaccharide composed of galactose and fructose. Lactulose is poorly absorbed and cannot be digested by intestinal enzymes. In the colon, resident bacteria metabolize lactulose to lactic acid, formic acid, and acetic acid. These acids exert a mild osmotic action, producing a soft, formed stool in 1 to 3 days. Although lactulose can relieve constipation, this agent is more expensive than equivalent drugs (bulk-forming laxatives) and also causes unpleasant side effects (flatulence and cramping are common). Accordingly,

lactulose should be reserved for patients who do not respond adequately to bulk-forming laxatives.

In addition to its laxative action, lactulose can enhance intestinal excretion of ammonia. This property has been exploited to lower blood ammonia content in patients with portal hypertension and hepatic encephalopathy secondary to chronic liver disease.

79.2.5.4 Glycerin Suppository.

Glycerin is an osmotic agent that softens and lubricates inspissated (hardened, impacted) feces. The drug may also stimulate rectal contraction. Evacuation occurs about 30 minutes after suppository insertion. Glycerin suppositories have been useful for re-establishing normal bowel function following termination of chronic laxative use.

79.2.5.5 Polyethylene Glycol–Electrolyte Solutions.

These bowel-cleansing solutions [CoLyte, GoLYTELY, others] contain a mixture of polyethylene glycol (a nonabsorbable osmotic agent) together with potassium chloride, sodium chloride, sodium sulfate, and sodium bicarbonate. The mixture is isosmotic with body fluids, and its composition is such that water and electrolytes are neither absorbed from nor secreted into the intestinal lumen. Hence, water is not lost and electrolyte balance is preserved. As a result, polyethylene glycol–electrolyte solutions can be used safely in patients who are dehydrated and in those who are especially sensitive to alterations in electrolyte levels (eg, patients with renal impairment or cardiovascular disease). These preparations are indicated primarily for cleansing the bowel prior to diagnostic procedures. The administered volume is huge (about 4 L). Patients must ingest 250 to 300 mL every 10 minutes for 2 to 3 hours. Bowel movements commence about 1 hour after initiating treatment.

79.3 LAXATIVE ABUSE

79.3.1 Causes.

Many people believe that a daily and bountiful bowel movement is a requisite of good health, and that any deviation from this pattern merits correction. Such misconceptions are reinforced by aggressive marketing of OTC laxative preparations. Not infrequently, the combination of tradition supported by advertising has led to habitual self-prescribing of laxatives by people who don't need them.

Laxatives can help perpetuate their own use. Strong laxatives can purge the entire bowel. When this occurs, spontaneous evacuation is impossible until bowel content has been replenished, which can take 2 to 5 days. During this time, the laxative user, having experienced no movement of the

bowel, often becomes convinced that constipation has returned. In response, he or she takes yet another dose, which purges the bowel once more, and thereby sets the stage for a repeating cycle of laxative use and purging.

79.3.2 Consequences.

Chronic exposure to laxatives can diminish defecatory reflexes, leading to further reliance on laxatives. Laxative abuse may also cause more serious pathologic changes, including electrolyte imbalance, dehydration, and colitis.

79.3.3 Treatment.

The first step in breaking the laxative habit is abrupt cessation of laxative use. Following drug withdrawal, bowel movements will be absent for several days; the patient should be informed of this fact. Any misconceptions that the patient has regarding bowel function should be corrected: The patient should be taught that a once-daily bowel movement may not be normal for him or her and that stool *quality* is more important than frequency or quantity. Instruction on bowel training (heeding the defecatory reflex, establishing a consistent time for bowel movements) should be provided. Increased consumption of fiber (bran, fruits, vegetables) and fluid should be stressed. The patient should be encouraged to exercise daily, especially after meals. Finally, the patient should be advised that, if a laxative must be used, it should be used briefly and in the smallest effective dose. Agents that produce catharsis must be avoided.

79.3.3.1

KEY POINTS

- Laxatives promote defecation.
- Constipation is defined primarily by stool consistency, not by frequency or volume of bowel movements.
- Legitimate indications for laxatives include cardiovascular disorders, episiotomy, hemorrhoids, emptying the bowel before surgery and diagnostic procedures, ileostomy or colostomy, prevention of fecal impaction in bedridden patients, and constipation associated with pregnancy and certain drugs, such as opioid analgesics.
- Like dietary fiber, bulk-forming laxatives swell in water to form a viscous solution or gel, thereby softening the feces and increasing fecal mass. Increased mass stretches the bowel wall, and thereby stimulates peristalsis.
- Administer bulk-forming laxatives with fluid to avoid esophageal obstruction.

- Patients receiving osmotic laxatives must increase fluid intake to avoid dehydration.
- Because of their relatively rapid onset, group I laxatives (castor oil, high-dose osmotic agents) should not be given at bedtime.
- Laxatives—especially the stimulant type—are commonly misused (abused) by the public. To reduce abuse, educate patients about normal bowel function and about alternatives to laxatives (diet high in fiber and fluids, exercise, establishing regular bowel habits).

934

79.3.3.2

Summary of Major Nursing Implications*

935

79.3.3.2.1

LAXATIVES

79.3.3.2...

Implications That Apply to All Laxatives

79.3.3.2...

Identifying High-Risk Patients

Laxatives are *contraindicated* for individuals with abdominal pain, nausea, cramps, and other symptoms of appendicitis, regional enteritis, diverticulitis, and ulcerative colitis. Laxatives are also *contraindicated* for patients with acute surgical abdomen, fecal impaction, and obstruction of the bowel.

Laxatives should be used with *caution* during pregnancy and lactation.

79.3.3.2...

Reducing Laxative Abuse

Patient education is a key factor in reducing laxative abuse. **Educate patients about normal bowel function to correct misconceptions, and provide instruction on establishing good bowel habits (heeding the defecatory reflex, establishing a consistent time for bowel movements). Advise patients to exercise—especially after meals—and to increase consumption of fluids and fiber (bran, fruits, vegetables). Inform patients that laxatives should be used only when clearly necessary and then only briefly in the lowest effective dosage. Warn patients against using cathartics.**

79.3.3.2... Implications That Apply to Specific Laxatives

79.3.3.2... Bulk-Forming Laxatives: Psyllium, Methylcellulose, and Polycarbophil

Instruct patients to take bulk-forming agents with a full glass of water or juice to prevent esophageal obstruction.

Bulk-forming laxatives are *contraindicated* for individuals with narrowing of the intestinal lumen, a condition that increases the risk of intestinal obstruction and impaction.

79.3.3.2... Surfactants: Docusate Salts

Instruct patients to take surfactant agents with a full glass of water.

79.3.3.2... Stimulant Laxatives

Stimulant agents are the laxatives most commonly abused by the general public.

Discourage patients from inappropriate use of these drugs. These drugs are commonly—and appropriately—used to manage opioid-induced constipation.

79.3.3.2... Bisacodyl.

Administer PO and by rectal suppository. **Instruct patients to take oral bisacodyl no sooner than 1 hour after ingesting milk or antacids. Instruct patients to swallow the tablets intact, without crushing or chewing.**

Inform patients that bisacodyl suppositories may cause a burning sensation, and warn them that prolonged use can cause proctitis.

79.3.3.2... Senna.

Inform patients that senna can impart a harmless yellowish-brown or pink color to urine.

79.3.3.2... Castor Oil.

Castor oil acts rapidly (in 2 to 6 hours); do not administer at bedtime. **Advise patients not to take castor oil late at night. Warn patients that castor oil is a powerful**

laxative and should not be used to treat routine constipation. Administer in chilled fruit juice to improve palatability.

79.3.3.2...

Osmotic Laxatives: Magnesium Salts and Sodium Salts

Effects are dose dependent. Low doses produce a soft or semifluid stool in 6 to 12 hours. Higher doses cause watery evacuation of the bowel in 2 to 6 hours.

To prevent dehydration, increase fluid intake during treatment.

Magnesium salts are contraindicated for patients with *renal dysfunction*.

Sodium phosphate is contraindicated for patients with *heart failure*, *hypertension*, or *edema*, and should be used with caution, if at all, by patients with kidney disease and by those taking drugs that alter renal function (eg, diuretics, ACE inhibitors, ARBs).

* Patient education information is highlighted as blue text.

⁸⁰CHAPTER 79 Other Gastrointestinal Drugs

In this chapter we discuss an assortment of GI drugs whose indications range from emesis to colitis to hemorrhoids. Four groups are emphasized: (1) antiemetics, (2) antidiarrheals, (3) drugs for irritable bowel syndrome, and (4) drugs for inflammatory bowel disease.

^{80.1} ANTIEMETICS

Antiemetics are given to suppress nausea and vomiting. We begin our discussion by reviewing the emetic response. Next we discuss the major antiemetic classes. We finish by considering the most important application of these drugs: management of chemotherapy-induced nausea and vomiting (CINV).

^{80.1.1} The Emetic Response

Emesis is a complex reflex brought about by activation of the vomiting center, a nucleus of neurons located in the medulla oblongata. Some stimuli activate the vomiting center directly; others act indirectly ([Fig. 79-1](#)). Direct-acting stimuli include signals from the cerebral cortex (anticipation or fear), signals from sensory organs (upsetting sights, noxious odors, or pain), and signals from the vestibular apparatus of the inner ear. Indirect-acting stimuli first activate the chemoreceptor trigger zone (CTZ), which in turn activates the vomiting center. Activation of the CTZ occurs in two ways: (1) by signals from the stomach and small intestine (traveling along vagal

Figure 79-1 The emetic response: stimuli, pathways, and receptors.
(CTZ = chemoreceptor trigger zone.)

afferents); and (2) by the direct action of emetogenic compounds (eg, anticancer drugs, opioids, ipecac) that are carried to the CTZ in the blood. Once activated, the vomiting center signals the stomach, diaphragm, and abdominal muscles; the resulting coordinated response expels gastric contents.

Several types of receptors are involved in the emetic response. Important among these are receptors for serotonin, glucocorticoids, substance P, neurokinin₁, dopamine, acetylcholine, and histamine. Many antiemetics, including ondansetron [Zofran], dexamethasone [Decadron], aprepitant [Emend], prochlorperazine [Compazine], and dimenhydrinate [Dramamine], act by blocking (or activating) one or more of these receptors.

936

80.1.2 Antiemetic Drugs

937

Several types of antiemetics are available. Their classes, trade names, and dosages are summarized in [Table 79-1](#). Uses and mechanisms are summarized in [Table 79-2](#). Properties of the principal classes are discussed below.

80.1.2.1 Serotonin Receptor Antagonists

The serotonin receptor antagonists are the most effective drugs available for suppressing nausea and vomiting caused by cisplatin and other highly emetogenic anticancer drugs. These agents are also used to suppress nausea and vomiting associated with radiation therapy and anesthesia. Four serotonin antagonists are available for treating emesis: ondansetron, granisetron, dolasetron, and palonosetron.

80.1.2.2 Ondansetron.

Ondansetron [Zofran] was the first serotonin receptor antagonist approved for CINV. The drug is also used to prevent nausea and vomiting associated with radiotherapy and anesthesia. In all cases, benefits derive from blocking type 3 serotonin receptors (5-HT₃ receptors^{*}) located in the CTZ and on afferent vagal neurons in the upper GI tract. The drug is very effective by itself, and even more effective when combined with dexamethasone. Administration may be oral or parenteral. The most common side effects are headache, diarrhea, and dizziness. Since ondansetron does not block dopamine receptors, it does not cause the extrapyramidal effects (eg, akathisia, acute dystonia) seen with antiemetic phenothiazines. As discussed in [Chapter 38](#), ondansetron is under investigation for treating early-onset alcoholism.

937

938

TABLE 79-1 Antiemetic Drugs: Classes, Trade Names, and Dosages

Class and Generic Name	Trade Name	Adult Dosage
Serotonin Antagonists		
Ondansetron	Zofran	See text
Granisetron	Granisol, Kytril, Sancuso	See text
Dolasetron	Anzemet	See text
Palonosetron	Aloxi	See text
Glucocorticoids		
Dexamethasone	Decadron	10–20 mg (IV) before chemotherapy, then 4–8 mg
Methylprednisolone	Solu-Medrol	2 doses of 125–500 mg (IV) 6 hr apart before chemotherapy
Substance P/Neurokinin₁ Antagonists		
Aprepitant	Emend	125 mg PO on day 1, then 80 mg PO on days 2 and 3
Fosaprepitant	Emend	115 mg IV, used in place of the first (125-mg) dose of aprepitant in the regimen above
Benzodiazepines		
Lorazepam	Ativan	1–1.5 mg (IV) before chemotherapy
Diazepam	Valium	2–5 mg (PO) every 3 hr
Dopamine Antagonists		
Phenothiazines		
Chlorpromazine	Thorazine	10–25 mg (PO, IM, IV) every 4–6 hr PRN
Perphenazine	Trilafon	8–30 mg/day in divided doses (PO, IM, IV)
Prochlorperazine	Compazine	5–10 mg (PO, IM, IV) 3–4 times a day PRN
Promethazine*	Phenergan	12.5–25 mg (PO, IM, IV) every 4–6 hr
Butyrophenones		
Haloperidol	Haldol	1–5 mg (PO, IM, IV) every 12 hr PRN
Droperidol	Inapsine	2.5–5 mg (IM, IV) every 4–6 hr PRN
Others		
Metoclopramide†	Reglan	See Table 79-3

Pharmacology for Nursing Care, 7th Edition

Domperidone	Motilium	10-20 mg PO every 6-8 hr
Cannabinoids		
Dronabinol	Marinol	5 mg/m ² (PO) every 4–6 hr PRN
Nabilone	Cesamet	1–2 mg (PO) twice daily
Anticholinergics		
Antihistamines		
Cyclizine	Marezine	50 mg (PO, IM) every 4–6 hr PRN
Dimenhydrinate	Dramamine	50–100 mg (PO, IM, IV) every 4–6 hr PRN
Diphenhydramine	Benadryl	10–50 mg (PO, IM, IV) every 4–6 hr PRN
Hydroxyzine	Vistaril, Atarax	25–100 mg (PO, IM) every 6 hr PRN
Meclizine	Bonine, Antivert	25–50 mg (PO) every 24 hr PRN
Others		
Scopolamine	Transderm Scop	0.5 mg (transdermal) every 72 hr PRN
	Scopace	0.4-0.8 mg PO every 8 hr PRN

* Promethazine is contraindicated for children under 2 years of age owing to a risk of fatal respiratory depression.

† Also blocks serotonin receptors.

TABLE 79-2 Antiemetic Drugs: Uses and Mechanism of Action

Class	Prototype	Antiemetic Use	Mechanism of Antiemetic Action
Serotonin antagonists	Ondansetron [Zofran]	Chemotherapy, radiation, postoperative	Blocks serotonin receptors on vagal afferents and in the CTZ
Glucocorticoids	Dexamethasone [Decadron]	Chemotherapy	Unknown
Substance P/neurokinin ₁ antagonists	Aprepitant [Emend]	Chemotherapy	Blocks receptors for substance P/neurokinin ₁ in the brain
Dopamine antagonists	Prochlorperazine [Compazine]	Chemotherapy, post-operative, general	Blocks dopamine receptors in the CTZ
Cannabinoids	Dronabinol [Marinol]	Chemotherapy	Unknown, but probably activate cannabinoid receptors associated with the vomiting center
Anticholinergics	Scopolamine [Transderm Scop]	Motion sickness	Blocks muscarinic receptors in the pathway from the inner ear to the vomiting center
Antihistamines	Dimenhydrinate [Dramamine]	Motion sickness	Blocks H ₁ receptors and muscarinic receptors in the pathway from the inner ear to the vomiting center

Administration is PO or IV. For prevention of CINV, the initial IV dose is 0.15 mg/kg infused slowly (over 15 minutes) beginning 30 minutes before chemotherapy; this dose is repeated 4 and 8 hours later. Alternatively, ondansetron can be given as a single 32-mg IV dose. The dosage for patients undergoing radiation therapy is 8 mg (tablets or oral solution) 3 times a day. The dosage for postoperative nausea and vomiting is 16 mg (tablets or oral solution) 1 hour before induction of anesthesia.

* Serotonin is also known as 5-hydroxytryptamine (5-HT). Hence the abbreviation *5-HT₃* for type 3 serotonin receptors.

80.1.2.3 Granisetron.

Like ondansetron, granisetron [Granisol, Kytril, Sancuso] suppresses emesis by blocking 5-HT₃ receptors on afferent vagal neurons and in the CTZ. The drug is approved for preventing nausea and vomiting associated with cancer chemotherapy, radiation therapy, and surgery. Principal adverse effects are headache (responsive to acetaminophen), weakness, tiredness, and either diarrhea or constipation. Administration is PO, IV, or transdermal. The recommended dosage

for CINV is either (1) 10 mcg/kg IV infused over 5 minutes, starting 30 minutes before chemotherapy, or (2) a single transdermal patch [Sancuso] applied 24 to 48 hrs before chemotherapy, and removed 24 hrs after chemotherapy is over (but no more than 7 days after application). The dosage for patients undergoing radiation therapy is 2 mg (tablets or oral solution) once daily given within 1 hour of radiation treatment. The dosage for preventing postoperative nausea and vomiting is 1 mg IV injected slowly (over 30 seconds) either prior to induction of anesthesia or just before reversing anesthesia.

80.1.2.4 Dolasetron.

Dolasetron [Anzemet] is approved for CINV and postoperative nausea and vomiting. Administration is PO or IV. Side effects are like those of other serotonin antagonists. The recommended dosage for CINV in adults is 100 mg PO 1 hour before chemotherapy or 1.8 mg/kg IV 30 minutes before chemotherapy. The dosage to prevent postoperative nausea and vomiting is 100 mg PO 2 hours before anesthesia or 12.5 mg IV 15 minutes before anesthesia is stopped. Dolasetron has been used investigationally to suppress nausea and vomiting associated with radiation therapy. The IV dosage for adults is 40 mg or 0.3 mg/kg.

80.1.2.5 Palonosetron.

Palonosetron [Aloxi], indicated for CINV and postoperative nausea and vomiting, has the same mechanism, efficacy, and side effects as other serotonin antagonists, but differs from the others in two clinically significant ways. First, palonosetron has a much longer half-life (40 hours versus about 8 hours). Second, because of its long half-life, palonosetron is effective against *delayed* emesis (as well as acute emesis), whereas the others are most effective against acute emesis. Palonosetron also has much greater affinity for 5-HT₃ receptors than do the other serotonin antagonists, but this difference does not appear to have clinical significance. The recommended dosage for CINV in adults is 0.5 mg PO 1 hr before chemotherapy *or* 250-mcg IV delivered over 30 seconds starting 30 minutes before chemotherapy. To prevent postoperative nausea and vomiting, the dosage is 75 mcg IV delivered over 10 seconds immediately before induction of anesthesia.

80.1.3 Glucocorticoids

Two glucocorticoids—*methylprednisolone* [Solu-Medrol] and *dexamethasone* [Decadron]—are commonly used to suppress CINV, even though they are not approved by the Food and Drug Administration (FDA) for this application. Glucocorticoids are effective alone and in combination with other antiemetics. The mechanism by which glucocorticoids suppress emesis is unknown. Both dexamethasone and methylprednisolone are administered IV. Because antiemetic use is

intermittent and short term, serious side effects are absent. The pharmacology of the glucocorticoids is discussed in [Chapter 71](#).

80.1.4 Substance P/Neurokinin₁ Antagonists

Two substance P/neurokinin₁ antagonists are available: aprepitant and fosaprepitant, a prodrug that undergoes conversion to aprepitant in the body. Their principal application is prevention of CINV.

80.1.4.1 Aprepitant.

Actions and Use. Aprepitant [Emend] is an important new antiemetic. The drug is approved for preventing postoperative nausea and vomiting and CINV. Owing to its unique mechanism of action—blockade of neurokinin₁-type receptors (for substance P) in the CTZ—aprepitant can enhance responses when combined with other antiemetic drugs. Aprepitant has a prolonged duration of action, and hence can prevent *delayed* CINV as well as *acute* CINV. Aprepitant can be used *alone* for managing postoperative nausea and vomiting, However, since the drug is only moderately effective, it must be combined with other antiemetic drugs—specifically, a glucocorticoid (eg, dexamethasone) and a serotonin antagonist (eg, ondansetron)—for managing CINV.

938

939

80.1.4.1.1 Pharmacokinetics.

Oral aprepitant is well absorbed, both in the presence and absence of food. Plasma levels peak 4 hours after dosing. The drug undergoes extensive hepatic metabolism—primarily by CYP3A4 (the 3A4 isozyme of cytochrome P450)—followed by excretion in the urine and feces. The plasma half-life is 9 to 13 hours.

80.1.4.1.2 Adverse Effects.

Aprepitant is generally well tolerated. Compared with patients receiving ondansetron and dexamethasone, those receiving aprepitant plus ondansetron and dexamethasone experience more fatigue and asthenia (17.8% vs. 11.8%), hiccups (10.8% vs. 5.6%), dizziness (6.6% vs. 4.4%), and diarrhea (10.3% vs. 7.5%). Aprepitant may also cause a mild, transient elevation of circulating aminotransferases, indicating possible liver injury.

80.1.4.1.3 Drug Interactions.

The potential for drug interactions is complex. Why? Because aprepitant is a substrate for, inhibitor of, and inducer of CYP3A4, a major drug-metabolizing enzyme. Inhibitors of

CYP3A4 (eg, itraconazole, ritonavir) can raise levels of aprepitant. Conversely, inducers of CYP3A4 (eg, rifampin, phenytoin) can decrease levels of aprepitant. By inhibiting CYP3A4, aprepitant can raise levels of CYP3A4 substrates, including many drugs used for cancer chemotherapy. Among these are docetaxel, paclitaxel, etoposide, irinotecan, ifosfamide, imatinib, vinorelbine, vinblastine, and vincristine. Also, aprepitant can raise levels of glucocorticoids used to prevent CINV. Accordingly, doses of these drugs (dexamethasone and methylprednisolone) should be reduced.

In addition to affecting CYP3A4, aprepitant can induce CYP2D6, another drug-metabolizing enzyme. As a result, aprepitant can decrease levels of CYP2D6 substrates, including warfarin (an anticoagulant) and ethinyl estradiol (found in oral contraceptives). Patients receiving warfarin should be monitored closely. Patients using oral contraceptives may need an alternative form of birth control.

80.1.4.1.4 Preparations, Dosage, and Administration.

Aprepitant [Emend] is available in 40-, 80- and 125-mg capsules. Dosing may be done with or without food.

For CINV, dosing is done once a day for 3 days. The first dose (125 mg) is given 1 hour before chemotherapy. The second and third doses (80 mg each) are given early on the following 2 days. As noted, aprepitant should be used in combination with dexamethasone and ondansetron.

For postoperative nausea and vomiting, treatment consists of a single 40-mg dose given within 3 hours of anesthesia induction.

80.1.4.2 Fosaprepitant.

Fosaprepitant [Emend] is an intravenous prodrug that undergoes rapid conversion to aprepitant in the body. Accordingly, the pharmacology of fosaprepitant is nearly identical to that of aprepitant. Fosaprepitant is indicated only for preventing CINV, unlike aprepitant, which is approved for CINV *and* postoperative nausea and vomiting. For prevention of CINV, fosaprepitant is used as a substitute for aprepitant—but only for the first dose in the three-dose regimen (see above). Because IV fosaprepitant has greater bioavailability than PO aprepitant, the dosage for fosaprepitant is only 115 mg, compared with 125 mg for aprepitant. In addition to causing the same adverse effects as aprepitant, fosaprepitant can cause pain and induration at the infusion site.

80.1.4.3 Benzodiazepines

Lorazepam [Ativan] is used in combination regimens to suppress CINV. The drug has three principal benefits: sedation, suppression of anticipatory emesis, and production of anterograde amnesia. In addition, lorazepam may help control extrapyramidal reactions caused by phenothiazine antiemetics. The basic pharmacology of lorazepam and other benzodiazepines is discussed in [Chapter 34](#).

80.1.4.4 Dopamine Antagonists

80.1.4.4.1 Phenothiazines.

The phenothiazines (eg, prochlorperazine) suppress emesis by blocking dopamine₂ receptors in the CTZ. These drugs can reduce emesis associated with surgery, cancer chemotherapy, and toxins. Side effects include extrapyramidal reactions, anticholinergic effects, hypotension, and sedation. The basic pharmacology of the phenothiazines is discussed in [Chapter 31](#) (Antipsychotic Agents and Their Use in Schizophrenia).

80.1.4.4.2 Butyrophenones.

Two butyrophenones—*haloperidol* [Haldol] and *droperidol* [Inapsine]—are used as antiemetics. Like the phenothiazines, the butyrophenones suppress emesis by blocking dopamine₂ receptors in the CTZ. Butyrophenones are useful for postoperative nausea and vomiting, and for emesis caused by cancer chemotherapy, radiation therapy, and toxins. Potential side effects are similar to those of the phenothiazines: extrapyramidal reactions, sedation, and hypotension. In addition, droperidol may pose a risk of fatal dysrhythmias owing to prolongation of the QT interval. Accordingly, patients receiving the drug should undergo electrocardiographic monitoring. The pharmacology of the butyrophenones is discussed in [Chapter 31](#).

80.1.4.4.3 Metoclopramide.

Metoclopramide [Reglan] suppresses emesis through blockade of dopamine receptors in the CTZ. The drug can suppress postoperative nausea and vomiting as well as emesis caused by anticancer drugs, opioids, toxins, and radiation therapy. The pharmacology of metoclopramide is discussed below under *Prokinetic Agents*.

80.1.4.5 Cannabinoids

Two cannabinoids—*dronabinol* [Marinol] and *nabilone* [Cesamet]^{*}—are approved for medical use in the United States. Both drugs are related to marijuana (*Cannabis sativa*). Dronabinol (delta-9-tetrahydrocannabinol; THC) is the principal psychoactive agent in *C. sativa*. Nabilone is a synthetic derivative of dronabinol. A third cannabinoid preparation, sold as *Sativex* (a combination of THC and cannabidiol), is available in Canada (for treating neuropathic pain) but is illegal here. The basic pharmacology of THC and other cannabinoids is discussed in [Chapter 39](#) (Drug Abuse III: Major Drugs of Abuse).

80.1.4.5.1 Therapeutic Uses.

Both dronabinol and nabilone are approved for suppressing CINV. The mechanism underlying benefits is unknown, but most likely results from activating cannabinoid receptors in and around the vomiting center. Because of their psychotomimetic effects and abuse potential (see below), the cannabinoids are considered second-line drugs for CINV, and hence should be reserved for patients who are unresponsive to or intolerant of preferred agents.

In addition to its use in CINV, dronabinol (but not nabilone) is approved for stimulating appetite in patients with AIDS. The goal is to reduce AIDS-induced anorexia and prevent or reverse weight loss.

* Nabilone was approved by the FDA in 1985, discontinued by the manufacturer (Eli Lilly) in 1989, and then reintroduced by a new manufacturer (Valeant) in 2006.

80.1.4.5.2 Adverse Effects and Drug Interactions.

In theory, the cannabinoids used medically can produce subjective effects identical to those caused by smoking marijuana. Potential un-pleasant effects include temporal disintegration, dissociation, depersonalization, and dysphoria. Because of these effects, cannabinoids are contraindicated for patients with psychiatric disorders. In addition to their subjective effects, cannabinoids can cause tachycardia and hypotension, and therefore must be used with caution in patients with cardiovascular diseases. The cannabinoids can cause drowsiness, and hence should not be combined with alcohol, sedatives, and CNS depressants.

80.1.4.5.3 Abuse Potential.

Because they can mimic the subjective effects of marijuana, cannabinoids have some potential for abuse. When first approved for medical use, both drugs were classified under Schedule II of the Controlled Substances Act—a classification reserved for drugs with a high abuse

potential. However, in 1998, the manufacturer of dronabinol petitioned the Drug Enforcement Agency (DEA) to reclassify the drug under Schedule III. Two arguments for the reduced classification were offered: (1) because of its slow onset, dronabinol does not produce the same “high” produced by smoking marijuana, and (2) there is little or no interest in dronabinol on the street. Apparently, the DEA agreed: Dronabinol is now classified under Schedule III. Nabilone remains under Schedule II, although its abuse potential seems no greater than that of dronabinol.

80.1.4.5.4 Preparations, Dosage, and Administration.

80.1.4.5.4.1 Dronabinol.

Dronabinol [Marinol] is supplied in capsules (2.5, 5, and 10 mg) for oral use. To *prevent emesis*, the usual dosage is 5 mg/m² every 4 to 6 hours as needed. To *stimulate appetite* in patients with AIDS, the recommended initial dosage is 2.5 mg twice daily, before lunch and supper. If this dosage is intolerable, 2.5 mg once daily may be tried.

80.1.4.5.4.2 Nabilone.

Nabilone [Cesamet] is supplied in 1-mg capsules for oral use. The usual dosage is 1 to 2 mg twice daily.

80.1.5 Management of Chemotherapy-Induced Nausea and Vomiting

Many anticancer drugs cause severe nausea and vomiting, leading to dehydration, electrolyte imbalances, nutrient depletion, and esophageal tears. Worse yet, these reactions can be so intense that patients may discontinue chemotherapy rather than endure further discomfort. Fortunately, CINV can be minimized with the antiemetics available today.

Chemotherapy is associated with three types of emesis: (1) anticipatory, (2) acute, and (3) delayed. *Anticipatory emesis* occurs before anticancer drugs are actually given; it is triggered by the memory of severe nausea and vomiting from a previous round of chemotherapy. *Acute emesis* begins within minutes to a few hours after receiving chemotherapy, and often resolves within 24 hours. In contrast, *delayed emesis* develops a day or more after drug administration. For example, with cisplatin, emesis is maximal 48 to 72 hours after dosing, and can persist for 6 to 7 days.

Antiemetics are more effective at *preventing* CINV than at *suppressing* CINV that has already begun. Accordingly, antiemetics should be administered *prior* to chemotherapy. For prevention, antiemetics may be given orally or parenterally. Both routes are equally effective (although

dosage may differ). In general, oral therapy is preferred. However, if emesis is ongoing, oral therapy won't work, and hence parenteral therapy is required.

The antiemetic regimen is based on the emetogenic potential of the chemotherapy drugs being used. For drugs with a low risk of causing emesis, a single antiemetic may be adequate. For drugs with a moderate or high risk of causing emesis, a combination of antiemetics is needed. The current regimen of choice for patients taking highly emetogenic drugs consists of three agents: aprepitant plus dexamethasone plus a 5-HT₃ antagonist (eg, ondansetron, palonosetron). Lorazepam may be added to reduce anxiety and anticipatory emesis, and to provide amnesia as well. The superior efficacy of combination therapy suggests that anticancer drugs may induce emesis by multiple mechanisms. [Table 79-3](#) shows representative regimens for preventing CINV in patients receiving anticancer drugs with low, moderate, and high emetogenic risk.

TABLE 79-3 Representative Regimens for Preventing Chemotherapy-Induced Nausea and Vomiting

High-Emetogenic-Risk Chemotherapy	
Aprepitant	125 mg PO on day 1, 80 mg PO on days 2 and 3 <i>plus</i>
Dexamethasone	12 mg PO or IV on day 1, 8 mg PO or IV on days 2–4 <i>plus</i>
Ondansetron	16–24 mg PO or 8–12 mg IV on day 1 <i>plus</i>
Lorazepam*	0.5–2 mg PO, IV, or sublingual every 6 hr on days 1–4
Moderate-Emetogenic-Risk Chemotherapy	
Dexamethasone	12 mg PO or IV <i>plus</i>
Palonosetron	0.25 mg IV <i>plus</i>
Lorazepam*	0.5–2 mg PO, IV, or sublingual every 6 hr <i>plus</i>
Aprepitant	125 mg PO (may be added for selected patients)
Low-Emetogenic-Risk Chemotherapy	
Dexamethasone	12 mg PO or IV <i>or</i>
Prochlorperazine	10 mg PO or IV every 4–6 hr or 15-mg spansule PO every 8–12 hr <i>or</i>
Metoclopramide	20–40 mg PO every 4–6 hr or 1–2 mg IV every 3–4 hr, with or without diphenhydramine, 25–50 mg PO or IV every 4–6 hr
Lorazepam*	0.5–2 mg PO or IV every 4–6 hr (may be combined with dexamethasone, prochlorperazine, or metoclopramide)

* Lorazepam is optional.

80.2 DRUGS FOR MOTION SICKNESS

Motion sickness can be caused by sea, air, automobile, and space travel. Symptoms are nausea, vomiting, pallor, and cold sweats. Drug therapy is most effective when given prophylactically, rather than after symptom onset.

80.2.1 Scopolamine

Scopolamine, a muscarinic antagonist, is our most effective drug for prevention and treatment of motion sickness. Benefits derive from suppressing nerve traffic in the neuronal pathway that connects the vestibular apparatus of the inner ear to the vomiting center (see [Fig. 79-1](#)). The most common side effects are dry mouth, blurred vision, and drowsiness. More severe but less common effects are urinary retention, constipation, and disorientation.

Scopolamine is available for oral, subcutaneous, and transdermal administration. The transdermal system [Transderm-Sco-p], an adhesive patch that contains scopolamine, is applied behind the ear. Anticholinergic side effects with transdermal administration may be less intense than with oral or subcutaneous dosing.

80.2.2 Antihistamines

The antihistamines used most often for motion sickness are *dimenhydrinate* [Dramamine, others], *meclizine* [Antivert, others], and *cyclizine* [Marezine]. Because these drugs block receptors for acetylcholine in addition to receptors for histamine, they appear in [Table 79-1](#) as a subclass under *Anticholinergics*. Suppression of motion sickness appears to result from blocking histaminergic (H_1) and muscarinic cholinergic receptors in the neuronal pathway that connects the inner ear to the vomiting center (see [Fig. 79-1](#)). The most prominent side effect—sedation—results from blocking H_1 receptors. Other side effects—dry mouth, blurred vision, urinary retention, and constipation—result from blocking muscarinic receptors. Antihistamines are less effective than scopolamine for treating motion sickness, and sedation further limits their utility.

80.3 ANTIDIARRHEAL AGENTS

Diarrhea is characterized by stools of excessive volume and fluidity, and by increased frequency of defecation. Diarrhea is a symptom of GI disease and not a disease per se. Causes include infection, maldigestion, inflammation, and functional disorders of the bowel (eg, irritable bowel syndrome). The most serious complications of diarrhea are dehydration and electrolyte depletion. Management is directed at (1) diagnosis and treatment of the underlying disease, (2) replacement of lost water and salts, (3) relief of cramping, and (4) reducing passage of unformed stools.

Antidiarrheal drugs fall into two major groups: (1) specific antidiarrheal drugs and (2) nonspecific antidiarrheal drugs. The specific agents are drugs that treat the underlying cause of diarrhea. Included in this group are anti-infective drugs and drugs used to correct malabsorption syndromes. Nonspecific antidiarrheals are agents that act on or within the bowel to provide symptomatic relief; these drugs do not influence the underlying cause.

80.3.1 Nonspecific Antidiarrheal Agents

80.3.1.1 Opioids

Opioids are our most effective antidiarrheal agents. By activating opioid receptors in the GI tract, these drugs decrease intestinal motility, and thereby slow intestinal transit, which allows more time for absorption of fluid and electrolytes. In addition, activation of opioid receptors decreases secretion of fluid into the small intestine and increases absorption of fluid and salt. The net effect is to present the large intestine with less water. As a result, the fluidity and volume of stools are reduced, as is the frequency of defecation.

At the doses employed to relieve diarrhea, subjective effects and dependence do not occur. However, excessive doses *can* elicit typical morphine-like subjective effects. If severe overdose occurs, it should be treated with an opioid antagonist (eg, naloxone). In patients with inflammatory bowel disease, opioids may cause toxic megacolon.

Several opioid preparations—diphenoxylate, difenoxin, loperamide, paregoric, and opium tincture—are approved for diarrhea. Of these, diphenoxylate [Lomotil, others] and loperamide [Imodium, others] are the most frequently employed. Pharmacologic properties of these agents are discussed below. Dosages for diarrhea are summarized in [Table 79-4](#).

80.3.1.1.1 Diphenoxylate.

Diphenoxylate is an opioid used only for diarrhea. The drug is insoluble in water, and hence cannot be abused by parenteral routes. When taken orally in antidiarrheal doses, diphenoxylate has no significant effect on the CNS. However, if taken in high doses, the drug can elicit typical morphine-like subjective responses.

Diphenoxylate is formulated in combination with atropine. The combination, best known as *Lomotil*, is available in tablets and an oral liquid. Each tablet or 5 mL of liquid contains 2.5 mg of diphenoxylate and 25 mg of atropine sulfate. The atropine is present to discourage diphenoxylate abuse: Doses of the combination that are sufficiently high to produce euphoria from the diphenoxylate would produce unpleasant side effects from the correspondingly high

dose of atropine. Accordingly, the combination has a very low potential for abuse and is classified under Schedule V of the Controlled Substances Act.

80.3.1.1.2 Loperamide.

Loperamide [Imodium, others] is a structural analog of meperidine. The drug is employed to treat diarrhea and to reduce the volume of discharge from ileostomies. Benefits derive from suppressing bowel motility and from suppressing fluid secretion into the intestinal lumen. The drug is poorly absorbed and does not readily cross the blood-brain barrier. Very large oral doses do not elicit morphine-like subjective effects. Loperamide has little or no potential for abuse, and is not regulated under the Controlled Substances Act. The drug is supplied in 2-mg capsules, in 2-mg tablets, and in two liquid formulations (0.2 and 1 mg/mL).

80.3.1.1.3 DifenoXin.

DifenoXin is the major active metabolite of diphenoxylate. Like diphenoxylate, difenoXin can elicit morphine-like subjective effects at high doses. To discourage excessive dosing, difenoXin, like diphenoxylate, is formulated only in combination with atropine. The combination is marketed as *Motofen*. Because its abuse potential is somewhat greater than that of diphenoxylate plus atropine, Motofen is classified as a Schedule IV product.

80.3.1.1.4 Paregoric.

Paregoric (camphorated tincture of opium) is a dilute solution of opium, containing morphine (0.4 mg/mL) as its main active ingredient. The primary use is diarrhea, although paregoric has the same approved uses as morphine. Antidiarrheal doses cause neither euphoria nor analgesia. Very high doses can cause typical morphine-like responses. Paregoric has a moderate potential for abuse and is classified under Schedule III of the Controlled Substances Act (CSA).

941

942

TABLE 79-4 Opioids Used to Treat Diarrhea

Generic Name	Trade Name	CSA* Schedule	Antidiarrheal Dosage
Diphenoxylate (plus atropine) [†]	Lomotil, Lonox, Logen, Lomanate	V	<i>Adults:</i> 5 mg, 4 times/day <i>Children (initial dosage):</i> Age 2–5 yr: 1 mg, 4 times/day Age 5–8 yr: 1–2 mg, 4 times/day Age 8–12 yr: 1–2 mg, 4 times/day
Difenoxin (plus atropine) [†]	Motofen	IV	<i>Adults:</i> 2 mg initially, then 1 mg after each loose stool
Loperamide	Imodium, Pepto Diarrhea Control, others	NR [‡]	<i>Adults (initial dose):</i> 4 mg <i>Children (initial dosage):</i> Age 2–5 yr: 1 mg, 3 times/day Age 5–8 yr: 2 mg, 2 times/day Age 8–12 yr: 2 mg, 3 times/day
Paregoric (camphorated tincture of opium; contains 0.4 mg morphine/mL)		III	<i>Adults:</i> 5–10 mL, 1–4 times/day <i>Children:</i> 0.25–0.5 mL/kg, 1–4 times/day
Opium tincture (opioid content equivalent to 10 mg morphine/mL)		II	0.6 mL 4 times/day

* Controlled Substances Act.

† Diphenoxylate and difenoxin are available only in combination with atropine. The atropine dose is subtherapeutic and is present to discourage abuse.

‡ Not regulated under the CSA.

80.3.1.1.5

Opium Tincture.

Opium tincture is an alcohol-based solution that contains 10% opium by weight. The principal active ingredient—morphine—is present at 10 mg/mL. The primary indication for opium tincture is diarrhea. In addition, the preparation (after dilution) may be given to suppress symptoms of withdrawal in opioid-dependent neonates. When administered in antidiarrheal doses, opium tincture does not produce analgesia or euphoria. However, high doses can cause

typical opioid agonist effects. Opium tincture has a high potential for abuse and is classified under CSA Schedule II.

80.3.1.2 Other Nonspecific Antidiarrheals

80.3.1.2.1 Bismuth Subsalicylate.

Bismuth subsalicylate [Pepto-Bismol, others] is effective for prevention and treatment of mild diarrhea. For prevention, the dosage is two 262-mg tablets 4 times a day for up to 3 weeks. For treatment, the dosage is 2 tablets every 30 minutes for up to eight doses. Users should be aware the drug may blacken stools and the tongue.

80.3.1.2.2 Bulk-Forming Agents.

Paradoxically, methylcellulose, polycarbophil, and other bulk-forming laxatives can help manage diarrhea. Benefits derive from giving the stool a more firm, less watery consistency. Stool volume is not decreased. The bulk-forming laxatives are discussed in [Chapter 78](#).

80.3.1.2.3 Anticholinergic Antispasmodics.

Muscarinic antagonists (eg, atropine) can relieve cramping associated with diarrhea, but do not alter fecal consistency or volume. Because of undesirable side effects (eg, blurred vision, photophobia, dry mouth, urinary retention, tachycardia), anticholinergic drugs are of limited use. The pharmacology of the muscarinic blockers is discussed in [Chapter 14](#).

80.3.2 Management of Infectious Diarrhea

80.3.2.1 General Considerations.

Infectious diarrhea may be produced by enteric infection with a variety of bacteria and protozoa. These infections are usually self-limited. Mild diarrhea can be managed with nonspecific antidiarrheals. In many cases, no treatment is required at all. Antibiotics should be administered only when clearly indicated. Indiscriminate use of antibiotics is undesirable in that it (1) can promote emergence of antibiotic resistance, and (2) can produce an asymptomatic carrier state by killing most, but not all, of the infectious agents. Conditions that *do* merit antibiotic treatment include severe infections with *Salmonella*, *Shigella*, *Campylobacter*, or *Clostridium*.

80.3.2.2 Traveler's Diarrhea.

Tourists are often plagued by infectious diarrhea. This condition is known variously as Montezuma's revenge, the Aztec two-step, or Rangoon runs. In most cases, the causative

organism is *Escherichia coli*. As a rule, treatment is unnecessary: Infection with *E. coli* is self-limited and will run its course in a few days. However, if symptoms are especially severe, treatment with one of the fluoroquinolone antibiotics—*ciprofloxacin* (500 mg twice daily), *levofloxacin* (500 mg once daily), *ofloxacin* (300 mg twice daily), or *norfloxacin* (400 mg twice daily)—is indicated. *Azithromycin* [Zithromax] is preferred for children (10 mg/kg on day 1 and 5 mg/kg on days 2 and 3) and for pregnant women (1000 mg once or 500 mg once daily for 3 days). *Rifaximin* [Xifaxan] (200 mg 3 times a day for 3 days) may also be used, provided the patient is not pregnant or febrile, and that stools are not bloody. For patients with mild symptoms, relief can be achieved with *loperamide*, a nonspecific antidiarrheal. However, by slowing peristalsis, loperamide may delay export of the offending organism, and may thereby prolong the infection.

Several measures can reduce acquisition of traveler's diarrhea. Two measures—avoiding local drinking water and carefully washing foods—are highly effective. Certain drugs—*ciprofloxacin*, *ofloxacin*, and *norfloxacin*—can be taken for prophylaxis. However, because these drugs can cause serious side effects, prophylaxis is not generally recommended. Lastly, travellers can be vaccinated against some pathogens. Oral vaccination with *Dukoral* protects against diarrhea caused by *E. coli* and *Vibrio cholera*. Oral vaccination with *Mutacol* protects against cholera only.

80.4 DRUGS FOR IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is the most common disorder of the GI tract, affecting an estimated 20% of Americans—about 54 million people. The incidence in women is 3 times the incidence in men. IBS is responsible for 12% of all visits to primary care physicians, and 28% of all visits to gastroenterologists. The direct medical costs are estimated at \$8 billion a year; the indirect costs are much higher—about \$25 billion a year. IBS is second only to the common cold as the leading cause of days missed from work.

942

943

What is IBS? A GI disorder characterized by crampy abdominal pain—sometimes severe—occurring in association with diarrhea, constipation, or both. Formally, IBS is defined by the presence, for at least 12 weeks in the past year, of abdominal pain or discomfort that cannot be explained by structural or chemical abnormalities and that has at least two of the following features:

- Pain is relieved by defecation.
- Onset of pain occurred in association with development of diarrhea or constipation.
- Onset of pain occurred in association with a change in stool consistency (from normal to loose, watery, or pellet-like).

IBS has three major forms, characterized by either

- Abdominal pain in association with diarrhea (diarrhea-predominant IBS, IBS-D)
- Abdominal pain in association with constipation (constipation-predominant IBS, IBS-C)
- Abdominal pain in association with alternating episodes of diarrhea and constipation

What causes IBS? No one knows. Despite extensive research, no underlying pathophysiologic mechanism has been identified. What we do know is that the bowel appears hypersensitive and hyper-responsive. As a result, mild stimuli that would have no effect on most people can trigger an intense response. In addition, we know that symptoms can be triggered by stress, depression, and dietary factors, including caffeine, alcohol, fried foods, fatty foods, gas-generating vegetables (beans, broccoli, cabbage), and too much sorbitol, a sweetener found in chewing gum and some diet products. Overproduction of gastric acid and excessive bacterial colonization of the small intestine have also been implicated.

Fortunately, many people achieve significant relief with treatment. Nondrug measures and drug therapy are employed. Patients should keep a log to identify foods and stressors that trigger symptoms. Because large meals stretch and stimulate the bowel, switching to smaller, more frequent meals may help. Increasing dietary fluid and fiber may reduce constipation.

Two groups of drugs are used for treatment: nonspecific drugs and drugs specific for IBS. Both groups are discussed below.

80.4.1 Nonspecific Drugs

Four groups of drugs—*antispasmodics* (eg, hyoscyamine, dicyclomine), *bulk-forming agents* (eg, psyllium, polycarbophil), *antidiarrheals* (eg, loperamide), and *tricyclic antidepressants* (TCAs)—have been employed for years to provide symptomatic relief. However, a report from the American College of Gastroenterology (ACG) concluded that, for most of these agents, there is no good proof of clinical benefits. Specifically, after reviewing available data, the authors concluded that loperamide and the bulk-forming agents are no better than placebo at relieving global symptoms of IBS. In contrast, they concluded there is good evidence that TCAs can reduce abdominal pain, and that this benefit is unrelated to relief of depression. Regarding antispasmodic agents, they concluded that the available data are insufficient to make a recommendation for or against use.

Two studies suggest that, for some patients, symptoms can be relieved with *antibiotics* or an *acid suppressant*. In one study, the authors observed that many patients with IBS have excessive

bacteria in the small intestine. When these people were treated with antibiotics, bacterial colonization was reduced, and so were symptoms of IBS. In the other study, researchers evaluated the impact of drugs that suppress production of stomach acid in patients who routinely experienced exacerbation of symptoms after eating. Two kinds of acid suppressants were used: proton pump inhibitors (lansoprazole or omeprazole) and histamine₂ receptor blockers (famotidine or ranitidine). In all cases, patients experienced a significant reduction of postprandial urgency and other symptoms. Benefits developed quickly (within days) and reversed when the drugs were stopped.

80.4.2 IBS-Specific Drugs

In this section we discuss the only three drugs approved for IBS. These are alosetron (approved for IBS-D), and lubiprostone and tegaserod (both approved for IBS-C). Owing to a risk of serious cardiovascular events, one of these drugs—tegaserod—is used rarely, and then only in emergency situations.

80.4.2.1 Alosetron

Alosetron [Lotronex] is a potentially dangerous drug approved for IBS-D in *women*. Safety and efficacy in men have not been demonstrated. Alosetron was first approved on February 9, 2000, and then, in response to reports of severe GI toxicity and several deaths, was withdrawn on November 28, 2000, less than 10 months after being introduced. However, on June 7, 2002, alosetron was *reapproved* by the FDA, marking the first time the agency has allowed a drug back on the market after it had been pulled for safety reasons. To reduce risk, prescribers, patients, and pharmacists must adhere to a strict risk management program (see below).

80.4.2.1.1 Indications.

At this time, alosetron is approved only for treating women with severe IBS-D that has lasted for 6 months or more and has not responded to conventional treatment. IBS-D is considered severe if the patient experiences one or more of the following: (1) frequent and severe abdominal pain or discomfort, (2) frequent bowel urgency or fecal incontinence, and (3) disability or restriction of daily activities because of IBS. Less than 5% of IBS cases qualify as severe.

80.4.2.1.2 Mechanism of Action and Clinical Effects.

Alosetron causes selective blockade of type 3 serotonin receptors (5-HT₃ receptors), which are found primarily on neurons that innervate the viscera. In patients with IBS-D, alosetron can decrease abdominal pain, increase colonic transit time, reduce intestinal secretions, and

increase absorption of water and sodium. As a result, the drug can increase stool firmness and decrease both fecal urgency and frequency. Presumably, all of these effects result from 5-HT₃ blockade. Symptoms decline 1 to 4 weeks after starting the drug, and recur 1 week after treatment stops.

80.4.2.1.3 Pharmacokinetics.

Administration is oral, and absorption is rapid but incomplete (50% to 60%). Bioavailability is decreased by food. Plasma levels peak about 1 hour after dosing. Alosetron undergoes extensive metabolism by hepatic cytochrome P450 enzymes, followed by excretion primarily in the urine. The half-life is 1.5 hours.

943

80.4.2.1.4 Drug Interactions.

944

Alosetron has no known adverse interactions with other drugs. It does not interact with theophylline, oral contraceptives, cisapride, ibuprofen, alprazolam, amitriptyline, fluoxetine, or hydrocodone combined with ace-taminophen. Because alosetron is metabolized by cytochrome P450 enzymes, drugs that induce these enzymes (eg, carba-mazepine, phenobarbital) may decrease alosetron levels.

80.4.2.1.5 Adverse Effects and Contraindications.

Although alosetron is generally well tolerated, it *can* cause severe adverse effects. Deaths have occurred. The most common problem is constipation (29%), which can be complicated by impaction, bowel obstruction, and perforation. In addition, alosetron can cause *ischemic colitis* (intestinal damage secondary to reduced blood flow). Ischemic colitis and complications of constipation have led to hospitalization, blood transfusion, surgery, and death. Because of its potential for GI toxicity, alosetron is *contraindicated* for patients with ongoing constipation or a history of

- Chronic constipation, severe constipation, or sequelae from constipation
- Intestinal obstruction or stricture, toxic megacolon, or GI perforation or adhesions
- Ischemic colitis, impaired intestinal circulation, thrombophlebitis, or hypercoagulable state
- Crohn's disease or ulcerative colitis
- Diverticulitis

80.4.2.1.6 Risk Management Program.

To ensure the best possible benefit/risk ratio, the manufacturer and the FDA have established a risk management program that involves active participation of the patient, prescriber, and pharmacist. The program emphasizes that

- Alosetron can cause potentially fatal GI toxicity.
- Only prescribers enrolled in the program can write prescriptions for the drug.
- Alosetron is indicated only for women with severe, chronic IBS-D that has not responded to conventional therapy.
- Treatment should be discontinued immediately if constipation or signs of ischemic colitis develop.

Each enrolled prescriber must attest that he or she

- Is qualified to diagnose and treat IBS
- Is qualified to diagnose and manage ischemic colitis
- Is qualified to diagnose and manage constipation and complications of constipation
- Understands the risks and benefits of alosetron for IBS-D
- Agrees to educate the patient about risks and benefits of alosetron, will confirm that each patient has signed a Patient-Physician Agreement, and will give each patient a copy of that agreement and a copy of an alosetron Medication Guide
- Will report serious adverse events to the manufacturer or the FDA
- Will place a qualification sticker on all prescriptions for alosetron (Pharmacists must not fill prescriptions that lack the sticker.)

Each patient must sign a Patient-Physician Agreement indicating that she

- Has been informed about and understands the severity of potential risks of alosetron treatment and understands the balance between risks and benefits
- Agrees to treatment with alosetron

- Will not take alosetron if she is constipated, and will immediately discontinue alosetron and contact the prescriber if she becomes constipated or develops signs of ischemic colitis
- Will stop taking alosetron and call the prescriber if the drug does not control IBS symptoms after 4 weeks

80.4.2.1.7 Preparations, Dosage, and Administration.

Alosetron [Lotronex] is available in 0.5- and 1-mg tablets. The recommended initial dosage is now 1 mg once a day—one-half the dosage recommended when alosetron was first approved. If, after 4 weeks, the dosage is well tolerated but inadequate, it can be increased to 1 mg twice a day. If, after 4 weeks at the higher dosage, treatment is still inadequate, the drug is not likely to help and therefore should be stopped.

Patients who develop constipation or signs of ischemic colitis (rectal bleeding, bloody diarrhea, new or worsening abdominal pain) should immediately inform the physician and discontinue the drug. Those with ischemic colitis should never use alosetron again. Those with constipation may resume treatment, but only after constipation has resolved, and only on the advice of the prescriber. If constipation does not resolve, the physician should be seen for evaluation.

80.4.2.2 Lubiprostone

Lubiprostone [Amitiza] is approved for IBS-C in women age 18 and older. Unfortunately, benefits are modest: the drug can reduce abdominal pain and discomfort, but only in a small percentage of patients. Efficacy against IBS-C in men has not been established. In addition to its use in IBS-C, lubiprostone is used for chronic idiopathic constipation (CIC) in women and men (see [Chapter 78](#)). As discussed in [Chapter 78](#), lubiprostone causes selective activation of chloride channels in epithelial cells of the intestine, and thereby (1) promotes secretion of chloride-rich fluid into the intestinal lumen and (2) enhances motility of the small intestine and colon. The dosage for IBS-C is lower than for CIC: 8 mcg twice daily versus 24 mcg twice daily. As a result, patients treated for IBS-C experience less nausea (8% vs. 30), diarrhea (7% vs. 13%), and chest discomfort (0.4% vs. 2.5%) compared with patients treated for CIC. To reduce the incidence of nausea, all doses should be taken with food and water.

80.4.2.3 Tegaserod

80.4.2.3.1 Therapeutic Use.

Tegaserod [Zelnorm] is a serotonin analog approved for short-term therapy of IBS-C and CIC in women under the age of 55, but only if they are free of cardiovascular disease, and then only if there is no alternative treatment. Although tegaserod is *approved* for these patients, *availability* has been restricted by the manufacturer to emergency situations.

80.4.2.3.2 Regulatory History.

The regulatory history of tegaserod parallels that of alosetron. Tegaserod was approved in July 2002 for IBS-C and in August 2004 for CIC. On March 30, 2007, the FDA requested that tegaserod be voluntarily withdrawn, owing to reports of serious cardiovascular events. Then, in July 2007, the FDA approved an Investigational New Drug (IND) program that made tegaserod available again, but with restricted access. However, on April 2, 2008, the manufacturer—Novartis—decided to close the restricted access program. Nonetheless, patients who have an emergency situation, defined as one that is immediately life threatening or serious enough to qualify for hospitalization, may still be able to obtain the drug through an emergency IND option. Prescribers may inquire about this option by contacting the FDA CDER Division of Drug Information at 301-796-3400.

80.4.2.3.3 Actions.

Tegaserod is a partial agonist at type 4 serotonin receptors (5-HT₄ receptors), which are found on neurons that innervate the viscera. By activating these receptors, the drug can decrease visceral sensation and increase GI motility and secretions. As a result, tegaserod can reduce bloating, constipation, and abdominal pain. Unfortunately, benefits are modest and may take a month to develop. Furthermore, some users develop severe diarrhea (see below).

80.4.2.3.4 Pharmacokinetics.

Tegaserod is rapidly absorbed, but bioavailability is low (about 10% in the absence of food and only 5% in the presence of food). In the blood, the drug is highly bound to plasma proteins. Tegaserod undergoes metabolism to inactive products followed by excretion in the bile.

944

945

80.4.2.3.5 Adverse Effects and Drug Interactions.

The most common adverse effect is *diarrhea*, which has been severe in some patients, leading to dehydration, hypovolemia, and hypotension. Most cases occur during the first week of treatment and resolve despite continued drug use. Furthermore, most patients who experience diarrhea have only one episode. Patients who develop severe diarrhea should discontinue tegaserod. People with ongoing diarrhea, and those who experience frequent diarrhea, should not use the drug.

Postmarketing data indicate that tegaserod can cause serious *cardiovascular events*, namely, myocardial infarction (MI), unstable angina, and stroke. Fortunately, these events are rare, and all have occurred in patients with known cardiovascular disease, cardiovascular risk factors, or both. Patients who experience signs of stroke or MI (eg, severe chest pain, shortness of breath, dizziness) should seek emergency medical attention. Because of the potential for cardiovascular harm, access to tegaserod is restricted.

Rarely, users develop *ischemic colitis*. However, there's no proof that tegaserod is the cause. Patients who develop signs of ischemic colitis (eg, rectal bleeding, bloody diarrhea, new or worsening abdominal pain) should discontinue tegaserod and undergo immediate diagnostic testing.

Tegaserod appears devoid of adverse interactions with other drugs.

80.4.2.3.6 Contraindications.

Tegaserod is contraindicated for women with known cardiovascular disease, severe renal impairment, moderate or severe hepatic impairment, a history of bowel obstruction, symptomatic gallbladder disease, abdominal adhesions, or sphincter of Oddi dysfunction.

80.4.2.3.7 Contrasts with Alosetron.

Although tegaserod and alosetron are both used for IBS, the drugs differ with regard to mechanism of action, pharmacologic effects, indications, and adverse effects. Specifically,

- Whereas tegaserod is a partial *agonist* at 5-HT₄ receptors, alosetron is an *antagonist* at 5-HT₃ receptors.
- Whereas tegaserod *increases* intestinal motility and secretions, alosetron *decreases* motility and secretions.

- Whereas tegaserod is used for *constipation*-predominant IBS, alosetron is used for *diarrhea*-predominant IBS.
- Whereas tegaserod can cause *diarrhea*, *stroke*, and *MI*, alosetron can cause *constipation* and *ischemic colitis*.

80.4.2.3.8 Preparations, Dosage, and Administration.

Tegaserod [Zelnorm] is formulated in 2- and 6-mg tablets for oral administration. When the drug was available for routine use, the recommended initial dosage was 6 mg twice daily (taken at least 30 minutes before meals) for 4 to 6 weeks. If there was a favorable response, treatment could continue for another 4 to 6 weeks.

80.5 DRUGS FOR INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) has two forms: *Crohn's disease* and *ulcerative colitis*. Crohn's disease is characterized by transmural inflammation, and usually affects the terminal ileum, but can also affect all other parts of the GI tract. Ulcerative colitis is characterized by inflammation of the mucosa and submucosa of the colon and rectum. Both diseases produce abdominal cramps and diarrhea. Ulcerative colitis may cause rectal bleeding as well. About 15% of patients with ulcerative colitis eventually have an attack severe enough to require hospitalization for IV glucocorticoid therapy, which produces remission in 60% of patients; the remaining 40% usually require total colectomy. In the United States, IBD afflicts about 1 million people.

What causes IBD? There is general agreement that IBD results from an exaggerated immune response directed against normal bowel flora—but only in genetically predisposed people.

Drug therapy of IBD is summarized in [Table 79-5](#). Five types of drugs are employed: 5-*aminosalicylates* (eg, sulfasalazine), *glucocorticoids* (eg, hydrocortisone), *immunosuppressants* (eg, azathioprine), *immunomodulators* (eg, in-fliximab), and *antibiotics* (eg, metronidazole). None of these drugs is curative; at best, drugs may control the disease process. Patients frequently require therapy with more than one agent.

80.5.1 5-Aminosalicylates

The 5-aminosalicylates are used to treat mild or moderate ulcerative colitis and Crohn's disease, and to maintain remission after symptoms have subsided. Four aminosalicylates are available: sulfasalazine, mesalamine, olsalazine, and balsalazide.

80.5.1.1 Sulfasalazine.

Sulfasalazine [Azulfidine] belongs to the same chemical family as the sulfonamide antibiotics. However, although similar to the sulfonamides, sulfasalazine is not employed to treat infections. Its only approved indications are IBD and rheumatoid arthritis (see [Chapter 72](#)).

80.5.1.1.1 Actions.

Sulfasalazine is metabolized by intestinal bacteria into two compounds: 5-aminosalicylic acid (5-ASA) and sulfapyridine. 5-ASA is the component responsible for reducing inflammation; sulfapyridine is responsible for adverse effects. Possible mechanisms by which 5-ASA reduces inflammation include suppression of prostaglandin synthesis and suppression of the migration of inflammatory cells into the affected region.

80.5.1.1.2 Therapeutic Uses.

Sulfasalazine is most effective against acute episodes of mild to moderate ulcerative colitis. Responses are less satisfactory when symptoms are severe. Sulfasalazine can also benefit patients with Crohn's disease.

80.5.1.1.3 Adverse Effects.

Nausea, fever, rash, and arthralgia are common. Hematologic disorders (eg, agranulocytosis, hemolytic anemia, macrocytic anemia) may also occur. Accordingly, complete blood counts should be obtained periodically. Sulfasalazine appears safe during pregnancy and lactation.

80.5.1.2 Preparations, Dosage, and Administration.

Sulfasalazine [Azulfidine] is available in 500-mg immediate- and delayed-release oral tablets. The initial adult dosage is 500 mg/day. Maintenance dosages range from 2 to 4 gm/day, given in divided doses.

80.5.1.3 Mesalamine.

Mesalamine [Asacol, Canasa, Lialda, Pentasa, Rowasa] is the generic name for 5-ASA, the active component in sulfasalazine. The drug is used for acute treatment of mild to moderate IBD and for maintenance therapy. Mesalamine can be administered by retention enema, by rectal suppository, or by mouth (in tablets and capsules that dissolve when they reach the terminal ileum). Adverse effects are milder than with sulfasalazine. The most common side effects of *oral* therapy are headache and GI upset. The adult oral dosage is 800 mg 3 times a day (for

Asacol tablets) *or* 1 gm 4 times a day (for Pentasa capsules) *or* 2.4 to 4.8 gm once a day (for Lialda tablets). The 500-mg rectal suppositories [Rowasa] are administered twice daily. The retention enema [Rowasa] is administered once daily (4 gm in 60 mL).

80.5.1.4 Olsalazine.

Olsalazine [Dipentum] is a dimer composed of two molecules of 5-ASA, the active component of sulfasalazine. Olsalazine is approved for maintenance therapy of ulcerative colitis in patients who can't tolerate sulfasalazine. The most common adverse effect is watery diarrhea, which occurs in 17% of patients. Other adverse effects include abdominal pain, cramps, acne, rash, and joint pain. Olsalazine is supplied in 250-mg oral tablets. The adult dosage is 500 mg twice daily with food.

80.5.1.5 Balsalazide.

Balsalazide [Colazal] is an aminosalicylate indicated for mildly to moderately active ulcerative colitis. As with sulfasalazine, colonic bacteria act on balsalazide to release 5-ASA, the active portion of the molecule. Practically all of the drug remains in the intestine; less than 1% is absorbed. As a result, balsalazide is well tolerated. The most common adverse effects are headache (8%), abdominal pain (6%), and diarrhea and nausea (5%). Balsalazide is available in 750-mg oral capsules. The recommended dosage is 3 capsules 3 times a day for 8 to 12 weeks. This dosage delivers 2.4 gm of free 5-ASA to the colon daily.

80.5.2 Glucocorticoids

The basic pharmacology of the glucocorticoids is presented in [Chapters 59](#) and [71](#); discussion here is limited to their use in IBD. Glucocorticoids (eg, dexamethasone, budesonide) can relieve symptoms of ulcerative colitis and Crohn's disease. Benefits derive from anti-inflammatory actions. Glucocorticoids are indicated primarily for induction of remission—not for long-term maintenance. Prolonged use can cause severe adverse effects, including adrenal suppression, osteoporosis, increased susceptibility to infection, and a cushingoid syndrome. Administration is IV or PO.

945

946

TABLE 79-5 Therapeutic Options for Inflammatory Bowel Disease

Disease Intensity	Disease Form	
	Ulcerative Colitis	Crohn's Disease
Mild	5-Aminosalicylate: PO or rectal	5-Aminosalicylate: PO Metronidazole: PO Budesonide: PO Ciprofloxacin: PO
Moderate	5-Aminosalicylate: PO or rectal Infliximab: IV	Glucocorticoid: PO Azathioprine: PO Mercaptopurine: PO Infliximab: IV Certolizumab: subQ Adalimumab: subQ Natalizumab: IV
Severe	Glucocorticoid: PO or IV Cyclosporine: IV Infliximab: IV	Glucocorticoid: PO or IV Methotrexate: IV or sub Q Infliximab: IV Certolizumab: subQ Adalimumab: subQ Natalizumab: IV
Refractory	Glucocorticoid: PO or IV Azathioprine: PO Mercaptopurine: PO	Infliximab: IV Certolizumab: subQ Adalimumab: subQ Natalizumab: IV

Remission	5-Aminosalicylate: PO	Mesalamine: PO
	Azathioprine: PO	Azathioprine: PO
	Mercaptopurine: PO	Metronidazole: PO
		Mercaptopurine: PO
		Infliximab: IV
		Certolizumab: subQ
		Adalimumab: subQ
		Natalizumab: IV

Oral *budesonide* [Entocort EC] is approved for mild to moderate Crohn's disease that involves the ileum and ascending colon. Entocort EC capsules are formulated to release budesonide when it reaches the ileum and ascending colon. As a result, high local concentrations are produced. Systemic effects are lower than with other glucocorticoids because absorbed budesonide undergoes extensive first-pass metabolism.

80.5.3 Immunosuppressants

Immunosuppressants are used for long-term therapy of selected patients with ulcerative colitis and Crohn's disease. Clinical experience is greatest with azathioprine and mercaptopurine.

80.5.3.1 Azathioprine and Mercaptopurine.

These drugs are discussed together because one is the active form of the other. (Mercaptopurine is the active drug; azathioprine is a prodrug that undergoes conversion to mercaptopurine in the body.)

Although not approved for IBD, azathioprine [Imuran] and mercaptopurine [Purinethol] have been employed with success to induce and maintain remission in both ulcerative colitis and Crohn's disease. Because onset of effects may be delayed for up to 6 months, these agents cannot be used for acute monotherapy. Furthermore, because these drugs are more toxic than aminosalicylates or glucocorticoids, they are generally reserved for patients who have not responded to traditional therapy. Major adverse effects are pancreatitis and neutropenia (secondary to bone marrow suppression). At the doses used for IBD, these drugs are neither carcinogenic nor teratogenic. The basic pharmacology of azathioprine and mercaptopurine is discussed in [Chapters 68](#) and [101](#), respectively.

80.5.3.2 Cyclosporine.

Cyclosporine [Sandimmune, Neoral, Gengraf] is a stronger immunosuppressant than azathioprine or mercaptopurine, and acts faster too. When used for IBD, the drug is generally reserved for patients with acute, severe ulcerative colitis or Crohn's disease that has not responded to glucocorticoids. For these patients, continuous IV infusion can rapidly induce remission. In addition to IV administration, the drug has been administered orally in low doses to maintain remission, but results have been inconsistent. Cyclosporine is a toxic compound that can cause renal impairment, neurotoxicity, and generalized suppression of the immune system. The basic pharmacology of cyclosporine is discussed in [Chapter 68](#).

946

80.5.3.3 Methotrexate.

In patients with Crohn's disease, methotrexate can promote short-term remission, and thereby reduce the need for glucocorticoids. Because the doses employed are low (25 mg once a week), the toxicity associated with high-dose therapy in cancer patients is avoided. The basic pharmacology of methotrexate is discussed in [Chapter 101](#).

947

80.5.4 Immunomodulators

The drugs discussed in this section are monoclonal antibody products that modulate immune responses. Three of these drugs—infliximab, certolizumab, and adalimumab—are inhibitors of *tumor necrosis factor-alpha* (TNF). The fourth drug—natalizumab—interferes with α_4 integrin. These drugs are generally considered second-line agents. However, some authorities now recommend their use early in treatment, with the hope of inducing remission quickly and maintaining remission longer.

80.5.4.1 Infliximab.

Infliximab [Remicade] is indicated for moderate to severe Crohn's disease and ulcerative colitis. This highly effective agent binds with and thereby inactivates TNF, a key immunoinflammatory modulator. In clinical trials, infliximab reduced symptoms in 65% of patients with moderate to severe Crohn's disease and produced clinical remission in 33%. Good responses are also seen in ulcerative colitis.

During clinical trials, 5% of patients dropped out because of serious adverse effects. Infections (21%) and infusion reactions (16%) were most common. Tuberculosis (TB) and opportunistic infections are of particular concern. Infusion reactions included fever, chills, pruritus, urticaria, and cardiopulmonary reactions (chest pain, hypotension, hypertension, dyspnea). Infliximab

may also increase the risk of lymphoma, especially among patients with highly active disease or those on long-term immunosuppressive therapy.

Infliximab is supplied as a powder to be reconstituted for IV infusion. For patients with Crohn's disease or ulcerative colitis, treatment consists of an induction regimen (5 mg/kg infused at 0, 2, and 6 weeks) followed by maintenance infusions of 5 mg/kg every 8 weeks thereafter.

The basic pharmacology of infliximab is discussed in [Chapter 72](#) (Drug Therapy of Rheumatoid Arthritis).

80.5.4.2 Certolizumab.

Certolizumab [Cimzia] is a monoclonal antibody derivative designed to neutralize TNF. The drug consists of a recombinant humanized antibody Fab fragment that has been covalently bound to polyethylene glycol (PEG). Because of this pegylation, the drug is eliminated slowly, and hence has a prolonged half-life (about 17 days). Certolizumab is approved for reducing signs and symptoms of Crohn's disease in patients who have not responded adequately to conventional therapy.

Certolizumab can cause serious adverse effects. In clinical trials, the most common adverse events were upper respiratory tract infections, urinary tract infections, and arthralgia. Like infliximab, certolizumab can increase the risk of TB and other serious infections (eg, hepatitis B, invasive fungal infection). Patients should be tested for *latent* TB before treatment. If the TB test is positive, antituberculosis therapy should be initiated before giving certolizumab. If the patient has *active* TB, certolizumab should not be used. Additional adverse effects include anaphylaxis, hematologic abnormalities (eg, thrombocytopenia, leukopenia), heart failure, and a syndrome similar to lupus erythematosus. If a lupus-like syndrome develops, certolizumab should be discontinued. The drug should be used with caution in patients with existing heart failure and those who develop hematologic abnormalities. Like infliximab, certolizumab may increase the risk of lymphoma.

Certolizumab [Cimzia] is supplied as a 200-mg powder for reconstitution in 1 mL of sterile water. The reconstituted solution should be used within 2 hours (if held at room temperature) or within 24 hours (if refrigerated). A single dose consists of two subQ injections (200 mg each, 400 mg total) made at separate sites on the abdomen or thigh. To initiate treatment, the patient is given a 400-mg dose at weeks 0, 2, and 4. If there is a clinical response, 400-mg maintenance doses are given every 4 weeks.

80.5.4.3 Adalimumab.

Like infliximab and certolizumab, adalimumab [Humira] is a monoclonal antibody product that neutralizes TNF. The drug is approved for Crohn's disease, rheumatoid arthritis, psoriasis, and other inflammatory disorders. The pharmacology of adalimumab, including its dosage for Crohn's disease, is presented in [Chapter 72](#) (Drug Therapy of Rheumatoid Arthritis).

80.5.4.4 Natalizumab.

Natalizumab [Tysabri] is monoclonal antibody that interferes with α_4 integrin, and thereby impedes migration of leukocytes from the vasculature into areas of inflammation. The drug is approved for Crohn's disease and multiple sclerosis. The pharmacology of natalizumab, including its dosage for Crohn's disease, is presented in [Chapter 23](#) (Drugs for Multiple Sclerosis).

80.5.5 Antibiotics

Antibiotics, such as metronidazole and ciprofloxacin, can help control symptoms in patients with mild or moderate Crohn's disease. In contrast, antibiotics are largely ineffective against ulcerative colitis.

80.5.5.1 Metronidazole.

In patients with mild or moderate Crohn's disease, metronidazole [Flagyl, Protostat] is as effective as sulfasalazine. The dosages employed—up to 750 mg 3 times a day—are high. Furthermore, because relapse is likely if metronidazole is discontinued, long-term therapy is required. Unfortunately, prolonged use of high-dose metronidazole poses a risk of peripheral neuropathy. Although metronidazole can help patients with Crohn's disease, benefits are minimal in those with ulcerative colitis.

80.5.5.2 Ciprofloxacin.

Like metronidazole, ciprofloxacin [Cipro] is highly effective in patients with mild or moderate Crohn's disease. A typical dosage is 500 mg twice daily. In one study, ciprofloxacin produced complete or partial remission in 72% of those treated. Combining ciprofloxacin with infliximab is superior to either drug used alone. Like metronidazole, ciprofloxacin is of little benefit in ulcerative colitis.

80.5.6 Nicotine

Observational and experimental evidence indicate that nicotine can help protect against ulcerative colitis. It is well known that ulcerative colitis occurs mainly in *nonsmokers*. Furthermore, the disease frequently develops soon after smoking cessation, and resumption of smoking can help reduce symptoms. These observations in smokers have been reinforced by controlled experiments, which have shown that transdermal nicotine (nicotine patches) and a nicotine enema can reduce symptoms in patients with mild to moderate ulcerative colitis. However, until more information is available, nicotine cannot be recommended for routine treatment.

80.6 PROKINETIC AGENTS

Prokinetic drugs increase the tone and motility of the GI tract. Indications include gastroesophageal reflux disease (GERD), chemotherapy-induced nausea and vomiting (CINV), and diabetic gastroparesis.

80.6.1 Metoclopramide

80.6.1.1 Actions.

Metoclopramide [Reglan, Maxolon, Octamide] has two beneficial actions: it (1) suppresses emesis (by blocking receptors for dopamine and serotonin in the CTZ); and (2) increases upper GI motility (by enhancing the actions of acetylcholine).

80.6.1.2 Therapeutic Uses.

Metoclopramide is used to suppress postoperative nausea and vomiting, as well as emesis associated with cancer chemotherapy, radiation therapy, toxins, and opioids. Other applications include relief of diabetic gastroparesis and suppression of gastroesophageal reflux.

80.6.1.3 Adverse Effects.

With high-dose therapy, sedation and diarrhea are common. Long-term high-dose therapy can cause irreversible *tardive dyskinesia*, characterized by repetitive, involuntary movements of the arms and legs. The elderly are especially vulnerable. Prolonged use of metoclopramide should be avoided. Because of its ability to increase gastric and intestinal motility, metoclopramide is contraindicated in patients with obstruction, hemorrhage, or perforation of the GI tract.

947

TABLE 79-6 Drugs That Can Increase the Risk of Cisapride-Induced Dysrhythmias

Drugs That Inhibit the CYP3A4 Enzyme System		
Anastrozole	Fluoxetine	Paroxetine
Cimetidine	Fluvoxamine	Propranolol
Clarithromycin	Indinavir	Quinidine
Clotrimazole	Itraconazole	Quinine
Danazol	Ketoconazole	Ranitidine
Delavirdine	Metronidazole	Ritonavir
Diethylthiocarbamate	Mirtazapine	Saquinavir
Diltiazem	Nefazodone	Sertraline
Efavirenz	Nelfinavir	Troglitazone
Erythromycin	Nevirapine	Troleandomycin
Fluconazole	Norfloxacin	Zafirlukast
Drugs That Prolong the QT Interval and Promote Dysrhythmias		
Class I Antidysrhythmics (some)	Beta Agonists	Tricyclic Antidepressants
Quinidine	Albuterol	Amitriptyline
Procainamide	Terbutaline	Imipramine
Flecainide	others	others
others		
Class II Antidysrhythmics	Antimicrobials	Antipsychotic Drugs (some)
Amiodarone	Chloroquine	Chlorpromazine
Bretylium	Erythromycin	Pimozide
Sotalol	Halofantrine	others
Bepridil	others	
Diuretics That Promote Hypokalemia		
Loop Diuretics	Thiazide Diuretics	
Furosemide	Chlorothiazide	
Torsemide	Hydrochlorothiazide	
others	others	

80.6.1.4 Preparations, Dosage, and Administration.

Metoclopramide [Reg-lan, Maxolon, Octamide] is available in three formulations: tablets (5 and 10 mg), syrup (1 mg/mL), and solution for injection (5 mg/mL). Oral preparations are used for diabetic gastroparesis and gastroesophageal reflux.

For prophylaxis of CINV, treatment is IV. Dosing is begun 30 minutes before chemotherapy. The initial dose is 1 to 2 mg/kg infused over 15 minutes or more. Additional doses of 1 to 2 mg/kg are administered 2, 4, 7, 10, and 13 hours after the first dose.

80.6.2 Cisapride

80.6.2.1 Therapeutic Use.

Cisapride [Propulsid] is a dangerous drug that can cause fatal cardiac dysrhythmias. In July of 2000, it was voluntarily withdrawn from the U.S. market. Today, it is once again available—but only through an investigational, limited-access program administered by the manufacturer, Janssen Pharmaceutical. Four indications are recognized: GERD, gastroparesis, pseudo-GI obstruction, and severe chronic constipation. In all cases, cisapride is considered a last resort, reserved for patients who have not responded to standard therapy.

80.6.2.2 Mechanism of Action.

Cisapride increases the tone and motility of GI smooth muscle by promoting release of acetylcholine from neurons of the myenteric plexus. In patients with GERD, the drug reduces symptoms by accelerating gastric emptying, increasing esophageal peristalsis, and increasing tone in the lower esophageal sphincter.

80.6.2.3 Pharmacokinetics.

Cisapride is rapidly absorbed following oral administration. Blood levels peak within 1.5 hours of dosing. The drug is highly (98%) bound to plasma proteins. Cisapride undergoes extensive hepatic metabolism—primarily by CYP3A4—followed by excretion in the urine.

80.6.2.4 Adverse Effects: Cardiac Dysrhythmias.

Cisapride prolongs the QT interval, and can thereby induce fatal cardiac dysrhythmias. At least 80 patients have died. The risk is greatest among patients with disorders that predispose to dysrhythmias. Accordingly, cisapride is contraindicated for patients with ischemic heart disease, heart failure, prolonged QT interval at baseline, history of torsades de pointes, sinus

node dysfunction, second- or third-degree atrioventricular block, or a history of ventricular dysrhythmias. Prior to receiving cisapride, patients should undergo electrocardiographic evaluation.

80.6.2.5 Drug Interactions.

A variety of drugs can increase the risk of cisapride-induced dysrhythmias. Several mechanisms are involved. Some drugs (eg, erythromycin, ketoconazole) inhibit CYP3A4, and thereby increase cisapride levels. Other drugs (eg, quinidine, bepridil) prolong the QT interval. And still others (eg, loop diuretics, thiazide diuretics) promote hypokalemia. [Table 79-6](#) lists many of the drugs that can interact adversely with cisapride. All of them should be avoided.

80.6.2.6 Preparations, Dosage, and Administration.

Cisapride [Propulsid] is formulated in tablets (10 and 20 mg) and an oral suspension (10 mg/mL). The recommended dosage is 10 mg 4 times a day. Dosing is done at least 15 minutes before meals and at bedtime. Some patients may need 20-mg doses. To reduce the risk of adverse effects, the lowest effective dosage should be used. Dosage should be reduced by 50% in patients with liver impairment. If nocturnal heartburn continues, cisapride should be stopped.

80.7 PALIFERMIN

Palifermin [Kepivance] is the first drug to be approved for decreasing oral mucositis (OM), a serious and painful complication of cancer chemoradiotherapy. For reasons discussed below, palifermin is currently indicated only for patients with hematologic malignancies. Side effects of the drug are generally mild.

80.7.1 Mechanism of Action

Palifermin is a synthetic form of human keratinocyte growth factor (KGF), a naturally occurring compound. Commercial production is by recombinant DNA technology. Palifermin acts through KGF receptors, which are found on epithelial cells in many structures, including the tongue,

buccal mu-cosa, esophagus, stomach, intestine, salivary gland, liver, lung, pancreas, kidney,

bladder, mammary glands, skin (hair follicles and sebaceous glands), and lens of the eye.

Importantly, KGF receptors are *not* found on cells of hematopoietic origin. When palifermin binds with KGF receptors, it stimulates proliferation, differentiation, and migration of epithelial cells. In mice and rats, KGF increased the thickness of epithelial tissue in the tongue, buccal mucosa, and GI tract. Similarly, in healthy human volunteers, palifermin produced dose-dependent proliferation of epithelial cells in the buccal mucosa.

948

949

80.7.2 Indications and Clinical Benefits

Palifermin is approved for decreasing the incidence and duration of severe OM—but only in patients with *hematologic* malignancies, and then only in those receiving high-dose chemotherapy and whole-body irradiation (to eradicate cancer cells prior to a hematopoietic stem cell transplant). In one trial, palifermin reduced the incidence of OM (67% vs. 80% with placebo) as well as the duration (4 days vs. 6 days with placebo). In a second trial, the results were similar: palifermin again reduced both the incidence of OM (63% vs. 98% with placebo) and the duration (6 days vs. 9 days with placebo). In both trials, palifermin reduced the need for pain relief with opioid analgesics, and the need for supplemental parenteral nutrition.

At this time, palifermin therapy is restricted to patients with hematologic malignancies. Why? Because, in experimental models, palifermin can stimulate proliferation of certain malignant cells of nonhematologic origin—specifically, malignant epithelial cells that bear KGF receptors. Palifermin is safe for patients with hematologic cancers because these cancers do not have KGF receptors. As we learn more about the safety of palifermin in nonhematologic cancers, indications for the drug are likely to expand.

80.7.3 Pharmacokinetics

Information on the kinetics of palifermin is limited. Plasma levels of the drug decline by 95% within 30 minutes of IV dosing, and decline at a slower rate thereafter. The terminal half-life is about 4.5 hours. Giving single doses on 3 consecutive days does result in drug accumulation.

80.7.4 Adverse Effects

Palifermin is generally well tolerated. The most common reactions affect the skin and the mouth. Among these are rash, erythema, edema, pruritus, distortion of taste, thickening and/or discoloration of the tongue, and oral or perioral dysesthesias (unpleasant sensations produced by ordinary stimuli). The most serious reaction is skin rash, which develops in less than 1% of patients. In some patients, serum levels of amylase and lipase rise, suggesting possible injury to the pancreas. Because palifermin can stimulate epithelial growth in the lens, there is concern that it might affect vision.

80.7.5 Drug Interactions

Palifermin binds with *heparin*. Accordingly, if there is heparin in the IV line to be used for palifermin administration, the line should be flushed with saline before giving the drug.

If the interval between giving palifermin and anticancer drugs is too small, palifermin may *increase* the severity and duration of oral mucositis. Accordingly, dosing with palifermin should cease at least 24 hours before giving chemotherapy, and should not resume for at least 24 hours after.

80.7.6 Preparations, Dosage, and Administration

Palifermin [Kepivance] is supplied as a powder (6.25 mg in single-dose vials) for reconstitution with 1.2 mL of sterile water for injection. Administration is by IV bolus. Dosing is done once daily on 3 consecutive days before chemotherapy and on 3 consecutive days after, for a total of six doses. Each dose is 60 mcg/kg. The first dose is given 3 to 4 days before chemotherapy (so that the third dose can be given 1 to 2 days before chemotherapy). The fourth is given at least 4 days after the third dose of palifermin, and at least 1 day after stem cell infusion. Palifermin should be stored under refrigeration, protected from light, and used immediately after reconstitution.

Palifermin is expensive: A six-dose course costs about \$10,000.

80.8 PANCREATIC ENZYMES

The pancreas produces four digestive enzymes: *lipase*, *amylase*, *chymotrypsin*, and *trypsin*. These enzymes are secreted into the duodenum, where they help digest fats, carbohydrates, and proteins. To protect the enzymes from stomach acid and pepsin, the pancreas secretes bicarbonate. The bicarbonate neutralizes acid in the duodenum, and the resulting elevation in pH inactivates pepsin.

Deficiency of pancreatic enzymes can compromise digestion, especially digestion of fats. Fatty stools are characteristic of the deficiency. When secretion of pancreatic enzymes is reduced, replacement therapy is needed. Causes of deficiency include pancreatectomy, cystic fibrosis, pancreatitis, and obstruction of the pancreatic duct.

Pancreatic enzymes are available as two basic preparations: *pancreatin* and *pancrelipase*. Pancreatin is made from hog or beef pancreas. Pancrelipase is made from hog pancreas. Pancrelipase has enzyme activity far greater than that of pancreatin. As a result, pancrelipase is preferred. Trade names for pancrelipase include *Viokase*, *Lipram*, *Pancrease MT*, and *Pancrecarb MS*.

Both pancreatin and pancrelipase are available in capsules that contain enteric-coated microspheres. The microsphere-containing preparations are preferred to conventional formulations (tablets, capsules) because the conventional formulations frequently fail to dissolve in the appropriate region of the intestine (ie, the duodenum and upper jejunum).

Acid suppressants (eg, histamine₂ receptor blockers, proton pump inhibitors) may be employed as adjuvants to pancreatic enzyme therapy. The objective is to reduce gastric pH, thereby protecting the

enzymes from inactivation. However, acid suppressants are beneficial only when acid secretion is excessive.

Adverse reactions to pancreatic enzymes are rare. Allergic reactions occur occasionally. Large doses can cause diarrhea, nausea, and cramping.

Dosage is adjusted on an individual basis. Determining factors include the extent of enzyme deficiency, dietary fat content, and enzyme activity of the preparation selected. The efficacy of therapy can be evaluated by measuring the reduction in 24-hour fat excretion. Pancreatic enzymes should be taken with every meal and snack.

^{80.9} DRUGS USED TO DISSOLVE GALLSTONES

The gallbladder serves as a repository for bile, a fluid composed of cholesterol, bile acids, and other substances. Following its production in the liver, bile may be secreted directly into the small intestine or it may be transferred to the gallbladder, where it is concentrated and stored.

Bile has two principal functions: it (1) aids in the digestion of fats, and (2) serves as the only medium by which cholesterol is excreted from the body. The acids in bile facilitate the absorption of fats. In addition, bile acids help solubilize cholesterol.

Cholelithiasis—development of gallstones—is the most common form of gallbladder disease. Most stones are formed from cholesterol. Stones made of cholesterol alone cannot be detected with x-rays, and hence are said to be *radiolucent*. In contrast, stones that contain calcium (in addition to cholesterol) are *radiopaque* (ie, they absorb x-rays and therefore can be seen in a radiograph). Risk factors for cholelithiasis include obesity and high plasma cholesterol.

For many people, gallstones can be present for years without causing symptoms. When symptoms do develop, they can be much like those of indigestion (bloating, abdominal discomfort, gassiness). If a stone should lodge in the bile duct, severe pain and jaundice may result.

Cholelithiasis may be treated by cholecystectomy (surgical removal of the gallbladder) or with drugs. As a rule, when intervention is required, cholecystectomy is the preferred modality. In asymptomatic patients, more conservative measures (weight loss and reduced fat intake) may be indicated. Medications employed to dissolve gallstones are discussed below.

949

80.9.1 Chenodiol (Chenodeoxycholic Acid)**80.9.1.1 Actions.**

Chenodiol [Chenix] is a naturally occurring bile acid that reduces hepatic production of cholesterol. Reduced cholesterol production lowers the cholesterol content of bile, which in turn facilitates the gradual dissolution of cholesterol gallstones. Chenodiol may also increase the amount of bile acid in bile, an effect that may enhance cholesterol solubility. It should be noted that chenodiol is useful only for dissolving radiolucent stones. Radiopaque stones (stones with significant calcium content) are not affected.

80.9.1.2 Therapeutic Use.

Chenodiol is given to promote dissolution of cholesterol gallstones, but only in carefully selected patients. Success is most likely in women who have low cholesterol levels, stones of small size, and the ability to tolerate high doses of the drug. Complete disappearance of stones occurs in only 20% to 40% of patients. Therapy is usually prolonged; 2 years is common.

80.9.1.3 Adverse Effects.

Dose-dependent diarrhea occurs in 30% to 40% of patients. Of much greater concern, chenodiol can injure the liver. Hence, patients must have periodic tests of liver function. Because chenodiol is hepatotoxic, the drug is contraindicated for patients with pre-existing liver disease. Chenodiol is also contraindicated during pregnancy (FDA Pregnancy Risk Category X).

80.9.2 Ursodiol (Ursodeoxycholic Acid)

Ursodiol [Actigall, URSO 250, URSO forte] is an analog of chenodiol. Like chenodiol, ursodiol reduces the cholesterol content of bile, thereby facilitating the gradual dissolution of cholesterol gallstones. In contrast to chenodiol, ursodiol does not increase production of bile acids. Like chenodiol, ursodiol promotes dissolution of *radiolucent* gallstones but not radiopaque gallstones. Ursodiol is indicated for dissolution of cholesterol gallstones in carefully selected patients.

Ursodiol is well tolerated. Significant adverse effects are rare. The drug is classified in FDA Pregnancy Risk Category B.

Ursodiol is formulated in capsules (300 mg) and tablets (250 and 500 mg). The usual adult dosage for dissolving gallstones is 4 to 5 mg/kg twice daily (1 capsule or tablet in the morning and 1 in the evening). Treatment lasts for months.

80... ANORECTAL PREPARATIONS

Anorectal preparations can provide symptomatic relief from the discomfort of hemorrhoids and other anorectal disorders. The composition of these preparations varies widely. *Local anesthetics* (eg, benzocaine, dibucaine) and *hydrocortisone* (a glucocorticoid) are common ingredients. Hydrocortisone suppresses inflammation, itching, and swelling. Local anesthetics reduce itching and pain. Anorectal preparations may also contain *emollients* (eg, mineral oil, lanolin), whose lubricant properties reduce irritation, and *astringents* (eg, bismuth subgallate, witch hazel, zinc oxide), which reduce irritation and inflammation. Anorectal preparations are available in multiple formulations: suppositories, creams, ointments, lotions, foams, tissues, and pads. Trade names include *Preparation H*, *Rectagene*, and *Anusol*.

80.10.1 KEY POINTS

- Emesis results from activation of the vomiting center, which receives its principal stimulatory inputs from the chemoreceptor trigger zone (CTZ), cerebral cortex, and inner ear.
- Serotonin antagonists, such as ondansetron [Zofran], are the most effective antiemetics available.
- Aprepitant (an antiemetic) is the first member of a new class of drugs: the substance P/neurokinin₁ receptor antagonists. Unlike most antiemetics, aprepitant can prevent *delayed* chemotherapy-induced nausea and vomiting (CINV) as well as *acute* CINV.
- To suppress CINV, a combination of drugs is more effective than monotherapy.
- For patients receiving highly emetogenic chemotherapy, the preferred antiemetic regimen consists of three drugs: aprepitant, a glucocorticoid (eg, dexamethasone), and a serotonin antagonist (eg, ondansetron).
- For management of CINV, antiemetics are more effective when given before chemotherapy (to prevent emesis) than when given after chemotherapy (in an effort to stop ongoing emesis).
- Opioids (eg, diphenoxylate) are the most effective antidiarrheal agents available.
- Traveler's diarrhea can be treated with loperamide (a nonspecific antidiarrheal drug), a fluoroquinolone antibiotic (eg, ciprofloxacin), or azithromycin (for children and pregnant women).

- Irritable bowel syndrome (IBS) is the most common disorder of the GI tract.
- Although three drugs are FDA approved for IBS, only two of them—alosetron and lubiprostone—are generally available.
- Alosetron is approved for IBS-D in women. Benefits derive from blocking 5-HT₃ receptors on neurons that innervate the viscera.
- Alosetron can cause ischemic colitis and severe constipation. Colitis and complications of constipation have led to hospitalization, blood transfusion, surgery, and death.
- Lubiprostone is approved for IBS-C in women. Benefits derive from activating (opening) chloride channels in the intestine.
- Inflammatory bowel disease (ulcerative colitis and Crohn's disease) is treated with 5-aminosalicylates (eg, sulfasalazine, mesalamine), glucocorticoids (eg, dexamethasone, budesonide), immunosuppressants (eg, azathioprine, mercaptopurine, infliximab), immunomodulators (eg, infliximab, certolizumab), and antibiotics (eg, metronidazole, ciprofloxacin).
- Metoclopramide, a prokinetic agent, has two beneficial actions: it increases upper GI motility and suppresses emesis.
- Palifermin is used to reduce the intensity and duration of oral mucositis in patients with hematologic malignancy undergoing intensive radiochemotherapy.

⁸¹CHAPTER 80 Vitamins

Vitamins have the following defining characteristics: (1) they are *organic compounds*, (2) they are required in *minute amounts* for growth and maintenance of health, and (3) they do not serve as a source of energy (in contrast to fats, carbohydrates, and proteins), but rather are *essential for energy transformation and regulation of metabolic processes*. Several vitamins are inactive in their native form and must be converted to active compounds in the body.

^{81.1}GENERAL CONSIDERATIONS

^{81.1.1}Dietary Reference Intakes

Reference values on dietary vitamin intake, as set by the Food and Nutrition Board of the Institute of Medicine of the National Academy of Sciences, were established to provide a standard for good nutrition. In a 1998 report—*Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B₆, Folate, Vitamin B₁₂, Pantothenic Acid, Biotin, and Choline*—the Food and Nutrition Board defined four reference values: *recommended dietary allowance* (RDA), *Adequate Intake* (AI), *Tolerable Upper Intake Level* (UL), and *Estimated Average Requirement* (EAR). Collectively, these four values are referred to as *Dietary Reference Intakes* (DRIs).

^{81.1.1.1}Recommended Dietary Allowance.

The RDA is the average daily dietary intake sufficient to meet the nutrient requirements of nearly all (97% to 98%) healthy individuals. RDAs are based on extensive experimental data. Because RDAs represent *average* daily intakes, low intake on one day can be compensated for by high intake on another day. RDAs change as we grow older. In addition, they often differ for males and females, and typically increase for women who are pregnant or breast-feeding. You should appreciate that RDAs apply only to individuals in good health. Vitamin requirements can be increased by illness, and therefore published RDA values may not be appropriate for sick people. RDAs are revised periodically as new information becomes available. [Table 80-1](#) summarizes when the most recent revisions were made.

^{81.1.1.2}Adequate Intake.

The AI is an *estimate* of the average daily intake required to meet nutritional needs. AIs are employed when experimental evidence is not strong enough to establish an RDA. AIs are set with the expectation that they will meet the needs of all individuals. However, because AIs are only estimates, there is no guarantee they are adequate.

81.1.1.3 Tolerable Upper Intake Level.

The UL is the highest average daily intake that can be consumed by nearly everyone without a significant risk of adverse effects. Please note that the UL is not a *recommended* upper limit for intake. It is simply an index of safety. There is no known benefit to exceeding the RDA.

81.1.1.4 Estimated Average Requirement.

The EAR is the level of intake that will meet nutrition requirements for 50% of the healthy individuals in any life-stage or gender group. By definition, the EAR will be insufficient for the other 50%. The EAR for a vitamin is based on extensive experimental data, and serves as the basis for establishing an RDA. If there is not enough information to establish an EAR, no RDA can be set. Instead, an AI is assigned, using the limited data on hand.

81.1.2 Classification of Vitamins

The vitamins are divided into two major groups: *fat-soluble vitamins* and *water-soluble vitamins*. In the fat-soluble group are vitamins A, D, E, and K. The water-soluble group consists of vitamin C and members of the vitamin B complex (thiamin, riboflavin, niacin, pyridoxine, pantothenic acid, biotin, folic acid, and cyanocobalamin). Except for vitamin B₁₂, water-soluble vitamins undergo minimal storage in the body, and hence frequent ingestion is needed to replenish supplies. In contrast, fat-soluble vitamins can be stored in massive amounts, which is good news and bad news. The good news is that extensive storage minimizes the risk of deficiency. The bad news is that extensive storage greatly increases the potential for toxicity if intake is excessive.

81.1.3 Should We Take Multivitamin Supplements?

In the United States, we spend about \$3.5 billion a year on multivitamin and multimineral supplements—with the hope of preventing cancer, heart disease, bone loss, and other chronic disorders. Is the money well spent? Maybe. Maybe not. According to an expert panel—convened by the Office of Dietary Supplements at the National Institutes of Health—there is insufficient evidence to recommend either for or against the use of multivitamins by Americans to prevent chronic disease. Hence, as one official put it, “If you're taking a multivitamin, there's no reason to stop—but if you're not taking a multivitamin, there's no reason to start, either.” The panel's findings were published in a January 2007 supplement to the *American Journal of Clinical Nutrition*.

951

952

TABLE 80-1 Where to Find Food and Nutrition Board Updates for Specific Vitamins^{*}

Vitamin	Publication	Date
Vitamin D	Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D, and Fluoride	1997
Biotin, folate, niacin, pantothenic acid, riboflavin, thiamin, and vitamins B ₆ and B ₁₂	Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B ₆ , Folate, Vitamin B ₁₂ , Pantothenic Acid, Biotin, and Choline	1998
Vitamins C and E	Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids	2000
Vitamins A and K	Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc	2002

* All publications are from the Food and Nutrition Board, Institute of Medicine, and published by the National Academy Press, Washington, DC.

For people who *do* take a multivitamin supplement, the dosage should be moderate. Why? Because excessive doses can cause harm. For example, too much vitamin A increases the risk of osteoporosis in postmenopausal women, and can cause birth defects when taken early in pregnancy. In people who smoke, too much beta-carotene (a precursor of vitamin A), increases the risk of lung cancer. And in older people with chronic health problems, too much vitamin E increases the risk of death. Because of these and other concerns, high-dose multivitamin supplements should be avoided. Instead, supplements that supply 100% or *less* of the RDA should be used.

Although research supporting the use of *multi* vitamin supplements is inconclusive, we do have solid data supporting the use of three *individual* vitamins—namely, vitamin B₁₂, folic acid, and vitamin D. Who should take these vitamins? Nutrition experts recommend vitamin B₁₂ for all people over age 50, folic acid for all women of child-bearing age, and vitamin D (plus calcium) for postmenopausal women and other people at risk of fractures.

81.2 FAT-SOLUBLE VITAMINS

81.2.1 Vitamin A (Retinol)

81.2.1.1 Actions.

Vitamin A, also known as retinol, has multiple functions. In the eyes, vitamin A plays an important role in adaptation to dim light. The vitamin also has a role in embryogenesis, spermatogenesis, immunity, growth, and maintaining the structural and functional integrity of the skin and mucous membranes.

81.2.1.2 Sources.

Requirements for vitamin A can be met by (1) consuming foods that contain *preformed vitamin A* (retinol) and (2) consuming foods that contain *provitamin A carotenoids* (beta-carotene, alpha-carotene, beta-cryptoxanthin), which are converted to retinol by cells of the intestinal mucosa. Preformed vitamin A is present only in foods of animal origin. Good sources are dairy products, meat, fish oil, and fish. Provitamin A carotenoids are found in darkly colored, carotene-rich fruits and vegetables. Especially rich sources are carrots, cantaloupe, mangoes, spinach, tomatoes, pumpkins, and sweet potatoes.

81.2.1.3 Units.

The unit employed to measure vitamin A activity is called the *retinol activity equivalent* (RAE). By definition, 1 RAE equals 1 mcg of retinol, 12 mcg of beta-carotene, 24 mcg of alpha-carotene, or 24 mcg of beta-cryptoxanthin. Why are the RAEs for the provitamin A carotenoids 12 to 24 times higher than the RAE for retinol? Because dietary carotenoids are poorly absorbed and incompletely converted into retinol. Hence, to produce the nutritional equivalent of retinol, we need to ingest much higher amounts of the carotenoids. In the past, vitamin A activity was measured in international units (IU). One IU is equal to 0.3 RAEs.

81.2.1.4 Requirements.

RDAs for vitamin A were revised in 2002. The new RDAs are slightly lower than the values established in 1989. The new RDA for adult males is 900 RAEs, and the RDA for adult females is 700 RAEs. RDAs for individuals in other life-stage groups are shown in [Table 80-2](#).

81.2.1.5 Pharmacokinetics.

Under normal conditions, dietary vitamin A is readily absorbed and then stored in the liver. As a rule, liver reserves of vitamin A are large and will last months if intake of retinol ceases. Normal plasma levels for retinol range between 30 and 70 mcg/dL. In the absence of vitamin A intake, levels are maintained through mobilization of liver reserves. As liver stores approach depletion, plasma levels begin to decline. Signs and symptoms of deficiency appear when plasma levels fall below 20 mcg/dL.

81.2.1.6 Deficiency.

Because vitamin A is needed for dark adaptation, night blindness is often the first indication of deficiency. With time, vitamin A deficiency may lead to *xerophthalmia* (a dry, thickened condition of the conjunctiva) and *keratomalacia* (degeneration of the cornea with keratinization of the corneal epithelium). When vitamin A deficiency is severe, blindness may occur. In addition to effects on the eye, deficiency can produce skin lesions and dysfunction of mucous membranes.

81.2.1.7 Toxicity.

In high doses, vitamin A can cause birth defects, liver injury, and bone-related disorders. To reduce risk, the Food and Nutrition Board has set the UL for vitamin A at 3000 mcg/day.

Vitamin A is highly *teratogenic*. Excessive intake during pregnancy can cause malformation of the fetal heart, skull, and other structures of cranial–neural crest origin. Risk is highest among women taking vitamin A supplements. Pregnant women should definitely not exceed the UL for vitamin A, and should probably not exceed the RDA.

Excessive doses can cause a toxic state, referred to as *hypervitaminosis A*. Chronic intoxication affects multiple organ systems, especially the liver. Symptoms are diverse and may include vomiting, jaundice, hepatosplenomegaly, skin changes, hypomenorrhea, and elevation of intracranial pressure. Most symptoms disappear following vitamin A withdrawal.

Vitamin A excess can damage bone. In infants and young children, vitamin A can cause bulging of the skull at sites where bone has not yet formed. In adult females, too much vitamin A can increase the risk of hip fracture—apparently by blocking the ability of vitamin D to enhance calcium absorption.

81.2.1.8 Therapeutic Uses.

The only indication for vitamin A is prevention or correction of vitamin A deficiency. Contrary to earlier hopes, it is now clear that vitamin A, in the form of beta-carotene supplements, does not decrease the risk of cancer or cardiovascular disease. In fact, in a study comparing placebo with dietary supplements (beta-carotene plus vitamin A), subjects taking the supplements had a significantly *increased* risk of lung cancer and overall mortality. As discussed in [Chapter 104](#), certain derivatives of vitamin A (eg, isotretinoin, etretinate) are used to treat acne and other dermatologic disorders.

81.2.1.9 Preparations, Dosage, and Administration.

Vitamin A (retinol) is available in drops, tablets, and capsules for oral administration and in solution for IM injection. Oral administration is generally preferred. To *prevent* deficiency, dietary plus supplemental vitamin A should add up to the RDA (see [Table 80-2](#)). To *treat* deficiency, doses up to 100 times the RDA may be required.

81.2.2 Vitamin D

Vitamin D plays a critical role in regulating metabolism of calcium and phosphorus. The classic effects of deficiency are *rickets* (in children) and *osteomalacia* (in adults). In addition to these effects on bone, vitamin D deficiency may increase the risk of breast cancer, colorectal cancer, type 1 diabetes (in children), falls (in the elderly), and overall mortality. Excessive amounts of vitamin D are toxic. Symptoms result primarily from hypercalcemia. The pharmacology and physiology of vitamin D are discussed at length in [Chapter 74](#). Values for adequate intake are summarized in [Table 80-2](#). At this time, RDAs are not available.

81.2.3 Vitamin E (Alpha-Tocopherol)

Vitamin E (alpha-tocopherol) is essential to the health of many animal species, but has no clearly established role in human nutrition. Unlike other vitamins, vitamin E has no known role in metabolism. Deficiency, which is rare, can result in neurologic deficits.

Vitamin E helps maintain health primarily through antioxidant actions. Specifically, the vitamin helps protect against peroxidation of lipids. Observational studies suggest that vitamin E may protect against cardiovascular disease and cancer. However, more rigorous studies have failed to show any such benefits ([Box 80-1](#)). Moreover, there *is* evidence that high doses of vitamin E may actually increase the risk of heart failure, cancer progression, and all-cause mortality.

81.2.3.1 Forms of Vitamin E.

Vitamin E exists in a variety of forms (eg, alpha-tocopherol, beta-tocopherol, alpha-tocotrienol), each of which has multiple stereoisomers. However, only four stereoisomers are found in our blood, all of them variants of *alpha-tocopherol*. These isomers are designated *RRR*-, *RRS*-, *RSR*-, and *RSS*-alpha-tocopherol. Of the four, only *RRR-alpha-tocopherol* occurs naturally in foods. However, all four can be found in fortified foods and dietary supplements. Why are other forms of vitamin E absent from blood? Because they are unable to bind to *alpha-tocopherol transfer protein* (alpha-TTP), the hepatic protein required for secretion of vitamin E from the liver and subsequent transport throughout the body.

81.2.3.2 Sources.

Most dietary vitamin E comes from vegetable oils (eg, corn oil, olive oil, cottonseed oil, safflower oil, canola oil). The vitamin is also found in nuts, wheat germ, whole-grain products, and mustard greens.

81.2.3.3 Requirements.

RDAs for vitamin E were revised in 2000 (see [Table 80-2](#)). For men and women, the RDA is 15 mg/day (22.5 IU). RDAs increase for women who are breast-feeding, but not for those who are pregnant. The UL for vitamin E is 1000 mg (1500 IU) daily.

81.2.3.4 Deficiency.

Vitamin E deficiency is rare. In the United States, deficiency is limited primarily to people with an inborn deficiency of alpha-TTP and to those who have fat malabsorption syndromes, and hence cannot absorb fat-soluble vitamins. Symptoms of deficiency include ataxia, sensory neuropathy, areflexia, and muscle hypertrophy.

81.2.3.5 Potential Benefits.

There is evidence that 200 IU of vitamin E daily may reduce the risk of colds in the elderly, and 400 IU daily (in combination with vitamin C, beta-carotene, zinc, and copper) may delay progression of age-related macular degeneration. Vitamin E does not prevent age-related wrinkles and, as discussed in [Box 80-1](#), does not protect against cardiovascular disease or cancer.

81.2.3.6 Potential Risks.

Excessive vitamin E may increase the risk of *bleeding*. In animals, vitamin E can suppress coagulation, increase prothrombin time, and cause hemorrhage—but only at *very* high doses (eg, 500 mg/kg/day). Furthermore, vitamin E–induced bleeding can be counteracted by vitamin K, which promotes synthesis of clotting factors. Data on the hemorrhagic effects of vitamin E in humans are inconsistent. Individuals who are vitamin K deficient may be at some risk.

A study published in 2005 showed that, in patients with head and neck cancer, vitamin E (400 IU daily) was associated with a *decrease* in cancer-free survival. These results are consistent with the theory that antioxidants may accelerate cancer progression.

A study published in 2004 concluded that doses of vitamin E only 9 times the RDA may increase the risk of *death*, especially in older people with additional risk factors. The study, a meta-analysis of 19 clinical trials, indicated that the risk of all-cause mortality was increased by long-term therapy with daily doses of 400 IU (266 mg) or higher. There was no increased risk at daily doses below 200 IU (133 mg). The authors recommend that the UL for vitamin E—currently set at 1500 IU daily—be reduced.

81.2.4 Vitamin K

81.2.4.1 Action.

Vitamin K is required for synthesis of prothrombin and three other clotting factors: VII, IX, and X. All of these vitamin K–dependent factors are needed for coagulation of blood.

81.2.4.2 Forms and Sources of Vitamin K.

Vitamin K occurs in nature in two forms: (1) vitamin K₁, or phytonadione (phylloquinone); and (2) vitamin K₂. Phytonadione is present in a wide variety of foods. Vitamin K₂ is synthesized by the normal flora of the gut. Two other forms—vitamin K₄ (menadiol) and vitamin K₃ (menadione)—are produced synthetically. At this time, phytonadione is the only form of vitamin K available for therapeutic use.

81.2.4.3 Requirements.

Human requirements for vitamin K have not been precisely defined. In 2002, the Food and Nutrition Board set the AI for adult males at 120 mcg, and the AI for adult females at 90 mcg. AIs for other life-stage groups are shown in [Table 80-2](#). For most individuals, vitamin K requirements are readily met through dietary sources, and through vitamin K synthesized by

953

intestinal bacteria. Since bacterial colonization of the gut is not complete until several days after birth, levels of vitamin K may be low in newborns.

TABLE 80-2 Recommended Vitamin Intakes for Individuals

Recommended Vitamin Intake Per Day													
Life-Stage Group	Vitamin A (mcg) ^a	Vitamin C (mg)	Vitamin D (mcg) ^{b,c}	Vitamin E (mg) ^d	Vitamin K (mcg)	Thiamin (mg)	Riboflavin (mg)	Niacin (mg) ^e	Vitamin B ₆ (mg)	Folate (mcg) ^f	Vitamin B ₁₂ (mcg)	Pantothenic Acid (mg)	Biotin (mcg)

Data from a summary table in Food and Nutrition Board, Institute of Medicine: Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc. Washington, DC: National Academy Press, 2002:770–771. However, except for the information on vitamins A and K, all of the information in this table was first released in the earlier publications listed in [Table 80-1](#).

NOTE: This table presents recommended dietary allowances (RDAs) in bold type and Adequate Intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97% to 98%) individuals in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life-stage and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

- a As retinol activity equivalents (RAEs): 1 RAE = 1 mcg retinol, 12 mcg beta-carotene, 24 mcg alpha-carotene, or 24 mcg beta-cryptoxanthin. To calculate RAEs from retinol equivalents (REs) of provitamin A carotenoids in foods, divide the REs by 2. For preformed vitamin A in foods or supplements and for provitamin A carotenoids in supplements, 1 RE = 1 RAE.
- b As cholecalciferol: 1 mcg cholecalciferol = 40 IU vitamin D.
- c In the absence of adequate exposure to sunlight.
- d As alpha-tocopherol. Alpha-tocopherol includes *RRR*-alpha-tocopherol, the only form of alpha-tocopherol that occurs naturally in foods, and the 2R-stereoisomeric forms of alpha-tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*-alpha-tocopherol) that occur in fortified foods and supplements. It does not include the 2S-stereoisomeric forms of alpha-tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*-alpha-tocopherol), also found in fortified foods and supplements.
- e As niacin equivalents (NE): 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE).
- f As dietary folate equivalents (DFEs): 1 DFE = 1 mcg food folate = 0.6 mcg of folic acid from fortified food or as a supplement consumed with food = 0.5 mcg of a supplement taken on an empty stomach.
- g In 2008, the American Academy of Pediatrics recommended that all children—from infancy through adolescence—take in 10 mcg cholecalciferol (400 IU of vitamin D) each day.
- h In view of evidence linking folate deficiency with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 mcg from supplements or fortified foods in addition to intake of food folate from a varied diet.
- i It is assumed that women will continue consuming 400 mcg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period—the critical time for formation of the neural tube.
- j Because 10% to 30% of older people may absorb food-bound B₁₂ poorly, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with B₁₂ or by consuming a supplement containing B₁₂.

81.2.4.3.1

BOX 80-1 Special Interest Topic

81.2.4.3.1.1

LOSING HOPE FOR ANTIOXIDANTS

On April 10, 2000, the National Academy of Sciences issued a report stating there is no conclusive evidence that megadoses of dietary antioxidants can protect against cancer, heart disease, Alzheimer's disease, or any other chronic disorder. Furthermore, they noted that excessive doses can cause harm. Accordingly, they recommended limiting intake of antioxidants to amounts that will prevent nutritional deficiency, and recommended avoiding doses that are potentially harmful. The report, titled *Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids*, is available from the National Academy Press. On February 28, 2007, the conclusions of this report were strongly reinforced by a study published in JAMA that found that antioxidants do not help users live longer, and may actually *increase* the risk mortality.

Dietary antioxidants are defined as substances present in food that can significantly decrease cellular and tissue injury caused by highly reactive forms of oxygen and nitrogen, known as “free radicals.” These free radicals, which are normal by-products of metabolism, readily react with other molecules. The result is tissue injury known as “oxidative stress.” Antioxidants help reduce oxidative stress by neutralizing free radicals before they can cause harm. There is no question that dietary antioxidants can decrease injury. However, the available data are insufficient to prove that taking large doses can reduce the risk of chronic disease.

Which dietary constituents function as antioxidants? There is good evidence that three compounds—*selenium*, *vitamin C*, and *vitamin E*—exert significant antioxidant actions. Data for *beta-carotene* (a precursor of vitamin A) are less clear: Although beta-carotene has antioxidant activity *in vitro*, convincing evidence of *in vivo* antioxidant activity is lacking.

How might antioxidants protect against chronic disease? By reducing oxidative damage to DNA, they could reduce the risk of cancer. By reducing oxidation of LDL cholesterol, a critical step in the formation of atherosclerotic plaque, they could protect against heart disease. Reducing oxidation of other biologic molecules could explain protection against other diseases.

Researchers have been studying the clinical effects of antioxidants for more than a decade. Unfortunately, although initial findings were encouraging, more recent studies indicate that benefits are generally lacking.

When evaluating antioxidants for clinical effects, scientists have conducted two kinds of studies: *observational studies* and *randomized controlled trials* (RCTs). Observational studies are based on patient histories: for example, what did patients eat, and what was their medical status? In contrast, RCTs are rigorous, prospective studies in which patients are randomly assigned to either an experimental group or a placebo group; conclusions are based on differences between the two. The results of RCTs are much more reliable than the results of observational studies.

Nearly all of the early studies on antioxidants were observational. These studies indicated that daily consumption of vegetables rich in antioxidants is associated with a reduced risk of heart disease and several types of cancer. The problem is, these results have more than one interpretation. Yes, they may mean that antioxidant vitamins protected against heart disease and cancer. However, they may also mean that protection was conferred by some other component of the diet (eg, high fiber content and/or low content of cholesterol and saturated fat). Or, perhaps diet had nothing to do with it: Maybe protection resulted from a generally healthy lifestyle, and not from a healthy diet. Hence, although observational studies suggest that antioxidants may protect against heart disease and cancer, they certainly don't prove it.

To establish definitive proof of cardiovascular benefits, scientists conducted large RCTs. The outcomes were both unexpected and discouraging. Two studies on vitamin E are especially noteworthy: (1) the *Heart Outcomes Prevention Evaluation (HOPE) Study* and (2) the *GISSI-Prevenzione* trial. Results of HOPE, the most definitive RCT on antioxidants to date, were reported in the January 20, 2000, issue of the *New England Journal of Medicine*. The HOPE trial enrolled 9541 patients ages 55 and older, of whom 80% had cardiovascular disease and 40% had diabetes. Half the patients were given 400 IU of vitamin E daily, and half received a placebo. In addition, the patients were randomly assigned to receive either ramipril (an angiotensin-converting enzyme inhibitor) or a second placebo. After 4.5 years, the results were conclusive: Ramipril provided clear protection against cardiovascular events, whereas vitamin E provided none. A 2.5-year extension of the HOPE trial, known as HOPE-TOO (for HOPE—The Ongoing Outcomes) reinforced the original data: Over a median interval of 7 years, vitamin E was no better than placebo at preventing cancer, cancer deaths, or the combined endpoint of stroke, myocardial infarction (MI), or cardiovascular death. In August 1999, an Italian group reported similar results in the British journal *Lancet*. Their study, the GISSI-Prevenzione trial, involved 11,000 patients who had suffered an MI. Half were randomly assigned treatment with vitamin E (300 IU daily) and half were given placebo. After 3.5 years, the incidence of nonfatal MI and death from coronary heart disease was the same for both

groups, indicating no protection from vitamin E. Results of other RCTs support the results of these two.

Not only has vitamin E failed to protect against cardiovascular disease in RCTs, there are data suggesting it may actually cause harm. In the HOPE trial, vitamin E was associated with an *increased* risk of heart failure. Furthermore, a recent meta-analysis of 19 clinical trials involving 135,967 subjects indicated that high-dose vitamin E (400 IU a day or more) increased the risk of all-cause mortality.

Do the HOPE trial and other RCTs tell us that antioxidants confer virtually no protection against cardiovascular disease? With each new study, the possibility of protective effects seems less and less likely. However, before we give up on antioxidants entirely, we need to investigate the following:

- *Prolonged treatment*—RCTs to date were conducted for a relatively short time (3.5 to 7 years). Perhaps giving vitamin E for a longer time would reveal benefits. However, the Physician's Health Study argues against this: 12 years of treatment with beta-carotene (a suspected antioxidant) offered no benefit.
- *Effect in healthy subjects*—RCTs to date have been conducted on people with pre-existing heart disease. Perhaps antioxidants can *prevent* heart disease in healthy subjects, even if they can't *reverse* it in sick ones.
- *Combination vitamin therapy*—Most RCTs to date evaluated monotherapy with vitamin E. Perhaps benefits would be revealed if vitamin E were combined with other antioxidants, as occurs when we eat vitamin-containing foods.

Even if vitamin E and other antioxidants prove devoid of cardiovascular benefits, the story doesn't end there. These agents may still offer protection against other disorders. For example, recent data indicate that vitamin E may delay the progression of age-related macular degeneration. Other target disorders under investigation include cataracts, Alzheimer's disease, the common cold, and advanced renal failure. Results of ongoing RCTs should provide further insight.

81.2.4.4 Pharmacokinetics.

Intestinal absorption of the natural forms of vitamin K (phytonadione and vitamin K₂) is adequate only in the presence of bile salts. Menadione and menadiol do not require bile salts for absorption. Following absorption, vitamin K is concentrated in the liver. Metabolism and secretion occur rapidly. Very little is stored.

81.2.4.5 Deficiency.

Vitamin K deficiency produces bleeding tendencies. If the deficiency is severe, spontaneous hemorrhage may occur. In newborns, intracranial hemorrhage is of particular concern.

An important cause of deficiency is reduced absorption. Since the natural forms of vitamin K require bile salts for their uptake, any condition that decreases availability of these salts (eg, obstructive jaundice) can lead to deficiency. Malabsorption syndromes (sprue, celiac disease, cystic fibrosis of the pancreas) can also decrease vitamin K uptake. Other potential causes of impaired absorption are ulcerative colitis, regional enteritis, and surgical resection of the intestine.

Disruption of intestinal flora may result in deficiency by eliminating vitamin K–synthesizing bacteria. Hence, deficiency may occur secondary to use of antibiotics. In infants, diarrhea may cause bacterial losses sufficient to result in deficiency.

The normal infant is born vitamin K deficient. Consequently, in order to rapidly elevate prothrombin levels, and thereby reduce the risk of neonatal hemorrhage, it is recommended that all infants receive a single injection of phytonadione (vitamin K₁) immediately after delivery.

As discussed in [Chapter 51](#), the anticoagulant warfarin acts as an antagonist of vitamin K, and thereby decreases synthesis of vitamin K–dependent clotting factors. As a result, warfarin produces a state that is functionally equivalent to vitamin K deficiency. If the dosage of warfarin is excessive, hemorrhage can occur secondary to lack of prothrombin.

81.2.4.6 Adverse Effects.

Severe Hypersensitivity Reactions. Intravenous phytonadione can cause serious reactions (shock, respiratory arrest, cardiac arrest) that resemble anaphylaxis or hypersensitivity reactions. Death has occurred. Consequently, phytonadione should not be administered IV unless other routes are not feasible, and then only if the potential benefits clearly outweigh the risks.

81.2.4.6.1 Hyperbilirubinemia.

When administered *parenterally* to newborns, vitamin K derivatives can elevate plasma levels of bilirubin, thereby posing a risk of *kernicterus*. The incidence of hyperbilirubinemia is greater in premature infants than in full-term infants. Although all forms of vitamin K can elevate bilirubin levels, the risk is higher with menadione and menadiol than with phytonadione.

81.2.4.7 Therapeutic Uses and Dosage.

Vitamin K has two major applications: (1) correction or prevention of hypoprothrombinemia and bleeding caused by vitamin K deficiency, and (2) control of hemorrhage caused by overdose with warfarin.

81.2.4.7.1 Vitamin K Deficiency.

As discussed, vitamin K deficiency can result from impaired absorption and from insufficient synthesis of vitamin K by intestinal flora. Rarely, deficiency results from inadequate diet. For children and adults, the usual dosage for correction of vitamin K deficiency ranges between 5 and 15 mg/day.

As noted above, infants are born vitamin K deficient. To prevent hemorrhagic disease in neonates, it is recommended that all newborns be given an injection of phytonadione (0.5 to 1 mg) immediately after delivery.

81.2.4.7.2 Warfarin Overdose.

Vitamin K reverses hypoprothrombinemia and bleeding caused by excessive dosing with warfarin, an oral anticoagulant. Bleeding is controlled within hours of vitamin K administration (see [Chapter 51](#) for dosage).

81.2.4.8 Preparations and Routes of Administration.

Phytonadione (vitamin K₁) is available in 5-mg tablets, marketed as Mephyton, and in parenteral formulations (2 and 10 mg/mL) sold generically. Parenteral phytonadione may be administered IM, subQ, and IV. However, since IV administration is dangerous, this route should be used only when other routes are not feasible, and only if the perceived benefits outweigh the substantial risks.

81.3 WATER-SOLUBLE VITAMINS

The group of water-soluble vitamins consists of vitamin C and members of the vitamin B complex (thiamin, riboflavin, niacin, pyridoxine, pantothenic acid, biotin, folic acid, and cyanocobalamin). The B vitamins differ widely from one another in structure and function. They are grouped together because they were first isolated from the same sources (yeast and liver). Vitamin C is not found in the same foods as the B vitamins, and hence is classified by itself. DRIs for the B vitamins were revised in 1998. DRIs for vitamin C were revised in 2000.

Two compounds—*pangamic acid* and *laetrile*—have been falsely promoted as B vitamins. Pangamic acid has been marketed as “vitamin B₁₅” and laetrile as “vitamin B₁₇.” There is no proof these compounds act as vitamins or have any other role in human nutrition.

81.3.1 Vitamin C (Ascorbic Acid)

81.3.1.1 Actions.

Vitamin C participates in multiple biochemical reactions. Among these are synthesis of adrenal steroids, conversion of folic acid to folinic acid, and regulation of the respiratory cycle in mitochondria. At the tissue level, vitamin C is required for production of collagen and other compounds that comprise the intercellular matrix that binds cells together. In addition, vitamin C has antioxidant activity (see [Box 80-1](#)) and facilitates absorption of dietary iron.

957

958

81.3.1.2 Sources.

The main dietary sources of ascorbic acid are citrus fruits and juices, tomatoes, potatoes, strawberries, melons, spinach, and broccoli. Orange juice and lemon juice are especially rich sources.

81.3.1.3 Requirements.

The RDAs for vitamin C were revised in 2000. The new RDAs (see [Table 80-2](#)) are higher than those set in 1989. As in the past, RDAs increase for women who are pregnant or breast-feeding. For smokers, the RDA is increased by 35 mg/day.

81.3.1.4 Deficiency.

Deficiency of vitamin C can lead to *scurvy*, a disease that is rare in the United States. Symptoms include faulty bone and tooth development, loosening of the teeth, gingivitis, bleeding gums, poor wound healing, hemorrhage into muscles and joints, and ecchymoses (skin discoloration caused by leakage of blood into subcutaneous tissues). Many of these symptoms result from disruption of the intercellular matrix of capillaries and other tissues.

81.3.1.5 Adverse Effects.

Excessive doses can cause *nausea*, *abdominal cramps*, and *diarrhea*. The mechanism is direct irritation of the intestinal mucosa. To protect against GI disturbances, the Food and Nutrition Board has set 2 gm/day as the adult UL for vitamin C.

81.3.1.6 Therapeutic Use.

The only established indication for vitamin C is prevention and treatment of scurvy. For severe, acute deficiency, parenteral administration is recommended. The usual adult dosage is 0.3 to 1 gm/day.

Vitamin C has been advocated for therapy of many conditions unrelated to deficiency, including cancers, asthma, osteoporosis, and the common cold. Claims of efficacy for several of these conditions have been definitively disproved. Other claims remain unproved. Studies have shown that large doses do not reduce the incidence of colds, although the intensity or duration of illness may be reduced slightly. Research has failed to show any benefit of vitamin C therapy for patients with advanced cancer, atherosclerosis, or schizophrenia. Vitamin C does not promote healing of wounds.

81.3.1.7 Preparations and Routes of Administration.

Vitamin C is available in formulations for oral and parenteral administration. Oral products include tablets (ranging from 25 to 1500 mg), timed-release capsules (500 mg), and syrups (20 and 100 mg/mL). For parenteral use, vitamin C is available as ascorbic acid, sodium ascorbate, and calcium ascorbate. Administration may be subQ, IM, or IV.

81.3.2 Niacin (Nicotinic Acid)

Niacin has a role as both a vitamin and a medicine. In its medicinal role, niacin is used to reduce cholesterol levels; the doses required are much higher than those used to correct or prevent nutritional deficiency. Discussion in this chapter focuses on niacin as a vitamin. Use of nicotinic acid to reduce cholesterol levels is discussed in [Chapter 49](#).

81.3.2.1 Physiologic Actions.

Before it can exert physiologic effects, niacin must first be converted into nicotinamide adenine dinucleotide (NAD) or nicotinamide adenine dinucleotide phosphate (NADP). NAD and NADP then act as coenzymes in oxidation-reduction reactions essential for cellular respiration.

81.3.2.2 Sources.

Nicotinic acid (or its nutritional equivalent, nicotinamide) is present in many foods of plant and animal origin. Particularly rich sources are liver, poultry, fish, potatoes, peanuts, cereal bran, and cereal germ.

In humans, the amino acid tryptophan can be converted to nicotinic acid. Hence, proteins can be a source of the vitamin. About 60 mg of dietary tryptophan is required to produce 1 mg of nicotinic acid.

81.3.2.3 Requirements.

RDAs for nicotinic acid are stated as niacin equivalents (NEs). By definition, 1 NE is equal to 1 mg of niacin (nicotinic acid) or 60 mg of tryptophan. Revised RDAs for niacin (see [Table 80-2](#)) were established in 1998.

81.3.2.4 Deficiency.

The syndrome caused by niacin deficiency is called *pellagra*, a term that is a condensation of the Italian words *pelle agra*, meaning “rough skin.” As suggested by this name, a prominent symptom of pellagra is dermatitis, characterized by scaling and cracking of the skin in areas exposed to the sun. Other symptoms involve the GI tract (abdominal pain, diarrhea, soreness of the tongue and mouth) and central nervous system (irritability, insomnia, memory loss, anxiety, dementia). All symptoms are readily reversed with niacin replacement therapy.

81.3.2.5 Adverse Effects.

Nicotinic acid has very low toxicity. Small doses are completely devoid of adverse effects. When taken in large doses, nicotinic acid can cause vasodilation with resultant *flushing*, *dizziness*, and *nausea*. Using flushing as an index of excess niacin consumption, the Food and Nutrition Board has set 50 mg as the adult UL for the vitamin. Toxicity associated with high-dose therapy is discussed in [Chapter 49](#).

Nicotinamide, a compound that can substitute for nicotinic acid in the treatment of pellagra, is not a vasodilator, and hence does not produce the adverse effects associated with large doses of nicotinic acid. Accordingly, nicotinamide is often preferred to nicotinic acid for treating pellagra, which requires high doses.

81.3.2.6 Therapeutic Uses.

In its capacity as a vitamin, nicotinic acid is indicated only for the prevention or treatment of niacin deficiency. As noted, if given in large doses, nicotinic acid may also be used to lower cholesterol levels (see [Chapter 49](#)).

81.3.2.7 Preparations, Dosage, and Administration.

Nicotinic acid (niacin) is available in standard tablets (50 to 500 mg), controlled-release tablets (250 to 1000 mg), and extended-release capsules (125 to 500 mg). Dosages for mild deficiency range from 10 to 20 mg/day. For treatment of pellagra, daily doses may be as high as 500 mg. Dosages for hyperlipidemia are given in [Chapter 49](#).

Nicotinamide (niacinamide) is available in 100- and 500-mg tablets. For treatment or prevention of pellagra, dosages range from 150 to 500 mg/day. Unlike nicotinic acid, nicotinamide has no effect on plasma lipoproteins, and hence is not used to treat hyperlipidemias.

81.3.3 Riboflavin (Vitamin B₂)

81.3.3.1 Actions.

Riboflavin participates in numerous enzymatic reactions. However, in order to exert physiologic effects, the vitamin must first be converted into one of two active forms: flavin adenine dinucleotide (FAD) or flavin mononucleotide (FMN). In the form of FAD or FMN, riboflavin acts as a coenzyme for multiple oxidative reactions.

81.3.3.2 Sources and Requirements.

In the United States, most dietary riboflavin comes from milk, yogurt, cheese, bread products, and fortified cereals. Organ meats are also rich sources. Revised RDAs for riboflavin (see [Table 80-2](#)) were established in 1998.

81.3.3.3 Toxicity.

Riboflavin appears devoid of toxicity to humans. When large doses are administered, the excess is rapidly excreted in the urine. Because large doses are harmless, no UL has been set.

81.3.3.4 Use in Riboflavin Deficiency.

Riboflavin is indicated only for prevention and correction of riboflavin deficiency, which usually occurs in conjunction with deficiency of other B vitamins. In its early state, riboflavin deficiency manifests as sore throat and angular stomatitis (cracks in the skin at the corners of the mouth). Symptoms that may appear later include cheilosis (painful cracks in the lips), glossitis (inflammation of the tongue), vascularization of the cornea, and itchy dermatitis of the scrotum or vulva. Oral riboflavin is used for treatment. The dosage is 10 to 15 mg/day.

958

959

81.3.3.5 Use in Migraine Headache.

As discussed in [Chapter 30](#), riboflavin can help prevent migraine headaches. The daily dosage is 400 mg—much higher than the dosage for riboflavin deficiency.

81.3.4 Thiamin (Vitamin B₁)

81.3.4.1 Actions and Requirements.

The active form of thiamin (thiamin pyrophosphate) is an essential coenzyme for carbohydrate metabolism. Thiamin requirements are related to caloric intake, and are greatest when carbohydrates are the primary source of calories. For maintenance of good health, thiamin consumption should be at least 0.3 mg/1000 kcal in the diet. The 1998 revised RDAs for thiamin appear in [Table 80-2](#). As indicated, thiamin requirements increase significantly during pregnancy and lactation.

81.3.4.2 Sources.

In the United States, the principal dietary sources of thiamin are enriched, fortified, or whole-grain products, especially breads and ready-to-eat cereals. The richest source of the natural vitamin is pork.

81.3.4.3 Deficiency.

Severe thiamin deficiency produces *beriberi*, a disorder having two distinct forms: *wet beriberi* and *dry beriberi*. *Wet beriberi* is so named because its primary symptom is fluid accumulation in the legs. Cardiovascular complications (palpitations, electrocardiogram abnormalities, high-output heart failure) are common and may progress rapidly to circulatory collapse and death. *Dry beriberi* is characterized by neurologic and motor deficits (eg, anesthesia of the feet, ataxic gait, footdrop, wristdrop); edema and cardiovascular symptoms are absent. *Wet beriberi* responds rapidly and dramatically to replacement therapy. In contrast, recovery from *dry beriberi* can be very slow.

In the United States, thiamin deficiency occurs most commonly among alcoholics. In this population, deficiency manifests as *Wernicke-Korsakoff syndrome* rather than frank beriberi. This syndrome is a serious disorder of the central nervous system, having neurologic and psychologic manifestations. Symptoms include nystagmus, diplopia, ataxia, and an inability to remember the recent past. Failure to correct the deficit may result in irreversible damage to the brain. Accordingly, if Wernicke-Korsakoff syndrome is suspected, parenteral thiamin should be administered immediately.

81.3.4.4 Adverse Effects.

When taken orally, thiamin is devoid of adverse effects. Accordingly, no UL for the vitamin has been established.

81.3.4.5 Therapeutic Use.

The only indication for thiamin is treatment and prevention of thiamin deficiency.

81.3.4.6 Preparations, Dosage, and Administration.

Thiamin is available in standard tablets (50, 100, and 250 mg) and enteric-coated tablets (20 mg) for oral use, and in solution (100 mg/mL) for IM or IV administration. For mild deficiency, oral thiamin is preferred. Parenteral administration is reserved for severe deficiency states (wet or dry beriberi, Wernicke-Korsakoff syndrome). The dosage for beriberi is 50 to 100 mg IM daily for 1 to 2 weeks, followed by 2.5 to 10 mg PO daily until recovery is complete.

81.3.5 Pyridoxine (Vitamin B₆)

81.3.5.1 Actions.

Pyridoxine functions as a coenzyme in the metabolism of amino acids and proteins. However, before it can influence biologic processes, pyridoxine must first be converted to its active form: pyridoxal phosphate.

81.3.5.2 Requirements.

RDAs for pyridoxine were revised in 1998. For most people, and especially young people, the new RDAs (see [Table 80-2](#)) are considerably lower than the RDAs set in 1989. As in the past, RDAs increase significantly for women who are pregnant or breast-feeding.

81.3.5.3 Sources.

In the United States, the principal dietary sources of pyridoxine are fortified, ready-to-eat cereals; meat, fish, and poultry; white potatoes and other starchy vegetables; and noncitrus fruits. Especially rich sources are organ meats (eg, beef liver) and cereals or soy-based products that have been highly fortified.

81.3.5.4 Deficiency.

Pyridoxine deficiency may result from poor diet, use of isoniazid, and inborn errors of metabolism. Symptoms include seborrheic dermatitis, microcytic anemia, peripheral neuritis, convulsions, depression, and confusion.

In the United States, dietary deficiency of vitamin B₆ is rare, except among alcoholics. Within the alcoholic population, vitamin B₆ deficiency has an incidence of about 20% to 30%, and occurs in combination with deficiency of other B vitamins.

Isoniazid (a drug for tuberculosis) prevents conversion of vitamin B₆ to its active form, and may thereby induce symptoms of deficiency (peripheral neuritis). Patients who are predisposed to this neuropathy (eg, alcoholics, diabetics) should receive daily pyridoxine supplements.

Inborn errors of metabolism can prevent efficient utilization of vitamin B₆, resulting in greatly increased pyridoxine requirements. Among infants, symptoms include irritability, convulsions, and anemia. Unless treatment with vitamin B₆ is initiated early, permanent retardation may result.

81.3.5.5 Adverse Effects.

At low doses, pyridoxine is devoid of adverse effects. However, if extremely large doses are taken, neurologic injury may result. Symptoms include ataxia and numbness of the feet and hands. To minimize risk, adults should not consume more than 100 mg/day, the UL for this vitamin.

81.3.5.6 Drug Interactions.

Vitamin B₆ interferes with the utilization of levodopa, a drug for Parkinson's disease. Accordingly, patients receiving levodopa should be advised against taking the vitamin.

81.3.5.7 Therapeutic Uses.

Pyridoxine is indicated for prevention and treatment of all vitamin B₆ deficiency states (dietary deficiency, isoniazid-induced deficiency, pyridoxine dependency syndrome).

81.3.5.8 Preparations, Dosage, and Administration.

Pyridoxine is available in standard tablets (25 to 500 mg) and enteric-coated tablets (25 mg) for oral use, and in solution (100 mg/mL) for IM or IV administration. To correct dietary

deficiency, the dosage is 10 to 20 mg/day for 3 weeks followed by 1.5 to 2.5 mg/day thereafter for maintenance. To treat deficiency induced by isoniazid, the dosage is 50 to 200 mg/day. To protect against isoniazid-induced deficiency, the dosage is 25 to 50 mg/day. Pyridoxine dependency syndrome may require initial doses up to 600 mg/day followed by 25 to 50 mg/day for life.

81.3.6 Cyanocobalamin (Vitamin B₁₂) and Folic Acid

Cyanocobalamin (vitamin B₁₂) and folic acid (folacin) are essential factors in the synthesis of DNA. Deficiency of either vitamin manifests as megaloblastic anemia. Cyanocobalamin deficiency produces neurologic damage as well. Because deficiency presents as anemia, folic acid and cyanocobalamin are discussed at length in [Chapter 54](#) (Drugs for Deficiency Anemias).

81.3.6.1 RDAs and ULs.

Revised RDAs for vitamin B₁₂ and folate (see [Table 80-2](#)) were published in 1998. The new adult RDA for B₁₂ (2.4 mcg) is about 20% higher than the RDA established in 1989, and the new adult RDA for folic acid (400 mcg) is 100% higher than the old one. Because adults over age 50 often have difficulty absorbing dietary vitamin B₁₂, they should ingest at least 2.4 mcg/day in the form of a supplement. A UL of 1000 mcg/day has been set for folic acid. Because of insufficient data, no UL has been set for B₁₂.

959

960

81.3.6.2 Food Folate Versus Synthetic Folate.

The form of folate that occurs naturally (food folate) has a different chemical structure than synthetic folate (pteroylglutamic acid). Synthetic folate is more stable than food folate, and has greater bioavailability. In the presence of food, the bioavailability of synthetic folate is at least 85%. In contrast, bioavailability of food folate is less than 50%.

To increase folate in the American diet, the Food and Drug Administration issued the following order: Beginning January 1, 1998, all enriched grain products (eg, enriched bread, pasta, flour, breakfast cereal, grits, rice) must be fortified with synthetic folate—specifically, 140 mcg/100 gm of grain. As a result of grain fortification, the incidence of folic acid deficiency in the United States has declined dramatically. Unfortunately, the incidence of birth defects from folate deficiency (see below) has only dropped by 32%.

81.3.6.3 Folic Acid Deficiency and Fetal Development.

Deficiency of folic acid during pregnancy can impair development of the central nervous system, resulting in *neural tube defects* (NTDs): *anencephaly* and *spina bifida*. Anencephaly

(failure of the brain to develop) is uniformly fatal. Spina bifida, a condition characterized by defective development of the bony encasement of the spinal cord, can result in nerve damage, paralysis, and other complications. The time of vulnerability for NTDs is days 21 through 28 after conception. Hence, the damage can occur before a woman recognizes her pregnancy by missing a period. Because NTDs occur very early in pregnancy, it is essential that adequate levels of folic acid be present *when pregnancy begins*; women cannot wait until pregnancy is confirmed before establishing adequate intake. To ensure sufficient folate at the onset of pregnancy, the U.S. Public Health Service recommends that *all women who may become pregnant consume 400 mcg of supplemental folic acid each day—in addition to the folate they get from food*. Since pregnancy can occur despite birth control measures, this recommendation applies even to women who don't intend to become pregnant.

81.3.6.4 Folic Acid and Colorectal Cancer.

Data from the Nurses' Health Study suggest that folate protects against colorectal cancer, the third most common cancer in the United States. In this study, women who took a vitamin supplement containing 400 mcg of folate every day for 15 or more years reduced their risk of colon cancer by 75%. Although the mechanism of protection is unknown, it may relate to the role of folate in DNA synthesis and repair: Researchers speculate that insufficient folate may predispose to cancer-causing genetic changes, whereas maintaining adequate folate may help protect against these changes.

81.3.7 Pantothenic Acid

Pantothenic acid is an essential component of two biologically important molecules: *coenzyme A* and *acyl carrier protein*. Coenzyme A is an essential factor in multiple biochemical processes, including gluconeogenesis, intermediary metabolism of carbohydrates, and biosynthesis of steroid hormones, porphyrins, and acetylcholine. Acyl carrier protein is required for synthesis of fatty acids. Pantothenic acid is present in virtually all foods. As a result, spontaneous deficiency has not been reported. There are insufficient data to establish RDAs for pantothenic acid. However, the Food and Nutrition Board *has* assigned AIs (see [Table 80-2](#)). There are no reports of toxicity from pantothenic acid. Accordingly, no UL has been set. Pantothenic acid is available in single-ingredient tablets and in multivitamin preparations. However, because deficiency does not occur, there is no reason to take supplements.

81.3.8 Biotin

Biotin is an essential cofactor for several reactions involved in the metabolism of carbohydrates and fats. The vitamin is found in a wide variety of foods, although the exact amount in most foods

has not been determined. In addition to being available in foods, biotin is synthesized by intestinal bacteria. Biotin deficiency is extremely rare. In fact, in order to determine the effects of deficiency, scientists had to induce it experimentally. When this was done, subjects experienced dermatitis, conjunctivitis, hair loss, muscle pain, peripheral paresthesias, and psychologic effects (lethargy, hallucinations, depression). At this time, the data are insufficient to establish RDAs for biotin. However, as with pantothenic acid, the Food and Nutrition Board *has* assigned AIs (see [Table 80-2](#)). Biotin appears devoid of toxicity: Subjects given large doses experienced no adverse effects. Accordingly, no UL has been set.

81.3.8.1

KEY POINTS

- Vitamins can be defined as organic compounds, required in minute amounts, that promote growth and health maintenance by participating in energy transformation and regulation of metabolic processes.
- Recommended dietary allowances (RDAs) for vitamins, which are set by the Food and Nutrition Board of the National Academy of Sciences, represent the average daily dietary intake sufficient to meet the nutrient requirements of nearly all (97% to 98%) healthy individuals in a particular life-stage or gender group.
- The Tolerable Upper Intake Limit (UL) for a vitamin is the highest average daily intake that can be consumed by nearly everyone without a significant risk of adverse effects. The UL is simply an index of safety—not a recommendation to exceed the RDA.
- There is no evidence that taking daily *multi* vitamin supplements can decrease the risk of chronic disease. However, there *is* evidence that taking supplements of vitamin B₁₂, folic acid, and vitamin D (plus calcium) can benefit certain individuals.
- Vitamins are divided into two major groups: fat-soluble vitamins (A, D, E, and K) and water-soluble vitamins (vitamin C and members of the vitamin B complex).
- Vitamin A deficiency can cause night blindness, xerophthalmia (a dry, thickened condition of the conjunctiva), and keratomalacia (degeneration of the cornea with keratinization of the corneal epithelium).
- Too much vitamin A can cause birth defects, liver injury, and bone abnormalities. Accordingly, vitamin A intake should not exceed the UL, set at 3000 mcg/day.
- Vitamin D plays a critical role in the regulation of calcium and phosphorus metabolism, and may help protect against breast cancer, colorectal cancer, type 1 diabetes, and overall mortality.

960

961

- In children, vitamin D deficiency causes rickets. In adults, deficiency causes osteomalacia.
- Vitamin K is required for synthesis of prothrombin and other clotting factors.
- Vitamin K deficiency causes bleeding tendencies. Severe deficiency can cause spontaneous hemorrhage.
- Vitamin K is used to treat vitamin K deficiency (including neonatal deficiency) and overdose with warfarin (an anticoagulant).
- Vitamin C deficiency can cause scurvy.
- Niacin (nicotinic acid) is both a vitamin and a drug.
- When niacin is used as a drug (to reduce cholesterol levels), doses are much higher than when niacin is used to prevent or correct deficiency.
- Niacin deficiency results in pellagra.
- Severe thiamin deficiency produces beriberi.
- In the United States, thiamin deficiency occurs most commonly among alcoholics. In this population, deficiency manifests as Wernicke-Korsakoff syndrome rather than beriberi.
- Pyridoxine (vitamin B₆) deficiency can cause peripheral neuritis and other symptoms.
- Isoniazid, a drug for tuberculosis, prevents conversion of pyridoxine to its active form, and can thereby induce deficiency.
- Folic acid deficiency during early pregnancy can cause neural tube defects (anencephaly and spina bifida). To ensure folic acid sufficiency at the start of pregnancy, all women with the potential for becoming pregnant should consume 400 mcg of supplemental folic acid every day (in addition to food folate).
- At this time, there are no convincing data that large doses of antioxidants (eg, vitamin E, vitamin C) reduce the risk of cancer, heart disease, or any other chronic disorder.

⁸²CHAPTER 81 Drugs for Obesity

Obesity is a public health epidemic. In the United States, nearly two-thirds of adults are overweight or obese. Excessive body fat increases the risk of morbidity from hypertension, coronary heart disease, stroke, type 2 diabetes, gallbladder disease, kidney stones, osteoarthritis, sleep apnea, dementia, and certain cancers. Among women, obesity also increases the risk of menstrual irregularities, amenorrhea, and polycystic ovary syndrome; during pregnancy, obesity increases the risk of morbidity and mortality for both the mother and child. Estimates of how many Americans die from obesity-related illnesses vary widely—from 120,000 a year to over 300,000. Regardless of which estimate is more accurate, obesity is still second only to smoking as the leading preventable cause of death.

Pediatric obesity is a special concern. One-third of American children and adolescents are overweight or obese. Since 1963, the average weight of 10-year-old children has increased by 11 pounds. Among children ages 6 to 11, the prevalence of obesity has tripled since 1980. This extra weight is exacting a profound toll on health—increasing the risk of hypertension, heart disease, and asthma. In addition, type 2 diabetes, formerly seen almost exclusively in adults, has increased 10-fold among children and teens, and gallbladder disease has tripled. Because of obesity, and for the first time in history, American children could have a shorter life span than their parents.

Obesity is now viewed as a chronic disease, much like hypertension and diabetes. Despite intensive research, the underlying cause remains incompletely understood. Contributing factors include genetics, metabolism, and appetite regulation, along with environmental, psychosocial, and cultural factors. Although obese people can lose weight, the tendency to regain weight cannot be eliminated. Put another way, obesity cannot yet be cured. Accordingly, for most patients, lifelong management is indicated.

Several important guidelines on obesity management have been published. In 1998, the National Heart, Lung, and Blood Institute (NHLBI), in cooperation with the National Institute of Diabetes and Digestive and Kidney Diseases, released the first federal clinical guidelines on obesity, titled *Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: Evidence Report*. Two years later, the NHLBI, in cooperation with the North American Association for the Study of Obesity, released a companion document—*The Practical Guide: Identification, Evaluation, and Treatment of Overweight and Obesity in Adults*—to give clinicians specific tools to help their patients lose weight and keep it off. In 2005, the American College of Physicians (ACP) released a new guideline—*Pharmacologic and Surgical Management of Obesity in Primary Care*—which addresses evidence-based treatments for obesity. Pediatric obesity is addressed in several guidelines, including *Expert Committee Recommendations Regarding the Prevention, Assessment, and Treatment of Child and Adolescent Overweight and Obesity*, released in 2007, and *Prevention and*

82.1 ASSESSMENT OF OBESITY-RELATED HEALTH RISK

Health risk is determined by (1) the degree of obesity (as reflected in the body mass index), (2) the pattern of fat distribution (as reflected in the waist circumference measurement), and (3) the presence of obesity-related diseases and/or cardiovascular risk factors. Accordingly, all three factors must be assessed when establishing a treatment plan.

82.1.1 Body Mass Index.

The body mass index (BMI), which is derived from the patient's weight and height, is a simple way to estimate body fat content. Studies indicate a close correlation between BMI and total body fat. The BMI is calculated by dividing a patient's weight (in kilograms) by the square of the patient's height (in meters). Hence, BMI is expressed in units of kg/m^2 . BMI can also be calculated using the patient's weight *in pounds* and height in *inches* ([Fig. 81-1](#)). According to the federal guidelines, a BMI of 30 or higher indicates obesity. Individuals with a BMI of 25 to 29.9 are considered overweight, but not obese. There is good evidence that the risk of cardiovascular disease and other disorders rises significantly when the BMI exceeds 25. When the BMI exceeds 30, there is an increased risk of death. These specific associations

962

963

Figure 81-1 Adult weight classification based on body mass index (BMI).

Adapted from National Heart, Lung, and Blood Institute: Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: Evidence Report. Bethesda, MD: National Institutes of Health, 1998.

between BMI and health risk do not apply to growing children or women who are pregnant or lactating. Nor do they apply to competitive athletes or bodybuilders, who are heavy because of muscle mass rather than excess fat. [Table 81-1](#) summarizes weight classifications based on BMI.

TABLE 81-1 Disease Risk Based on BMI and WC

BMI (kg/m ²)	Weight Class	Obesity Class	Disease Risk [*]	
			Nonexcessive WC [†]	Excessive WC [‡]
Below 18.5	Underweight	—	—	—
18.5–24.9	Normal	—	—	—
25–29.9	Overweight	—	Increased	High
30–34.9	Obesity	I	High	Very high
35–39.9	Obesity	II	Very high	Very high
40 or more	Extreme obesity	III	Extremely high	Extremely high

Adapted from National Heart, Lung, and Blood Institute: Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults: Evidence Report. Bethesda, MD: National Institutes of Health, 1998.

* Risk for hypertension, cardiovascular disease, and type 2 diabetes, relative to individuals of normal weight.

† Nonexcessive WC = waist circumference of 40 inches or less for men, and 35 inches or less for women.

‡ Excessive WC = waist circumference above 40 inches for men, and above 35 inches for women.

82.1.2 Waist Circumference.

Waist circumference (WC) is an indicator of *abdominal* fat content, an independent risk factor for obesity-related diseases. Accumulation of fat in the upper body, and especially within the abdominal cavity, poses a greater risk to health than does accumulation of fat in the lower body (hips and thighs). People with too much abdominal fat are at increased risk of insulin resistance, diabetes, hypertension, coronary atherosclerosis, ischemic stroke, and dementia. Fat distribution can be estimated simply by looking in the mirror: an apple shape indicates too much abdominal fat, whereas a pear shape indicates fat on the hips and thighs. Measurement of WC provides a quantitative estimate of abdominal fat. A WC exceeding 40 inches (102 cm) in men or 35 inches (88 cm) in women signifies an increased health risk—but only for people with a BMI between 25 and 34.9 (see [Table 81-1](#)).

82.1.3 Risk Status.

963

Overall obesity-related health risk is determined by BMI, WC, and the presence of obesity-related diseases and cardiovascular risk factors. Certain obesity-related diseases—established coronary heart disease, other atherosclerotic diseases, type 2 diabetes, and sleep apnea—confer a very high risk for complications and mortality. Other obesity-related diseases—gynecologic abnormalities, osteoarthritis, gallstones, and stress incontinence—confer less risk. Cardiovascular risk factors—smoking, hypertension, high levels of low-density lipoprotein (LDL) cholesterol, low levels of high-density lipoprotein (HDL) cholesterol, high fasting glucose, family history of premature coronary heart disease, physical inactivity, and advancing age—confer a high risk when three or more of these factors are present.

964

Not surprisingly, health risk rises as BMI gets larger (see [Table 81-1](#)). In addition, the risk is increased by the presence of an excessive WC. The risk is further increased by obesity-related diseases and cardiovascular risk factors. In the absence of an excessive WC and other risk factors, health risk is minimal with a BMI below 25, and relatively low with a BMI below 30. Conversely, a BMI of 30 or more indicates significant risk. In the presence of an excessive WC, health risk is high for all individuals with a BMI above 25.

82.2 OVERVIEW OF OBESITY TREATMENT

The strategy for losing weight is simple: take in fewer calories per day than are burned. Of course, implementation is tough. The key components of a weight-loss program are diet and exercise. Drugs and other measures are employed only as adjuncts.

82.2.1 Who Should Be Treated?

According to the federal guidelines, weight-loss therapy is indicated for people with

- A BMI of 30 or more
- A BMI of 25 to 29.9 *plus* two risk factors
- A WC greater than 40 inches (in men) or greater than 35 inches (in women) *plus* two risk factors

82.2.2 Benefits of Treatment

It is well established that obesity increases morbidity and mortality. It is also well established that weight reduction reduces morbidity, and probably mortality. In overweight and obese people, weight reduction confers these proven benefits:

- Reduction of high blood pressure in patients with hypertension
- Improvement of blood lipid status (elevation of HDL cholesterol and reduction of LDL cholesterol, total cholesterol, and triglycerides)
- Reduction of elevated blood glucose in patients with type 2 diabetes
- Reduced mortality

82.2.3 Treatment Goal

The goal of treatment is to promote and maintain weight loss. The initial objective is to reduce weight by 10% over 6 months. For patients with a BMI of 27 to 35, this can usually be achieved by reducing energy intake by 300 to 500 kcal/day, which should allow a loss of 0.5 to 1 pound a week—or 13 to 26 pounds in 6 months. More severely obese people (BMI above 35) require greater caloric restriction (500 to 1000 kcal/day) to lose 10% of their weight in 6 months. After 6 months, the goal for all patients is to prevent lost weight from returning. This can be accomplished by a combination of diet, physical activity, and behavioral therapy. If appropriate, additional weight reduction can be attempted.

82.2.4 Treatment Modalities

Weight loss can be accomplished with five treatment modalities: diet therapy, physical activity, behavior therapy, drug therapy, and surgery. For any individual, the treatment mode is determined by the degree of obesity and personal preference.

82.2.4.1 Diet Therapy.

A reduced-calorie diet is central to any weight-loss program. As noted, the only way to lose weight is to take in fewer calories than we burn. Depending on the individual, the caloric deficit should range from 300 to 1000 kcal/day. Because fats contain more calories than either carbohydrates or proteins (on an ounce-for-ounce basis), reducing dietary fat is the easiest way to reduce calorie intake.

What's the best diet for losing weight? Answer: The one that you actually stick to. In one study, 160 overweight subjects were randomized to follow one of four popular diet plans: Atkins (low-carbohydrate), Ornish (fat-restricted), Weight Watchers (portion- and calorie-restricted), and Zone (low-glycemic-index). Mean weight loss after 1 year was modest—ranging from 4.6 to 7.3 pounds—and did not differ significantly between the plans. However, what did matter was adherence: There was a direct correlation between weight lost and adherence to the plan, regardless of which plan was followed.

To succeed at losing weight, it helps to know just how many calories you take in each day and how many you burn. The following web sites, which are free, have databases on foods and physical activities, along with tools to calculate and log calories taken in and calories burned:

- MyPyramid—www.mypyramidtracker.gov
- Fitday—www.fitday.com
- Sparkpeople—www.sparkpeople.com
- NutritionData—www.nutritiondata.com

82.2.4.2 Exercise.

Physical activity should be a component of all weight-loss and weight-maintenance programs. Exercise makes a modest contribution to weight loss by increasing energy expenditure. In addition, exercise can help reduce abdominal fat, increase cardiorespiratory fitness, and maintain weight once loss has occurred. According to federal guidelines, people trying to *lose* weight should exercise 60 minutes a day, and those trying to *maintain* weight loss should exercise 90 minutes a day.

82.2.4.3 Behavior Modification.

Behavior therapy is directed at modifying eating and exercise habits. As such, behavior therapy can strengthen a program of diet and exercise. In the absence of continuing behavior therapy, most patients regain lost weight when treatment stops. Techniques of behavior therapy include self-monitoring of eating and exercise habits, stress management (because stress can trigger eating), and stimulus control (limiting exposure to stimuli that promote eating). There is no evidence that any one of these techniques is superior to others.

82.2.4.4 Drug Therapy.

Drugs can be used as an adjunct to diet and exercise—but only for people at increased health risk, and only after a 6-month program of diet and exercise has failed. Drugs should never be used alone. Rather, they should be part of a comprehensive weight-reduction program—one that includes exercise, behavior modification, and a reduced-calorie diet.

964

965

TABLE 81-2 Some Drugs for Weight Loss

Drug	FDA-Approved Indications	Mechanism	Weight Loss Beyond That with Placebo	Adverse Effects	Schedule IV Controlled Substance
Sibutramine [Meridia]	Weight loss: long term	Appetite suppression: inhibits NE and 5-HT reuptake	5%	Increased heart rate and blood pressure, insomnia, nervousness, headache	Yes
Orlistat [Alli, Xenical]	Weight loss: long term	Reduced fat absorption: inhibits lipase	3%	Oily spotting, flatulence, diarrhea, fecal urgency	No
Phentermine [Adipex-P, Ionamin]	Weight loss: short term	Appetite suppression: sympathomimetic amine	4%	Nervousness, insomnia, palpitations, tachycardia, mild increase in blood pressure	Yes
Diethylpropion (generic only)	Weight loss: short term	Appetite suppression: sympathomimetic amine	3%	Same as phentermine	Yes
Rimonabant [Acomplia]	Investigational drug in the U.S.	Appetite suppression: blocks cannabinoid receptors	5%	Nausea, diarrhea, anxiety, depression	—
5-HT = serotonin, NE = norepinephrine.					

Candidates for drug therapy should be at increased health risk owing to excessive body fat. Specifically, drugs should be reserved for patients whose BMI is 30 or greater (in the absence of additional risk factors), or 27 or greater (in the presence of additional risk factors). Drugs are not appropriate for patients whose BMI is relatively low.

Benefits of drugs are usually modest. Weight loss attributable to drugs generally ranges between 4.4 and 22 pounds, although some people lose significantly more. As a rule, the majority of weight loss occurs during the first 6 months of treatment.

Expert opinion regarding duration of therapy has changed. In the past, drug therapy was limited to a few months. Today, long-term treatment is recommended. Why? Because we now know

that, when drugs are discontinued, most patients regain lost weight. This is similar to the return of high blood pressure when antihypertensive drugs are withdrawn. Accordingly, when treatment has been effective and well tolerated, it should continue indefinitely. At this time, only two drugs—sibutramine and orlistat—are approved for long-term use, and hence are preferred to other agents.

Not everyone responds to drugs, and hence regular assessment is required. Patients should lose at least 4 pounds during the first 4 weeks of drug treatment. If this initial response is absent, further drug use should be questioned. For patients who *do* respond, ongoing assessment must show that (1) the drug is effective at *maintaining* weight loss, and that (2) serious adverse effects are absent. Otherwise, drug therapy should cease.

In theory, drugs can promote weight loss in three ways: They can suppress appetite, reduce absorption of nutrients, or increase metabolic rate. With one exception—*orlistat*—all of the drugs used for obesity work by suppressing appetite. *Orlistat* works by reducing absorption of fat. None of the available drugs increases metabolic rate.

[Table 81-2](#) lists the major drugs for obesity, and summarizes approved indications, mechanism of action, major side effects, and status under the Controlled Substances Act (CSA).

82.2.4.5 Bariatric Surgery.

Surgical procedures can produce significant weight loss. However, they are indicated only for severely obese patients—that is, people with a BMI of 40 or more (in the absence of comorbidity) or 35 or more (in the presence of comorbidity). Furthermore, surgery should be reserved for patients who have failed to respond to less invasive therapies and who are at high risk for obesity-related morbidity or mortality. The two most widely used procedures are gastric resection (vertical banded gastroplasty) and gastric bypass (Roux-en-Y procedure). Unlike surgeries used in the past, which were designed to reduce nutrient absorption, these procedures are designed to reduce food consumption. Surgery is highly effective: In 6 months to a year, patients can lose between 110 and 220 pounds. Furthermore, benefits are sustained.

Unfortunately, although surgery is very effective, it can carry significant risk: In one study, mortality rates at 30 days, 90 days, and 1 year after gastric surgery were 2%, 2.8%, and 4.6%, respectively.

82.3 WEIGHT-LOSS DRUGS APPROVED FOR LONG-TERM USE

Sibutramine and orlistat are the only antiobesity drugs currently approved for long-term use.

Sibutramine promotes weight loss by suppressing appetite; orlistat decreases absorption of fats.

Because management of obesity requires prolonged treatment, these two drugs are preferred to all others. Both drugs are approved for use in adults and children.

82.3.1 Sibutramine, an Appetite Suppressant

82.3.1.1 Actions and Use

Sibutramine [Meridia], in combination with a reduced-calorie diet, is indicated for promoting and maintaining weight loss in obese patients ages 16 and older. Candidates should have a BMI of 30 or greater (in the absence of other risk factors), or 27 or greater (in the presence of other risk factors, such as hypertension, diabetes, or hyperlipidemia). Sibutramine promotes weight loss by *suppressing appetite*, and possibly by increasing metabolic rate. The underlying mechanism is blockade of serotonin (5-hydroxytryptamine [5-HT]) and norepinephrine (NE) reuptake, which increases availability of these transmitters at synapses in the brain. Like other drugs that increase concentrations of 5-HT and/or NE, sibutramine has antidepressant actions.

965

966

In clinical trials, sibutramine was moderately effective. In one 6-month trial, subjects taking sibutramine (5, 10, 15, or 20 mg/day) lost 6.8, 9.7, 11.7, and 12.8 pounds, respectively, compared with 2 pounds for those taking placebo. In a 12-month trial, subjects taking sibutramine (10 or 15 mg/day) lost 10 pounds and 14 pounds, respectively, compared with 3.5 pounds for those taking placebo. As a rule, early responders to sibutramine—that is, those who lose at least 4 pounds during the first 4 weeks of treatment—do better than late responders. The safety and efficacy of sibutramine beyond 1 year of use have not been studied.

82.3.1.2 Pharmacokinetics

Sibutramine is well absorbed following oral administration. On its first pass through the liver, the drug is rapidly converted into two active metabolites by the 3A4 isozyme of cytochrome P450 (CYP3A4). Concentrations of the metabolites peak in 3 to 4 hours, and decline with half-lives of 14 to 16 hours. The metabolites undergo enzymatic inactivation followed by excretion in the urine.

82.3.1.3 Adverse Effects

The most common adverse effects are headache (30%), dry mouth (17%), constipation (11.5%), and central nervous system (CNS) stimulation, manifested as insomnia (10.7%), nervousness (5.2%), and anxiety (4.5%). Unlike two other serotonergic drugs—fenfluramine and dexfenfluramine (see below)—sibutramine has not been associated with valvular heart disease or primary pulmonary hypertension. Sibutramine has a low potential for abuse, and hence is classified under Schedule IV of the CSA.

Sibutramine can *elevate blood pressure*. For most patients, the increase is small, only 1 to 3 mm Hg. However, in a few patients, a substantial increase has occurred. Accordingly, blood pressure should be measured before treatment and periodically thereafter. Sibutramine should be avoided in patients with uncontrolled hypertension or with a history of coronary artery disease, heart failure, dysrhythmias, or stroke.

Sibutramine can *increase heart rate*. For most patients, the increase is small, only 4 to 5 beats/min. Rarely, patients develop tachycardia (heart rate above 100 beats/min).

82.3.1.4 Drug Interactions

82.3.1.4.1 Serotonergic Agents.

Combining sibutramine with another serotonergic drug may cause *serotonin syndrome*, a potentially fatal reaction characterized by incoordination, myoclonus, hyperreflexia, tremor, fever, sweating, and mental changes (eg, agitation, anxiety, hallucinations). Accordingly, sibutramine should not be used with other drugs that enhance serotonin-ergic transmission. Among these are *selective serotonin reuptake inhibitors* (eg, fluoxetine [Prozac]), *serotonin agonists taken for migraine* (eg, sumatriptan [Imitrex]), and *lithium*. Certain opioids—including meperidine [Demerol], fentanyl [Sublimaze], and pentazocine [Talwin]—also increase the risk of serotonin syndrome, and should be avoided.

82.3.1.4.2 Monoamine Oxidase Inhibitors.

By blocking reuptake of NE, sibutramine can increase the risk of hypertensive crisis in patients taking monoamine oxidase inhibitors (MAOIs). Accordingly, MAOIs should be withdrawn at least 2 weeks before starting sibutramine, and sibutramine should be discontinued at least 2 weeks before starting an MAOI.

82.3.1.4.3 Sympathomimetics.

Because sibutramine can elevate blood pressure, it should be used cautiously with other drugs that raise blood pressure. Among these are ephedrine and pseudoephedrine—drugs that are commonly found in over-the-counter (OTC) remedies for colds, allergies, and nasal congestion. Amphetamines should also be avoided.

82.3.1.4.4 Cytochrome P450 3A4 Inhibitors.

In theory, drugs such as ketoconazole and erythromycin, which inhibit CYP3A4, could slow the metabolism of sibutramine, and thereby alter its effects. However, in actual practice this interaction appears insignificant.

82.3.1.5 Preparations, Dosage, and Administration

Sibutramine [Meridia] is available in 5-, 10-, and 15-mg capsules for oral dosing. The recommended initial dosage is 10 mg once a day, administered in the morning to minimize insomnia. For patients who fail to lose at least 4 pounds in the first 4 weeks, the prescriber should consider either increasing the dosage to 15 mg daily or discontinuing treatment. Dosages above 15 mg/day should be avoided.

Although sibutramine is usually taken continuously, intermittent dosing may be just as effective. In one study, patients lost weight while taking sibutramine on a repeating cycle consisting of once-daily dosing for 12 weeks followed by 6 weeks off.

82.3.2 Orlistat, a Lipase Inhibitor

82.3.2.1 Actions and Use.

Orlistat [Xenical, Alli] is a novel drug approved for promoting and maintaining weight loss in obese patients age 12 and older. Unlike most other weight-loss drugs, which act in the brain to curb appetite, orlistat acts in the GI tract to reduce absorption of fat. Specifically, the drug acts in the stomach and small intestine to inhibit gastric and pancreatic lipases, enzymes that break down triglycerides into monoglycerides and free fatty acids. If triglycerides are not broken down, they can't be absorbed. In patients taking orlistat, absorption of dietary fat is reduced about 30%. Like sibutramine, orlistat should be reserved for patients with a BMI of at least 30—or 27 in the presence of other risk factors (eg, diabetes, hypertension, hyperlipidemia). Patients must adopt a reduced-calorie diet in which 30% of calories come from fat.

In clinical trials, orlistat produced modest but sustained benefits. When taken for 2 years, the drug enhanced weight loss, reduced regain of lost weight, and improved some obesity-related risk factors. Patients treated for 2 years lost an average of 19 pounds, compared with 12 pounds for those taking placebo. In addition, treatment reduced total and LDL cholesterol, raised HDL cholesterol, reduced fasting blood glucose, and lowered systolic and diastolic blood pressure. Safety and efficacy beyond 2 years of treatment have not been evaluated.

82.3.2.2 Adverse Effects and Interactions.

Orlistat undergoes less than 1% absorption, and hence systemic effects are absent. In contrast, GI effects are common. Patients frequently experience oily spotting (27%), flatulence with discharge (24%), fecal urgency (22%), fatty or oily stools (20%), oily evacuation (12%), increased defecation (11%), and fecal incontinence (8%). All of these are the direct result of reduced fat absorption, and all can be minimized by reducing fat intake. For many patients, these unpleasant effects provide strong motivation for adhering to a low-fat diet, and hence may be viewed as beneficial as well as adverse. Dosing with psyllium [Metamucil, others], a bulk-forming laxative, can greatly reduce GI effects. The underlying mechanism is adsorption of dietary fat.

966

967

By reducing fat absorption, orlistat can reduce absorption of fat-soluble vitamins (vitamins A, D, E, and K). To avoid deficiency, patients should take a daily multivitamin supplement. Administration should be done 2 hours before or 2 hours after taking orlistat.

Vitamin K deficiency can intensify the effects of warfarin, an anticoagulant. In patients taking warfarin, anticoagulant effects should be monitored closely.

Orlistat is contraindicated for patients with malabsorption syndrome or cholestasis.

82.3.2.3 Preparations, Dosage, and Administration.

Orlistat is available in two strengths: 60-mg capsules sold as Alli, and 120-mg capsules sold as Xenical. Xenical requires a prescription; Alli does not. Of note, the efficacy and side effects of both products are nearly identical, even though one is twice the strength of the other. With either product, patients should take 1 capsule 3 times a day. Each dose should be administered during a major meal or up to 1 hour after. There is no benefit to exceeding three daily doses. Orlistat dosing can be omitted if a meal is missed, or if a meal has little or no fat.

82.4 MISCELLANEOUS APPETITE SUPPRESSANTS

In this section, we consider a group of drugs that can suppress appetite. Unlike sibutramine and orlistat, none of these drugs is approved for long-term therapy of obesity. In fact, most are not approved for obesity at all.

82.4.1 Sympathomimetic Amines

The sympathomimetic amines suppress appetite by increasing availability of NE at receptors in the brain. These drugs are approved for *short-term* use only (3 months or less). The

sympathomimetics fall into two groups: amphetamines and nonamphetamines. The amphetamines have a much higher abuse potential than the nonamphetamines, and hence should be avoided.

82.4.1.1 Nonamphetamines: Diethylpropion and Phentermine.

Of the four nonamphetamines approved for weight loss, two—diethylpropion (formerly available as Tenuate) and phentermine [Adipex-P, Ionamin]—are preferred. As with other drugs for obesity, drug-induced weight loss is modest: about 8 pounds with phentermine and 6.6 pounds with diethylpropion.

Diethylpropion and phentermine are CNS stimulants. Consequently, like the amphetamines, they can increase alertness, decrease fatigue, and induce nervousness and insomnia. Because they can interfere with sleep, these drugs should be administered no later than 4:00 PM. Upon discontinuation of treatment, fatigue and depression may replace CNS stimulation.

Like the amphetamines, the nonamphetamines have effects in the periphery as well as the CNS. Peripheral effects of greatest concern are tachycardia, anginal pain, and hypertension. Accordingly, these drugs should be used with caution in patients with cardiovascular disease.

Although the risk of abuse with the nonamphetamine anorexiant is lower than with the amphetamines, abuse can nonetheless occur. Both diethylpropion and phentermine are regulated under Schedule IV of the CSA. To reduce the risk of abuse, try to identify abuse-prone patients prior to treatment.

Tolerance is common and may be seen in 6 to 12 weeks. If tolerance develops, the appropriate response is to discontinue the drug rather than increase the dosage.

For two reasons, these drugs are not recommended during pregnancy. First, they are not very effective during pregnancy, and hence there is little point in taking them. Second, *in utero* exposure to these agents poses an increased risk of cleft palate and congenital heart defects.

Both diethylpropion and phentermine require a prescription. For diethylpropion, the recommended dosage is 25 mg 3 times a day taken 1 hour before meals (using immediate-release tablets) *or* 75 mg once a day in midmorning (using sustained-release tablets). For phentermine, dosing options include 8 mg 3 times a day before meals *or* 15 to 37.5 mg once daily before breakfast.

82.4.1.2 Nonamphetamines: Phenylpropanolamine.

Phenylpropanolamine (PPA) is a nonamphetamine sympathomimetic agent that had been widely available in over-the-counter (OTC) cold remedies and weight-loss products. The drug is

effective for both applications, and had once been considered safe. However, a study released on May 10, 2000—*Phenylpropanolamine and Risk of Hemorrhagic Stroke: Final Report of the Hemorrhagic Stroke Project*—showed that PPA increases the risk of hemorrhagic stroke in women, but not in men. This information led the Food and Drug Administration (FDA) to conclude that the benefits from using PPA for nasal decongestion or weight loss do not justify exposing users to the risk of stroke—even though that risk is very small. Accordingly, on November 6, 2000, the FDA *requested*, but did not *demand*, that PPA be removed from all OTC cold remedies and weight-loss products. As a result, OTC products containing PPA are no longer available. For people with colds, there are many OTC alternatives to PPA. In contrast, for people trying to lose weight, there is no OTC alternative to PPA: All other weight-loss drugs require a prescription.

82.4.1.3 Amphetamines.

Because of their ability to suppress appetite, the amphetamines have been employed as adjunctive aids in programs for weight loss. However, because of their high abuse potential, and because they offer no advantages over less dangerous sympathomimetics, amphetamines are not recommended—nor are they approved by the FDA for either short-term or long-term therapy of obesity.

82.4.2 Bupropion

Bupropion [Wellbutrin, Zyban], a drug indicated for depression (see [Chapter 32](#)) and smoking cessation (see [Chapter 39](#)), can also suppress appetite although it is not approved for this use. Benefits are thought to result from blocking reuptake of dopamine and NE. In three clinical trials, the average weight loss was modest—about 6 pounds after 6 to 12 months. Dosage for weight loss is 300 to 400 mg/day, using a sustained-release formulation. The basic pharmacology of bupropion is discussed in [Chapter 32](#).

82.4.3 Fluoxetine

Fluoxetine [Prozac, Sarafem], our most widely used antidepressant, causes weight loss with initial use, but weight gain later on. Like sibutramine, fluoxetine increases serotonin availability at synapses in the brain. Presumably, the increase in serotonin depresses appetite, which leads to initial weight loss. Why is weight later regained? One possibility is that serotonin receptors become desensitized over time, and hence appetite returns to pretreatment levels. The results of nine trials in obese patients (average BMI of 35.5) show weight loss of 10.4 pounds at 6 months, but only 6.9 pounds at 12 months. Common adverse effects include agitation, insomnia, and sexual dysfunction (eg, decreased libido, anorgasmia, impotence). Use late in pregnancy can

produce a withdrawal syndrome in the neonate. Daily doses used for weight loss are much higher than those used for depression (60 mg vs. 20 mg). The basic pharmacology of fluoxetine is presented in [Chapter 32](#).

82.4.4 Topiramate and Zonisamide

Topiramate and zonisamide are antiseizure drugs that, when used for epilepsy, produce weight loss as an adverse effect. Because of this effect, both have been studied for treatment of obesity. The basic pharmacology of these drugs is presented in [Chapter 24](#).

82.4.4.1 Topiramate.

When tested in obese patients, topiramate [Topamax] produced a 6% to 8% reduction in weight. Two mechanisms are involved: appetite suppression and, possibly, increased expenditure of energy. Unfortunately, many patients experienced unacceptable side effects, including memory impairment, difficulty concentrating, visual problems, fatigue, insomnia, and numbness and tingling in the limbs. The ACP guidelines conclude there are insufficient data to recommend this drug.

82.4.4.2 Zonisamide.

Information on using zonisamide [Zonegran] for weight loss is limited. However, in one trial, the drug did produce dramatic results: In patients with a mean BMI of 36.3 at baseline, mean weight loss was 13 pounds after 16 weeks, and 20 pounds after an additional 16 weeks. Side effects include somnolence, dizziness, and cognitive problems (eg, confusion, impaired concentration, and speech abnormalities). As with topiramate, the ACP guidelines conclude there are insufficient data to recommend this drug.

82.4.5 Dexfenfluramine and Fenfluramine

Dexfenfluramine [Redux] and fenfluramine [Pondimin]—two highly effective appetite suppressants—can damage valves of the heart. Accordingly, in 1997, they were voluntarily withdrawn from the market. Prior to being withdrawn, fenfluramine was the “fen” in the widely used combination known as “*fen-phen*” (fenfluramine plus phentermine). For more information on fenfluramine, dexfenfluramine, and “fen-phen,” refer to the fifth edition of this text.

967

82.5 INVESTIGATIONAL WEIGHT-LOSS DRUGS**82.5.1 Rimonabant**

Rimonabant [Acomplia] is highly effective for promoting weight loss, but also carries a high risk of depression. The drug has a unique mechanism of action: selective blockade of cannabinoid receptors, the same receptors that marijuana works through. By blocking cannabinoid receptors, rimonabant produces multiple beneficial effects: It works in the brain to reduce food intake and nicotine craving, and it works in the periphery to decrease insulin resistance, improve glucose tolerance, reduce triglyceride levels, and increase HDL cholesterol (good cholesterol). In one study, obese subjects who took rimonabant for 1 year lost a mean of 14.7 pounds, and also had a significant decrease in waist circumference. In addition, the drug increased HDL cholesterol levels, reduced triglyceride levels, and increased levels of adiponectin, a cardioprotective molecule. Unfortunately, even though rimonabant improves these risk factors for coronary artery disease (CAD), the drug does not slow CAD progression, as shown in the Strategy to Reduce Atherosclerosis Development Involving Administration of Rimonabant—The Intravascular Ultrasound Study (STRADIVARIUS). Compared with patients taking a placebo, those taking rimonabant experienced greater weight loss along with improvements in lipid profile and in levels of C-reactive protein and glycated hemoglobin. However, there was no decrease in the volume of coronary artery atheromas. Furthermore, there was an alarmingly high rate of depression (44%). Given that obese people are already prone to depression, it would seem imprudent to treat them with a drug that further increases the risk—especially since rimonabant does not slow progression of CAD. In 2007, an FDA panel recommended unanimously against approving the drug, primarily because of concerns about depression and other psychiatric effects. Rimonabant was approved in Europe for treating obesity in 2006.

82.5.2 Leptin

In 1994, Jeffrey Friedman of Rockefeller University announced the discovery of leptin, a hormone that helps regulate appetite and energy metabolism. In addition, leptin participates in sexual development. The name *leptin* derives from *leptos*, the Greek word for *thin*. Mice and humans that lack the gene for leptin are obese. For this reason, leptin is also known as the *antiobesity hormone*.

The physiology of leptin is only partly understood. The hormone is released by adipocytes (fat cells) when they fill with fat. Leptin then acts in the hypothalamus to reduce appetite, increase physical activity, and increase fat metabolism. These actions serve to halt further fat accumulation. Hence, the leptin system behaves like a typical feedback loop: When fat storage climbs too high, leptin is released and suppresses further storage; when fat storage falls too low,

leptin release is suppressed, allowing more fat to accumulate. The evolutionary purpose of this system is unknown, although there are two obvious possibilities: it may serve to protect against storing too much fat, or it may serve to ensure storage of sufficient fat.

Genetic deficiency of leptin causes extreme obesity. Congenital deficiency is characterized by hyperphagia (overeating), excessive weight gain early in life, and severe obesity. In addition, sexual development is delayed. In 1999, researchers from England described the effects of leptin deficiency and leptin replacement therapy in a young girl. The child had a normal weight at birth, but began gaining excessive weight after 4 months. She was constantly hungry (despite hyperphagia), demanded food continuously, and expressed great discontent when food was denied. By age 6, she weighed 125 pounds and needed leg liposuction to improve mobility. By age 9, she weighed 208 pounds. At that time, she began daily subQ injections of leptin. Within a week, her appetite subsided. After 1 year, she had lost 36 pounds, almost all of it fat. Interestingly, she also showed signs of early puberty. (As noted, leptin stimulates sexual development.) This was the first report that leptin replacement is effective in a leptin-deficient person.

Can exogenous leptin help obese people lose weight? Yes—but only if they are like the girl just described. That is, for leptin to work, patients must be unable to make leptin themselves. Unfortunately, the vast majority of obese people have no problem making leptin. In fact, their leptin levels are usually high—not low, as might be expected. High levels suggest leptin resistance. Possible causes include failure to produce enough leptin receptors or production of receptors that are faulty. When tested in such people, leptin did not induce significant loss of weight.

82.6 CALORIE-SAVING FOODS

82.6.1 Sugar Substitutes

82.6.1.1 Calorie-Free Sweeteners

Five non-nutritive sweeteners are available: *saccharin* [Sweet 'N Low], *aspartame* [NutraSweet, Equal], *sucralose* [Splenda], *acesulfame* [Sunett, Sweet One], and *neotame* (no trade name yet). Their calorie content is negligible. As indicated in [Table 81-3](#), all five are much sweeter than sucrose (table sugar), when compared ounce-for-ounce. With the exception of aspartame, which is unstable at high heat, all can be used for cooking. These sweeteners are present in literally thousands of commercial food products, including soft drinks, alcoholic beverages, canned goods, baked goods, candies, and various desserts. For people trying to lose pounds or keep them off, switching to foods made with these sweeteners may help.

968

969

TABLE 81-3 Sugar Substitutes

Generic Name	Trade Name	Relative Sweetness*	Heat Stability	Comments
Calorie-Free Products				
Saccharin	Sweet 'N Low	300	Good	Bitter aftertaste. High doses cause bladder cancer in rats, but there is no evidence of cancer in humans. OK for cooking.
Aspartame	NutraSweet, Equal	180	Poor	No aftertaste. Made of two amino acids: aspartate and phenylalanine. Phenylalanine makes it dangerous for phenylketonurics. Because of poor heat stability, it is not good for cooking.
Sucralose	Splenda	600	Very good	No aftertaste. The only low-calorie sweetener derived from sucrose. Very heat stable, and hence excellent for cooking.
Acesulfame	Sunett, Sweet One	200	Good	No aftertaste. Derived from acetoacetic acid. OK for cooking.
Neotame		8000	Good	No aftertaste. OK for cooking.
Reduced-Calorie Product				
Tagatose	Slimsweet, Nutratose	1	Good	An isomer of fructose with 38% of the calories of sucrose. No aftertaste. OK for cooking.

* Intensity of sweetness relative to sucrose (eg, saccharin is 300 times sweeter than sucrose).

Calorie-free sweeteners have been used extensively for years, and have proved very safe. At very high doses, saccharin can cause bladder cancer in rats. However, at the doses consumed in the diet, there is no evidence that it causes cancer in humans. Aspartame contains phenylalanine, and hence can harm people with phenylketonuria. All of these sweeteners are safe for diabetes patients. There is no evidence to support rumors that aspartame contributes to multiple sclerosis, systemic lupus erythematosus, Alzheimer's disease, and other disorders.

82.6.1.2 Reduced-Calorie Sweetener: Tagatose

Tagatose [Slimsweet, Nutratose], an isomer of fructose, is a naturally occurring sugar with properties much like those of sucrose—but with only 38% of the calories. Tagatose tastes like sucrose and, unlike saccharin, has no bitter aftertaste. When used for cooking and baking, tagatose behaves the same as sucrose. Tagatose received FDA approval in October 2001.

82.6.2 Olestra, a Fat Substitute

Olestra [Olean] is a nonabsorbable, calorie-free fat substitute used to make potato chips, corn chips, crackers, and other snack foods. Olestra cannot be broken down by pancreatic enzymes, and hence cannot be absorbed. As a result, it provides no dietary fat or calories.

Olestra is very well tolerated. Two randomized, double-blind trials failed to support anecdotal reports of olestra-induced GI symptoms. In one trial, subjects were given a large bag of potato chips—fried in olestra or a traditional fat—to eat while watching a movie. Later, 563 subjects were interviewed. The result? Olestra produced virtually no increase in gas, diarrhea, or abdominal cramping—although the participants did rate the olestra chips as less tasty (5.6 vs. 6.4 on a 9-point scale). In the second study, 3181 subjects ate traditional potato chips or olestra potato chips over 6 weeks. Again, olestra caused no increase in GI symptoms (heartburn, nausea, vomiting, gas, bloating, cramping, frequency of bowel movements, or loose stools).

Olestra can reduce the absorption of fat-soluble vitamins (A, D, E, and K). When these vitamins are ingested at the same time as olestra, they can dissolve in the olestra, and then pass through the intestine without being absorbed. To compensate for this action, snack foods made with olestra are fortified with fat-soluble vitamins. Hence, there is no risk of vitamin deficiency.

82.6.2.1

KEY POINTS

- Obesity increases the risk of morbidity and mortality.
- Obesity is a chronic disease that requires lifelong treatment.
- The body mass index (BMI) is a measure of body fat content.
- A BMI of 25 to 29.9 indicates overweight, and a BMI of 30 or more indicates obesity.
- Waist circumference (WC) is an index of abdominal fat. Accumulation of abdominal fat poses a greater risk to health than accumulation of fat in the hips and thighs.
- Obesity-related health risk is determined by the degree of obesity, excessive abdominal fat, and the presence of obesity-related diseases (eg, type 2 diabetes, sleep apnea) and cardiovascular risk factors (eg, smoking, hypertension, high LDL cholesterol).
- Weight reduction reduces morbidity and probably mortality.
- Weight reduction can be accomplished with diet therapy, physical activity, behavior therapy, drug therapy, and surgery.

- Antiobesity drugs should be used only as adjuncts to a comprehensive weight-loss program that includes exercise, behavior modification, and a reduced-calorie diet.
- Antiobesity drugs are indicated for patients with a BMI of 30 or more (in the absence of other risk factors) or 27 or more (in the presence of other risk factors).
- Most patients regain lost weight when antiobesity drugs are discontinued. Hence, to remain effective, these drugs must be taken indefinitely.
- Only two drugs—sibutramine and orlistat—are approved for long-term therapy of obesity.
- Sibutramine promotes weight loss by suppressing appetite. The underlying mechanism is blockade of NE and 5-HT reuptake.
- Sibutramine can elevate blood pressure and heart rate, and hence must be used with caution in patients with hypertension or a history of dysrhythmias.
- Sibutramine poses a risk of serotonin syndrome, and hence must not be combined with other serotonergic drugs. Among these are selective serotonin reuptake inhibitors (eg, fluoxetine [Prozac]), serotonin agonists used for migraine (eg, sumatriptan [Imitrex]), and lithium.
- By blocking reuptake of norepinephrine, sibutramine can increase the risk of hypertensive crisis in patients taking MAOIs. At least 2 weeks should separate use of these drugs.
- Orlistat promotes weight loss by decreasing absorption of dietary fat. The underlying mechanism is inhibition of gastric and pancreatic lipases.
- Orlistat frequently causes GI symptoms (oily spotting, fecal urgency, oily stools, and fecal incontinence). These symptoms, which are a direct result of reduced fat absorption, can be minimized by reducing fat intake, and by taking the bulk-forming laxative psyllium [Metamucil, others].
- Orlistat can reduce absorption of fat-soluble vitamins (vitamins A, D, E, and K). To avoid deficiency, patients should take a daily multivitamin supplement.

⁸³CHAPTER 82 Basic Principles of Antimicrobial Therapy

With this chapter we begin our study of drugs used to treat infectious diseases. These drugs are given to about 30% of all hospitalized patients, and constitute one of our most widely used groups of medicines.

Modern antimicrobial agents had their debut in the 1930s and 1940s, and have greatly reduced morbidity and mortality from infection. As newer drugs are introduced, our ability to fight infections increases even more. However, despite impressive advances, continued progress is needed. Why? Because there are organisms that respond poorly to available drugs; there are effective drugs whose use is limited by toxicity; and there is, because of evolving microbial resistance, the constant threat that currently effective antibiotics will be rendered useless.

In this introductory chapter, we focus on two principal themes. The first is microbial susceptibility to drugs, with special emphasis on resistance. The second is clinical usage of antimicrobials. Topics addressed include criteria for drug selection, host factors that modify drug use, use of antimicrobial combinations, and use of antimicrobial agents for prophylaxis.

Before going further, we need to consider three terms: *chemotherapy*, *antibiotic*, and *antimicrobial agent*. Although we often think of *chemotherapy* as the use of drugs to kill or suppress cancer cells, this term was first defined as *the use of chemicals against invading organisms* (eg, bacteria, viruses, fungi). Today, the word is applied to the treatment of both cancer and infection. Hence, not only do we speak of cancer chemotherapy, we also speak of chemotherapy of infectious diseases.

In common practice, the terms *antibiotic* and *antimicrobial drug* are used interchangeably, as they are in this book. However, be aware that the formal definitions of these words are not identical. Strictly speaking, an *antibiotic* is a chemical that is produced by one microbe and has the ability to harm other microbes. Under this definition, only those compounds that are actually made by microorganisms qualify as antibiotics. Drugs such as the sulfonamides, which are produced in the laboratory, would not be considered antibiotics under the strict definition. In contrast, an *antimicrobial drug* is defined as any agent, natural or synthetic, that has the ability to kill or suppress microorganisms. Under this definition, no distinction is made between compounds produced by microbes and those made by chemists. From the perspective of therapeutics, there is no benefit to distinguishing between drugs made by microorganisms and drugs made by chemists. Hence, the current practice is to use the terms *antibiotic* and *antimicrobial drug* interchangeably.

83.1 SELECTIVE TOXICITY

83.1.1 What Is Selective Toxicity?

The term *selective toxicity* is defined as the ability of a drug to injure a target cell or target organism without injuring other cells or organisms that are in intimate contact with the target. As applied to antimicrobial drugs, selective toxicity indicates the ability of an antibiotic to kill or suppress microbial pathogens without causing injury to the host. Selective toxicity is the property that makes antibiotics valuable. If it weren't for selective toxicity—that is, if antibiotics were as harmful to the host as they are to infecting organisms—these drugs would have no therapeutic utility.

970

83.1.2 How Is Selective Toxicity Achieved?

971

How can a drug be highly toxic to microbes but harmless to the host? The answer lies with differences in the cellular chemistry of mammals and microbes. There are biochemical processes critical to microbial well-being that do not take place in mammalian cells. Hence, drugs that selectively interfere with these unique microbial processes can cause serious injury to microorganisms while leaving mammalian cells intact. Three examples of how we achieve selective toxicity are discussed below.

83.1.2.1 Disruption of the Bacterial Cell Wall.

Unlike mammalian cells, bacteria are encased in a rigid cell wall. The protoplasm within this wall has a high concentration of solutes, making osmotic pressure within the bacterium high. If it were not for the cell wall, bacteria would absorb water, swell, and then burst. Several families of drugs (eg, penicillins, cephalosporins) weaken the cell wall and thereby promote bacterial lysis. Because mammalian cells have no cell wall, drugs directed at this structure do not affect us.

83.1.2.2 Inhibition of an Enzyme Unique to Bacteria.

The sulfonamides represent antibiotics that are selectively toxic because they inhibit an enzyme critical to bacterial survival but not to our survival. Specifically, sulfonamides inhibit an enzyme needed to make folic acid, a compound required by all cells, both mammalian and bacterial. If we need folic acid, why don't sulfonamides hurt us? Because we can use folic acid from dietary sources. In contrast, bacteria must synthesize folic acid themselves (because, unlike us, they can't take up folic acid from the environment). Hence, to meet their needs, bacteria first take up

para-aminobenzoic acid (PABA), a precursor of folic acid, and then convert the PABA into folic acid. Sulfonamides block this conversion. Since mammalian cells do not make their own folic acid, sulfonamide toxicity is limited to microbes.

83.1.2.3 Disruption of Bacterial Protein Synthesis.

In bacteria as in mammalian cells, protein synthesis is done by ribosomes. However, bacterial and mammalian ribosomes are not identical, and hence we can make drugs that disrupt function of one but not the other. As a result, we can impair protein synthesis in bacteria while leaving mammalian protein synthesis untouched.

83.2 CLASSIFICATION OF ANTIMICROBIAL DRUGS

Various schemes are employed to classify antimicrobial drugs. The two schemes most suited to our objectives are considered below.

83.2.1 Classification by Susceptible Organism

Antibiotics differ widely in their antimicrobial activity. Some agents, called *narrow-spectrum antibiotics*, are active against only a few species of microorganisms. In contrast, *broad-spectrum antibiotics* are active against a wide variety of microbes. As discussed below, *narrow-spectrum drugs are generally preferred to broad-spectrum drugs*.

[Table 82-1](#) classifies the major antimicrobial drugs according to susceptible organisms. The table shows three major groups: *antibacterial drugs*, *antifungal drugs*, and *antiviral drugs*. In addition, the table subdivides the antibacterial drugs into narrow-spectrum and broad-spectrum agents, and indicates the principal classes of bacteria against which they are active.

TABLE 82-1 Classification of Antimicrobial Drugs by Susceptible Organisms

ANTIBACTERIAL DRUGS
Narrow Spectrum
Gram-Positive Cocci and Gram-Positive Bacilli
Penicillin G and V
Penicillinase-resistant penicillins: methicillin, nafcillin
Vancomycin
Erythromycin
Clindamycin
Gram-Negative Aerobes
Aminoglycosides: gentamicin, others
Cephalosporins (first and second generations)
Mycobacterium tuberculosis
Isoniazid
Rifampin
Ethambutol
Pyrazinamide
Broad Spectrum
Gram-Positive Cocci and Gram-Negative Bacilli
Broad-spectrum penicillins: ampicillin, others
Extended-spectrum penicillins: carbenicillin, others
Cephalosporins (third generation)
Tetracyclines: tetracycline, others
Carbapenems: imipenem, others
Trimethoprim

Sulfonamides: sulfisoxazole, others
Fluoroquinolones: ciprofloxacin, others
ANTIVIRAL DRUGS
Drugs for HIV Infection
Reverse transcriptase inhibitors: zidovudine, others
Protease inhibitors: ritonavir, others
Fusion inhibitors: enfuvirtide
Integrase inhibitors: raltegravir
CCR5 antagonists: maraviroc
Drugs for Influenza
Adamantanes: amantadine, others
Neuraminidase inhibitors: oseltamivir, others
Other Antiviral Drugs
Acyclovir
Ribavirin
Interferon alfa
ANTIFUNGAL DRUGS
Polyene antibiotics: amphotericin B, others
Azoles: itraconazole, others
Echinocandins: caspofungin, others

83.2.2 Classification by Mechanism of Action

The antimicrobial drugs fall into seven major groups based on mechanism of action. This classification is summarized in [Table 82-2](#). Properties of the seven major classes are discussed briefly below.

- *Drugs that inhibit bacterial cell wall synthesis or activate enzymes that disrupt the cell wall*
—These drugs (eg, penicillins, cephalosporins) weaken the cell wall and thereby promote bacterial lysis and death.

971

TABLE 82-2 Classification of Antimicrobial Drugs by Mechanism of Action

Drug Class	Representative Antibiotics
Inhibitors of cell wall synthesis	Penicillins Cephalosporins Imipenem Vancomycin Caspofungin
Drugs that disrupt the cell membrane	Amphotericin B Daptomycin Itraconazole
<i>Bactericidal</i> inhibitors of protein synthesis	Aminoglycosides
<i>Bacteriostatic</i> inhibitors of protein synthesis	Clindamycin Erythromycin Linezolid Tetracyclines
Drugs that interfere with synthesis or integrity of bacterial DNA and RNA	Fluoroquinolones Metronidazole Rifampin
Antimetabolites	Flucytosine Sulfonamides Trimethoprim
Drugs that suppress viral replication	
Viral DNA polymerase inhibitors	Acyclovir Ganciclovir
HIV reverse transcriptase inhibitors	Zidovudine Lamivudine

HIV protease inhibitors	Ritonavir
	Saquinavir
HIV fusion inhibitors	Enfuvirtide
HIV integrase inhibitors	Raltegravir
HIV CCR5 antagonists	Maraviroc
Influenza neuraminidase inhibitors	Oseltamivir
	Zanamivir

- *Drugs that increase cell membrane permeability*—Drugs in this group (eg, amphotericin B) increase the permeability of cell membranes, causing leakage of intracellular material.
- *Drugs that cause lethal inhibition of bacterial protein synthesis*—The aminoglycosides (eg, gentamicin) are the only drugs in this group. We do not know why inhibition of protein synthesis by these agents results in cell death.
- *Drugs that cause nonlethal inhibition of protein synthesis*—Like the aminoglycosides, these drugs (eg, tetracyclines) inhibit bacterial protein synthesis. However, in contrast to the aminoglycosides, these agents only slow microbial growth; they do not kill bacteria at clinically achievable concentrations.
- *Drugs that inhibit bacterial synthesis of DNA and RNA or disrupt DNA function*—These drugs inhibit synthesis of DNA or RNA by binding directly to nucleic acids or by interacting with enzymes required for nucleic acid synthesis. They may also bind with DNA and disrupt its function. Members of this group include rifampin, metronidazole, and the fluoroquinolones (eg, ciprofloxacin).
- *Antimetabolites*—These drugs disrupt specific biochemical reactions. The result is either a decrease in the synthesis of essential cell constituents or synthesis of nonfunctional analogs of normal metabolites. Examples of antimetabolites include trimethoprim and the sulfonamides.
- *Drugs that suppress viral replication*—Most of these drugs inhibit specific enzymes—DNA polymerase, reverse trans-cryptase, protease, integrase, or neuraminidase—required for viral replication and infectivity. One agent—enfuvirtide—inhibits viral entry into host cells.

When considering the *antibacterial* drugs, it is useful to distinguish between agents that are *bactericidal* and agents that are *bacteriostatic*. *Bactericidal* drugs are directly lethal to bacteria at clinically achievable concentrations. In contrast, *bacteriostatic* drugs can slow bacterial growth

but do not cause cell death. When a bacteriostatic drug is used, elimination of bacteria must ultimately be accomplished by host defenses (ie, the immune system working in concert with phagocytic cells).

83.3 ACQUIRED RESISTANCE TO ANTIMICROBIAL DRUGS

Over time, an organism that had once been highly responsive to an antibiotic may become less susceptible, or it may lose drug sensitivity entirely. In some cases, resistance to several drugs develops. Acquired resistance is of great concern in that it can render currently effective drugs useless, thereby creating a clinical crisis and a constant need for new antimicrobial agents.

Organisms for which drug resistance is now a serious clinical problem include *Enterococcus faecalis*, *Enterococcus faecium*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, and *Klebsiella pneumoniae* ([Table 82-3](#)). One of these resistant bacteria—methicillin-resistant *Staphylococcus aureus*—is discussed at length in [Chapter 83](#) (see [Box 83-1](#)).

In the discussion that follows, we examine the mechanisms by which microbial drug resistance is acquired and the measures by which emergence of resistance can be delayed. As you read this section, keep in mind that it is the *microbe* that becomes drug resistant, *not the patient*.

83.3.1 Microbial Mechanisms of Drug Resistance

Microbes have four basic mechanisms for resisting drugs. They can (1) decrease the concentration of a drug at its site of action, (2) inactivate a drug, (3) alter the structure of drug target molecules, and (4) produce a drug antagonist.

83.3.1.1 Reduction of Drug Concentration at Its Site of Action.

For most antimicrobial drugs, the site of action is intracellular. Accordingly, if a bug can reduce the intracellular concentration of a drug, it can resist harm. Two basic mechanisms are involved. First, microbes can *cease active uptake* of certain drugs—tetracyclines and gentamicin, for example. Second, microbes can *increase active export* of certain drugs—tetracyclines, fluoroquinolones, and macrolides, for example.

83.3.1.2 Drug Inactivation.

Microbes can resist harm by producing drug-metabolizing enzymes. For example, many bacteria are now resistant to penicillin G because of increased production of penicillinase, an enzyme that inactivates penicillin. Through production of enzymes, some bacteria can inactivate several different kinds of antibiotics.

83.3.1.3 Alteration of Drug Target Molecules.

972

973

Most antibiotics, like most other drugs, must interact with target molecules (receptors) to produce their effects. Hence, if the structure of the target molecule is altered, resistance can result. For example, some bacteria are now resistant to streptomycin because of structural changes in bacterial ribosomes, the sites at which streptomycin acts to inhibit protein synthesis.

TABLE 82-3 Drugs for Some Highly Resistant Bacteria

Bacterium	Resistant to	Preferred Treatment
<i>Enterococcus faecalis</i>		
Beta-lactamase negative	Vancomycin + streptomycin or gentamicin	Penicillin G or ampicillin
Beta-lactamase producing	Penicillin	Vancomycin, ampicillin/sulbactam
<i>Enterococcus faecium</i>	Vancomycin, streptomycin, gentamicin	Penicillin G or ampicillin
	Vancomycin, streptomycin, gentamicin, penicillin G, ampicillin	Linezolid, quinupristin/dalfopristin
<i>Staphylococcus aureus</i> *	Methicillin	Vancomycin
	Methicillin, vancomycin	Possibly: linezolid, quinupristin/dalfopristin, very high doses of vancomycin
<i>Staphylococcus epidermidis</i>	Methicillin	Vancomycin
	Methicillin, vancomycin, and other glycopeptides	Quinupristin/dalfopristin
<i>Streptococcus pneumoniae</i>	Penicillin G (MIC 0.1–1 mcg/mL)	Ceftriaxone, cefotaxime
	Penicillin G (MIC 2 mcg/mL or higher)	Vancomycin ± rifampin
	Penicillin G, erythromycin, tetracycline, chloramphenicol, TMP/SMZ	Vancomycin ± rifampin
<i>Klebsiella pneumoniae</i>	Ceftazidime, third-generation cephalosporins	Imipenem/cilastatin, meropenem, a fluoroquinolone
MIC = minimum inhibitory concentration, TMP/SMZ = trimethoprim/sulfamethoxazole.		

* Methicillin-resistant *Staphylococcus aureus* is discussed at length in [Chapter 83 \(Box 83-1\)](#).

83.3.1.4 Antagonist Production.

In rare cases, a microbe can synthesize a compound that antagonizes drug actions. For example, by acquiring the ability to synthesize increased quantities of PABA, some bacteria have developed resistance to sulfonamides.

83.3.2 Mechanisms by Which Resistance Is Acquired

How do microbes acquire mechanisms of resistance? Ultimately, all of the alterations in structure and function discussed above result from changes in the microbial genome. These genetic changes may result either from spontaneous mutation or from acquisition of DNA from an external source. One important mechanism of DNA acquisition is conjugation with other bacteria.

83.3.2.1 Spontaneous Mutation.

Spontaneous mutations produce random changes in a microbe's DNA. The result is a gradual increase in resistance. Low-level resistance develops first. With additional mutations, resistance becomes greater. As a rule, spontaneous mutations confer resistance *to only one drug*.

83.3.2.2 Conjugation.

Conjugation is a process by which extrachromosomal DNA is transferred from one bacterium to another. In order to transfer resistance by conjugation, the donor organism must possess two unique DNA segments, one that codes for the mechanisms of drug resistance and one that codes for the “sexual” apparatus required for DNA transfer. Together, these two DNA segments constitute an *R factor* (resistance factor).

Conjugation takes place primarily among *gram-negative* bacteria. Genetic material may be transferred between members of the same species or between members of different species. Because transfer of R factors is not species specific, it is possible for pathogenic bacteria to acquire R factors from the normal flora of the body. Because R factors are becoming common in normal flora, the possibility of transferring resistance from normal flora to pathogens is a significant clinical concern.

In contrast to spontaneous mutation, conjugation frequently confers *multiple drug resistance*. This can be achieved, for example, by transferring DNA that codes for several different drug-metabolizing enzymes. Hence, in a single event, a drug-sensitive bacterium can become highly drug resistant.

83.3.3 Relationships Between Antibiotic Use and Emergence of Drug-Resistant Microbes

Use of antibiotics promotes the emergence of drug-resistant microbes. Please note, however, that although antibiotics promote drug resistance, they are not mutagenic and do not directly cause the genetic changes that underlie reduced drug sensitivity. Spontaneous mutation and conjugation are random events whose incidence is independent of drug use. Drugs simply make conditions favorable for overgrowth of microbes that have already acquired mechanisms for resistance.

83.3.3.1 How Do Antibiotics Promote Resistance?

To answer this question, we need to recall two aspects of microbial ecology: (1) microbes secrete compounds that are toxic to other microbes, and (2) microbes within a given ecologic niche (eg, large intestine, urogenital tract, skin) compete with one another for available nutrients. Under drug-free conditions, the various microbes in a given niche keep one another in check. Furthermore, if none of these organisms is drug resistant, introduction of antibiotics will be equally detrimental to all members of the population, and therefore will not promote the growth of any individual. However, *if a drug-resistant organism is present, antibiotics will create selection pressure favoring its growth.* How? By killing off sensitive organisms, the drug will eliminate the toxins they produce, and will thereby facilitate survival of the microbe that is drug resistant. Also, elimination of sensitive organisms will remove competition for available nutrients, thereby making conditions even more favorable for the resistant microbe to flourish. Hence, although drug resistance is of no benefit to an organism when there are no antibiotics present, when antibiotics are introduced, they create selection pressure favoring overgrowth of microbes that are resistant.

973

974

83.3.3.2 Which Antibiotics Promote Resistance?

All antimicrobial drugs promote the emergence of drug-resistant organisms. However, some agents are more likely to promote resistance than others. Because broad-spectrum antibiotics kill more competing organisms than do narrow-spectrum drugs, broad-spectrum agents do the most to facilitate emergence of resistance.

83.3.3.3 Does the Amount of Antibiotic Use Influence the Emergence of Resistance?

You bet! The more that antibiotics are used, the faster drug-resistant organisms will emerge. Not only do antibiotics promote emergence of resistant pathogens, they also promote overgrowth of

normal flora that possess mechanisms for resistance. Because drug use can increase resistance in normal flora, and because normal flora can transfer resistance to pathogens, every effort should be made to avoid use of antibiotics by individuals who don't actually need them (ie, individuals who don't have a treatable infection). Because all antibiotic use will further the emergence of resistance, there can be no excuse for casual or indiscriminate dispensing of these drugs.

83.3.3.4 Nosocomial Infections.

Because hospitals are sites of intensive antibiotic use, resident organisms can be extremely drug resistant. As a result, *nosocomial infections* (defined as infections acquired in hospitals) are among the most difficult to treat. According to the Centers for Disease Control and Prevention (CDC), about 1.7 million patients acquire an infection while hospitalized each year, resulting in 99,000 deaths. Measures to delay emergence of resistant organisms in hospitals are discussed below.

83.3.4 Suprainfection (Superinfection)

Suprainfection is simply a special example of the emergence of drug resistance. A suprainfection is defined as a *new* infection that appears during the course of treatment for a primary infection. New infections develop when antibiotics eliminate the inhibitory influence of normal flora, thereby allowing a second infectious agent to flourish. Because broad-spectrum antibiotics kill off more normal flora than do narrow-spectrum drugs, suprainfections are more likely in patients receiving broad-spectrum agents. Because suprainfections are caused by drug-resistant microbes, these infections are often difficult to treat. It should be noted that, in most texts, suprainfections are referred to as *superinfections*; this term may have been chosen to reflect the difficulties of treatment.

83.3.5 Delaying the Emergence of Resistance in Hospitals

In the Spring of 2002, the CDC launched its *Campaign to Prevent Antimicrobial Resistance*. The campaign is directed primarily at hospitals, which are major breeding grounds for resistant pathogens. As shown in [Figure 82-1](#), the campaign

Figure 82-1 Pocket card from the CDC's Campaign to Prevent Antimicrobial Resistance.

Pharmacology for Nursing Care, 7th Edition

consists of 12 action steps that fall under four major headings:

- Prevent infection
- Diagnose and treat infection effectively
- Use antimicrobials wisely
- Prevent transmission

The 12 steps are discussed briefly below. You can get more information online at www.cdc.gov/drugresistance.

Because the CDC campaign is limited to antibiotic use by humans, there is a major cause of resistance that it doesn't address: Feeding thousands of tons of antibiotics to livestock to promote growth. This important and contentious topic is discussed in [Box 82-1](#).

83.3.5.1 Step 1. Vaccinate.

By preventing infection, vaccination reduces the need to use antimicrobial drugs, and thereby helps prevent emergence of resistance. Accordingly, the CDC recommends predischARGE vaccination of all at-risk patients, especially against two respiratory infections: influenza and pneumococcal pneumonia. In addition, all healthcare personnel who have patient care duties should receive a flu shot annually.

83.3.5.2 Step 2. Get the catheters out.

Catheters and other invasive devices are the leading exogenous cause of nosocomial infections. Infections can occur in association with IV catheters, arterial catheters, urinary tract catheters, endotracheal tubes, and other devices. Every year, an estimated 250,000 Americans develop bacteremia related to use of central ve-nous catheters alone; the cost of treatment ranges from \$35,000 to \$56,000 *per patient*. To help prevent these infections, catheters should be used only when essential, and should be removed as soon as they are no longer needed.

974

975

83.3.5.2.1 BOX 82-1 Special Interest Topic

83.3.5.2.1.1 ANTIBIOTICS IN ANIMAL FEED: DYING FOR A BIG MAC AND CHICKEN MCNUGGETS

Drug-resistant infection resulting from use of antibiotics in agriculture is a global public health concern. Antibiotics are employed extensively in the livestock and poultry

industries. Not surprisingly, this practice has created a large reservoir of drug-resistant bacteria, some of which now infect humans. In addition to being a direct detriment to health, these infections pose an even larger threat: passage of resistance genes to normal intestinal flora, and then from normal flora to other human pathogens.

The amount of antibiotics given to food animals is staggering. According to estimates made by the Union for Concerned Scientists, of the 14,800 tons of antibiotics produced in the United States each year, nearly 90% (13,300 tons) goes to animals. Even more surprisingly, of the antibiotics that animals receive, only 7.5% (1000 tons) is given to treat infection. The vast majority—12,300 tons—is mixed with feed to promote growth. Both uses encourage the emergence of resistance.

Of the two agricultural uses—growth promotion and treatment of infection—growth promotion is by far the more controversial. Few authorities would argue that we shouldn't give animals antibiotics to treat infection. In contrast, there are strong arguments against giving antibiotics to promote growth. The doses employed for growth promotion are much lower than those used for infection, and hence are *more* likely to encourage emergence of resistance. Moreover, since growth can be promoted by other means, giving antibiotics for this purpose is unnecessary.

Which antibiotics are employed in agriculture? Essentially all of the antibiotics used in humans are also used in animals—including fluoroquinolones and third-generation cephalosporins, agents that are among the most effective we have. Because all antibiotics are being used, we are hastening the day when all will be useless.

The story of virginiamycin and Synercid illustrates the potentially serious consequences of giving antibiotics to farm animals. Virginiamycin is a mixture of two streptogramins. For 30 years, the drug has been used to promote animal growth. In 1999, a mixture of two similar streptogramins—quinupristin and dalfopristin, sold as Synercid—was approved for medical use in the United States. Synercid is an extremely important drug because it can kill vancomycin-resistant *Enterococcus faecium*, a dangerous pathogenic strain that is resistant to all other antibiotics. Unfortunately, agricultural use of virginiamycin is likely to shorten Synercid's useful life: A study of chickens that were fed virginiamycin indicates that 50% of the birds carried Synercid-resistant *E. faecium*. Sooner or later, these birds will pass these resistant pathogens on to humans—if they haven't already.

How can we reduce agriculture-related resistance? Clearly, if we want to delay emergence of resistance, and thereby extend the useful life of our antibiotics, we must limit

agricultural use of these drugs. To this end, the World Health Organization has recommended that all antibiotics used by humans be banned from use to promote growth in animals. Fifteen countries in the European Union have banned four widely used antibiotics, including virginiamycin, from use as growth promoters. In Denmark, use of antibiotics in animal feed has stopped entirely—with no apparent detriment to either animal health or the incomes of producers. Furthermore, within a few years after these drugs were discontinued, rates of antibiotic resistance among farm animals dropped dramatically. For example, resistance to avoparcin dropped from 73% to 5% in less than 5 years.

In the United States, public health and agriculture officials have discussed and debated the issue for more than 25 years, but no legislation has been enacted. A major stumbling block has been the inability to quantify the problem. That is, although there is universal agreement that giving antibiotics to animals represents a threat to public health, we lack sufficient data to determine just how big that threat is. Hopefully, Congress and the Food and Drug Administration (FDA) will take appropriate action before the threat has grown too large to overcome.

Although restrictive rules are not yet in place, they may be forthcoming: In 2002, the FDA proposed a draft “guidance” on antibiotic use in animals. If adopted, the guidance would require manufacturers of agricultural antibiotics to assess the ability of new drugs to promote emergence of pathogens resistant to antibiotics used in humans; drugs that did so could be kept off the market. In addition, the guidance proposes to review the impact of drugs already in use. Important among these are virginiamycin, penicillins, fluoroquinolones, tetracyclines, and third-generation cephalosporins.

In 2005, the FDA took a big step forward: For the first time, they banned the agricultural use of a specific drug. The FDA ruling, which took effect September 12, 2005, banned the use of enrofloxacin [Baytril] in chickens and turkeys. (Enrofloxacin is a fluoroquinolone similar to ciprofloxacin [Cipro].) The ban was based on concerns that widespread use of enrofloxacin in poultry was promoting resistance to ciprofloxacin and other fluoroquinolones in humans. This case is important in that it sets a precedent for FDA action against other animal antibiotics.

Note: Use of antibiotics by vegetable and fruit growers is just as widespread as in animal husbandry, and probably just as detrimental to public health—but that's another story.

83.3.5.3 Step 3. Target the pathogen.

Proper antimicrobial therapy requires that we choose drugs that are active against the causative organism. To do so, we must determine both the identity and drug sensitivity of the pathogen. This important issue is discussed in depth later under *Selection of Antibiotics*.

83.3.5.4 Step 4. Access the experts.

Not surprisingly, input from an infectious disease expert can improve patient outcomes, decrease treatment costs, and shorten the time to discharge. Expert assistance can be especially helpful for (1) patients with serious infections, (2) patients receiving complex antimicrobial regimens, (3) patients who fail to respond as expected, and (4) patients with a complicated underlying illness.

975

976

83.3.5.5 Step 5. Practice antimicrobial control.

To facilitate antimicrobial control, institutions are encouraged to implement procedures and programs that can help clinicians use antimicrobial drugs more wisely. Perhaps the most effective option is to implement a computerized support system designed to help clinicians select antimicrobial regimens. Other effective measures include use of standardized antimicrobial order forms, providing interactive education for prescribers, giving individual prescribers critical feedback on their choices, and establishing a multidisciplinary system to evaluate drug utilization.

83.3.5.6 Step 6. Use local data.

Drug susceptibility of microbes varies over time and according to locale, patient population, and hospital unit. To facilitate drug selection, institutions often compile data on drug susceptibility into an “antibiogram,” which provides an overview of common local pathogens and their current pattern of drug sensitivity. Clinicians use the antibiogram to guide initial drug selection while awaiting patient-specific data on drug susceptibility from the microbiology lab.

83.3.5.7 Step 7. Treat infection, not contamination.

Contamination of culture samples can lead to false-positive results on bacteriologic tests, and hence can lead to unneeded treatment with antimicrobial drugs. Studies indicate, in fact, that contamination is a major cause of unnecessary antimicrobial use. To decrease contamination, clinicians should simply use approved procedures to obtain and process all culture samples. For

example, to prevent contamination when drawing blood, clinicians can decontaminate the skin with tincture of iodine.

83.3.5.8 Step 8. Treat infection, not colonization.

A small, localized colony of bacteria does not constitute an infection. However, for two reasons, colonization is a concern. First, in patients who do *not* have an active infection, treatment because of colonization would be an unnecessary use of antibiotics. Second, in patients who *do* have an active infection, wrongly attributing the infection to colonizing bacteria could lead to treatment with drugs that are inactive against the real cause. To avoid both problems, it is essential that we differentiate between bacteria that are simply colonizing a region and those that are causing an actual infection.

83.3.5.9 Step 9. Know when to say “no” to vanco.

“Vanco” (ie, vancomycin) is a drug of last resort against several important pathogens, including methicillin-resistant *Staph. aureus* (MRSA) and multidrug-resistant *Streptococcus pneumoniae*. To delay emergence of vancomycin-resistant organisms, we must use the drug only when clearly necessary. Guidelines from the CDC spell out situations in which using vancomycin is deemed appropriate and situations in which using the drug should be discouraged.

83.3.5.10 Step 10. Stop treatment when infection is cured or unlikely.

Common sense dictates that we administer antibiotics only when they are actually needed: If the patient doesn't have an infection, we shouldn't use these drugs. When an infection has been cured, antibiotics should be discontinued. Similarly, if antibiotics were started before culture results were available, and if the culture comes back negative, then the antibiotics should be stopped.

83.3.5.11 Step 11. Isolate the pathogen.

By using standard infection control procedures, such as proper containment and disposal of contagious body fluids, we can isolate the pathogen, and can thereby reduce the risk of transferring resistant organisms from one patient to another.

83.3.5.12 Step 12. Break the chain of contagion.

This step could also be titled *Wash your hands!* All too often, bacteria are transferred from patient to patient on the hands of physicians, nurses, and other hospital workers. Fortunately, this transfer can be stopped by following a simple rule: Wash your hands before and after

touching any patient. Unfortunately, at least 50% of the time, clinicians fail to do so. The issue of hand hygiene is discussed at length in [Chapter 95](#) (Antiseptics and Disinfectants).

83.4 SELECTION OF ANTIBIOTICS

When treating infection, the therapeutic objective is to produce maximal antimicrobial effects while causing minimal harm to the host. To achieve this goal, we must select the most appropriate antibiotic for the individual patient. When choosing an antibiotic, three principal factors must be considered: (1) the identity of the infecting organism, (2) drug sensitivity of the infecting organism, and (3) host factors, such as the site of infection and the status of host defenses.

For any given infection, several drugs may be effective. However, for most infections, there is usually one drug that is superior to the alternatives ([Table 82-4](#)). This drug of first choice may be preferred for several reasons, such as greater efficacy, lower toxicity, or more narrow spectrum. Whenever possible, the drug of first choice should be employed. Alternative agents should be used only when the first-choice drug is inappropriate. Conditions that might rule out a first-choice agent include (1) allergy to the drug of choice, (2) inability of the drug of choice to penetrate to the site of infection, and (3) unusual susceptibility of the patient to toxicity of the first-choice drug.

83.4.1 Empiric Therapy Prior to Completion of Laboratory Tests

Optimal antimicrobial therapy requires identification of the infecting organism and determination of its drug sensitivity. However, when the patient has a severe infection, we may have to initiate treatment before test results are available. Under these conditions, drug selection must be based on clinical evaluation and knowledge of which microbes are most likely to cause infection at a particular site. If necessary, a broad-spectrum agent can be used for initial treatment. Once the identity and drug sensitivity of the infecting organism have been determined, we can switch to a more selective antibiotic. When conditions demand that we start therapy in the absence of laboratory data, it is essential that samples of exudates and body fluids be obtained for culture *prior to initiation of treatment*; if antibiotics are present at the time of sampling, they can suppress microbial growth in culture, and can thereby confound identification.

83.4.2 Identifying the Infecting Organism

The first rule of antimicrobial therapy is to *match the drug with the bug*. Hence, whenever possible, the infecting organism should be identified prior to initiation of therapy. If treatment is begun in the absence of a definitive diagnosis, positive identification should be established as soon as possible, so as to permit adjustment of the regimen to better conform with the drug sensitivity of the infecting organism.

976

979

TABLE 82-4 Antibacterial Drugs of Choice

Organism	Drug of First Choice	Some Alternative Drugs
Gram-Positive Cocci		
<i>Enterococcus</i> *		
Endocarditis and other severe infections	Penicillin G or ampicillin <i>with either</i> gentamicin or streptomycin	Vancomycin <i>with either</i> gentamicin or streptomycin, quinupristin/dalfopristin, linezolid, daptomycin
Uncomplicated urinary tract infection	Ampicillin, amoxicillin	Nitrofurantoin, a fluoroquinolone, fosfomycin
<i>Staphylococcus aureus</i> or <i>epidermidis</i> *		
Penicillinase producing	A penicillinase-resistant penicillin	A cephalosporin, vancomycin, imipenem, linezolid, clindamycin, daptomycin, a fluoroquinolone
Methicillin resistant	Vancomycin <i>with or without</i> gentamicin <i>with or without</i> rifampin	Linezolid, quinupristin/dalfopristin, daptomycin, tigecycline, doxycycline, trimethoprim/sulfamethoxazole, a fluoroquinolone
<i>Streptococcus pyogenes</i> (group A) and groups C and G	Penicillin G, penicillin V	Clindamycin, vancomycin, erythromycin, clarithromycin, azithromycin, daptomycin, linezolid, a cephalosporin
<i>Streptococcus</i> , group B	Penicillin G or ampicillin	A cephalosporin, vancomycin, erythromycin, daptomycin
<i>Streptococcus viridans</i> group	Penicillin G <i>with or without</i> gentamicin	A cephalosporin, vancomycin
<i>Streptococcus bovis</i>	Penicillin G	A cephalosporin, vancomycin
<i>Streptococcus</i> , anaerobic	Penicillin G	Clindamycin, a cephalosporin, vancomycin
<i>Streptococcus pneumoniae</i> * (pneumococcus)	Penicillin G, penicillin V, amoxicillin	A cephalosporin, erythromycin, azithromycin, clarithromycin, levofloxacin, gemifloxacin, moxifloxacin, meropenem, imipenem, ertapenem, trimethoprim/sulfamethoxazole, clindamycin, a tetracycline, vancomycin
Gram-Negative Cocci		
<i>Neisseria gonorrhoeae</i> (gonococcus)	See Chapter 94 , Table 94-1	

<i>Neisseria meningitides</i> (meningococcus)	Penicillin G	Cefotaxime, ceftriaxone, ceftizoxime, chloramphenicol, a sulfonamide, a fluoroquinolone
Gram-Positive Bacilli		
<i>Bacillus anthracis</i> (anthrax)	See Chapter 109	
<i>Clostridium difficile</i>	Metronidazole	Vancomycin (PO)
<i>Clostridium perfringens</i>	Penicillin G, clindamycin	Metronidazole, chloramphenicol, imipenem, meropenem, ertapenem
<i>Clostridium tetani</i>	Metronidazole	Penicillin G, doxycycline
<i>Corynebacterium diphtheriae</i>	Erythromycin	Penicillin G
<i>Listeria monocytogenes</i>	Ampicillin <i>with or without</i> gentamicin	Trimethoprim/sulfamethoxazole
Enteric Gram-Negative Bacilli		
<i>Campylobacter jejuni</i>	Erythromycin, azithromycin	A fluoroquinolone, gentamicin, a tetracycline
<i>Enterobacter</i>	Imipenem, meropenem, cefepime	Trimethoprim/sulfamethoxazole, gentamicin, tobramycin, amikacin, ciprofloxacin, cefotaxime, ticarcillin/clavulanic acid, piperacillin/tazobactam, aztreonam, ceftizoxime, ceftazidime, tigecycline
<i>Escherichia coli</i>	Cefotaxime, ceftazidime, cefepime, ceftriaxone	Ampicillin <i>with or without</i> gentamicin, ticarcillin/clavulanic acid, trimethoprim/sulfamethoxazole, imipenem, meropenem, others
<i>Klebsiella pneumoniae</i> *	Cefotaxime, ceftriaxone, cefepime, ceftazidime	Imipenem, meropenem, ertapenem, gentamicin, tobramycin, amikacin, others
<i>Proteus</i> , indole positive (including <i>Providencia rettgeri</i> and <i>Morganella morganii</i>)	Cefotaxime, ceftriaxone, cefepime, ceftazidime	Imipenem, meropenem, ertapenem, gentamicin, a fluoroquinolone, trimethoprim/sulfamethoxazole, others
<i>Proteus mirabilis</i>	Ampicillin	A cephalosporin, ticarcillin, trimethoprim/sulfamethoxazole, imipenem, meropenem, ertapenem, gentamicin, others
<i>Salmonella typhi</i>	Ceftriaxone, a fluoroquinolone	Trimethoprim/sulfamethoxazole, ampicillin, amoxicillin, chloramphenicol, azithromycin
Other <i>Salmonella</i>	Ceftriaxone, cefotaxime, a fluoroquinolone	Trimethoprim/sulfamethoxazole, chloramphenicol, ampicillin, amoxicillin

Pharmacology for Nursing Care, 7th Edition

<i>Serratia</i>	Imipenem, meropenem	Gentamicin, amikacin, cefotaxime, a fluoroquinolone, trimethoprim/sulfamethoxazole, aztreonam, others
<i>Shigella</i>	A fluoroquinolone	Trimethoprim/sulfamethoxazole, ampicillin, ceftriaxone, azithromycin
<i>Yersinia enterocolitica</i>	Trimethoprim/sulfamethoxazole	A fluoroquinolone, gentamicin, tobramycin, amikacin, cefotaxime
Other Gram-Negative Bacilli		
<i>Acinetobacter</i>	Imipenem, meropenem	An aminoglycoside, trimethoprim/sulfamethoxazole, doxycycline, ciprofloxacin, ceftazidime, ticarcillin/clavulanic acid, piperacillin/tazobactam
<i>Bacteroides</i>	Metronidazole	Imipenem, ertapenem, meropenem, amoxicillin/clavulanic acid, ticarcillin/clavulanic acid, piperacillin/tazobactam, ampicillin/sulbactam, chloramphenicol
<i>Bordetella pertussis</i> (whooping cough)	Azithromycin, clarithromycin, erythromycin	Trimethoprim/sulfamethoxazole
<i>Brucella</i> (brucellosis)	A tetracycline <i>plus</i> rifampin	A tetracycline <i>plus either</i> gentamicin or streptomycin, trimethoprim/sulfamethoxazole <i>with or without</i> gentamicin, chloramphenicol <i>with or without</i> streptomycin, ciprofloxacin <i>plus</i> rifampin
<i>Calymmatobacterium granulomatis</i>	Trimethoprim/sulfamethoxazole	Doxycycline or ciprofloxacin
<i>Francisella tularensis</i> (tularemia)	See Chapter 109	
<i>Gardnerella vaginalis</i>	Metronidazole (PO)	Topical clindamycin or metronidazole, clindamycin (PO)
<i>Haemophilus ducreyi</i> (chancroid)	Azithromycin, ceftriaxone	Ciprofloxacin, erythromycin
<i>Haemophilus influenzae</i>		
Meningitis, epiglottitis, arthritis, and other serious infections	Cefotaxime, ceftriaxone	Cefuroxime, chloramphenicol, meropenem
Upper respiratory infection and bronchitis	Trimethoprim/sulfamethoxazole	Cefuroxime, amoxicillin/clavulanic acid, a fluoroquinolone, others

<i>Helicobacter pylori</i>	Clarithromycin <i>plus</i> amoxicillin <i>plus</i> esomeprazole (a proton pump inhibitor)	Tetracycline <i>plus</i> metronidazole <i>plus</i> bismuth subsalicylate <i>plus</i> esomeprazole (a proton pump inhibitor)
<i>Legionella</i> species	Azithromycin, a fluoroquinolone <i>with or without</i> rifampin	Doxycycline <i>with or without</i> rifampin, trimethoprim/sulfamethoxazole, erythromycin
<i>Pasteurella multocida</i>	Penicillin G	Doxycycline, a second- or third-generation cephalosporin, amoxicillin/clavulanic acid, ampicillin/sulbactam
<i>Pseudomonas aeruginosa</i>		
Urinary tract infection	Ciprofloxacin	Levofloxacin, piperacillin/tazobactam, ceftazidime, cefepime, imipenem, meropenem, gentamicin, tobramycin, amikacin, aztreonam
Other infections	Piperacillin/tazobactam (or ticarcillin/clavulanic acid) <i>with or without</i> tobramycin, gentamicin, or amikacin	Ceftazidime, ciprofloxacin, imipenem, meropenem, aztreonam, or cefepime, <i>either one with or without</i> tobramycin, gentamicin, or amikacin
<i>Spirillum minus</i> (rat bite fever)	Penicillin G	Doxycycline, streptomycin
<i>Streptobacillus moniliformis</i> (rat bite fever)	Penicillin G	Doxycycline, streptomycin
<i>Vibrio cholerae</i> (cholera)	A tetracycline	Trimethoprim/sulfamethoxazole, a fluoroquinolone
<i>Yersinia pestis</i> (plague)	See Chapter 109	
Mycobacteria		
<i>Mycobacterium avium</i> complex	See Chapter 89	
<i>Mycobacterium leprae</i> (leprosy)	See Chapter 89	
<i>Mycobacterium tuberculosis</i>	See Chapter 89	
Actinomycetes		
<i>Actinomycetes israelii</i>	Penicillin G	Doxycycline, erythromycin, clindamycin
<i>Nocardia</i>	Trimethoprim/sulfamethoxazole	Sulfisoxazole, imipenem, meropenem, amikacin, a tetracycline, linezolid, ceftriaxone, cycloserine

Chlamydiae		
<i>Chlamydia psittaci</i>	Doxycycline	Chloramphenicol
<i>Chlamydia trachomatis</i>	See Chapter 94, Table 94-1	
Mycoplasma		
<i>Mycoplasma pneumoniae</i>	Erythromycin, clarithromycin, azithromycin, a tetracycline	A fluoroquinolone
<i>Ureaplasma urealyticum</i>	Azithromycin	A tetracycline, clarithromycin, erythromycin, ofloxacin
Rickettsia		
Rocky Mountain spotted fever, endemic typhus (murine), trench fever, typhus, scrub typhus, Q fever	Doxycycline	Chloramphenicol, a fluoroquinolone
Spirochetes		
<i>Borrelia burgdorferi</i> (Lyme disease)	Doxycycline, amoxicillin, cefuroxime	Ceftriaxone, cefotaxime, penicillin G, azithromycin, clarithromycin
<i>Borrelia recurrentis</i> (relapsing fever)	A tetracycline	Penicillin G, erythromycin
<i>Leptospira</i>	Penicillin G	Doxycycline, ceftriaxone
<i>Treponema pallidum</i> (syphilis)	Penicillin G	Doxycycline, ceftriaxone
<i>Treponema pertenue</i> (yaws)	Penicillin G	Doxycycline

* Drugs for highly resistant strains are listed in [Table 82-3](#).

The quickest, simplest, and most versatile technique for identifying microorganisms is microscopic examination of a *Gram-stained preparation*. Samples for examination can be obtained from pus, sputum, urine, blood, and other body fluids. The most useful samples are direct aspirates from the site of infection.

In some cases, only a small number of infecting organisms will be present. Under these conditions, positive identification may require that the microbes be grown out in culture. As stressed above, material for culture should be obtained prior to initiating treatment. Furthermore, the samples should be taken in a fashion that minimizes contamination with normal body flora. Also, the samples should not be exposed to low temperature, antiseptics, or oxygen.

83.4.3 Determining Drug Susceptibility

Because of the emergence of drug-resistant organisms, testing for drug sensitivity is common. However, sensitivity testing is not always needed. Rather, testing is indicated only when the infecting organism is one in which resistance is likely. Hence, for microbes such as the group A streptococci, which have remained highly susceptible to penicillin G, sensitivity testing is unnecessary. In contrast, when resistance is common, as it is with *Staph. aureus* and the gram-negative bacilli, tests for drug sensitivity should be performed.

83.4.3.1 Disk-Diffusion Test.

The most widely used method for assessing drug sensitivity is the disk-diffusion test, also known as the Kirby-Bauer test. This test is performed by inoculating an agar plate with the infecting organism and then placing on that plate several small disks, each of which is impregnated with a different antibiotic. Because of diffusion, an antibiotic-containing zone becomes established around each disk. As the bacteria proliferate, growth will be inhibited around the disks that contain an antibiotic to which the bacteria are sensitive. The degree of drug sensitivity is proportional to the size of the bacteria-free zone. Hence, by measuring the diameter of these zones, we can determine the drugs to which the organism is more susceptible, as well as those to which it is highly resistant.

83.4.3.2 Broth Dilution Procedure.

In this procedure, bacteria are grown in a series of tubes containing different concentrations of an antibiotic. The advantage of this method over the disk-diffusion test is that it provides a more precise measure of drug sensitivity. With the broth dilution procedure, we can establish close estimates of two clinically useful values: (1) the *minimum inhibitory concentration* (MIC), defined as the lowest concentration of antibiotic that produces complete inhibition of bacterial growth (but does not *kill* bacteria); and (2) the *minimum bactericidal concentration* (MBC), defined as the lowest concentration of drug that produces a 99.9% decline in the number of bacterial colonies (indicating bacterial kill). Because of the quantitative information provided, broth dilution procedures are especially useful for guiding therapy of infections that are unusually difficult to treat.

83.5 HOST FACTORS THAT MODIFY DRUG CHOICE, ROUTE OF ADMINISTRATION, OR DOSAGE

In addition to matching the drug with the bug and determining the drug sensitivity of an infecting organism, we must consider host factors when prescribing an antimicrobial drug. Two host factors—host defenses and the site of infection—are unique to the selection of antibiotics. Other host factors, such as age, pregnancy, and previous drug reactions, are the same factors that must be considered when choosing any other drug.

83.5.1 Host Defenses

Host defenses consist primarily of the immune system and phagocytic cells (macrophages, neutrophils). Without the contribution of these defenses, successful antimicrobial therapy would be rare. In most cases, the drugs we use do not cure infection on their own. Rather, they work in concert with host defense systems to subdue infection. Accordingly, the usual objective of antibiotic treatment is not outright kill of infecting organisms. Rather, the goal is to suppress microbial growth to the point at which the balance is tipped in favor of the host. Underscoring the critical role of host defenses is the grim fact that people whose defenses are impaired, such as those with AIDS and those undergoing cancer chemotherapy, frequently die from infections that drugs alone are unable to control. When treating the immunocompromised host, our only hope lies with drugs that are rapidly bactericidal, and even these may prove inadequate.

979

980

83.5.2 Site of Infection

To be effective, an antibiotic must be present at the site of infection in a concentration greater than the MIC. At some sites, drug penetration may be hampered, making it difficult to achieve the MIC. For example, drug access can be impeded in meningitis (because of the blood-brain barrier), endocarditis (because bacterial vegetations in the heart are difficult to penetrate), and infected abscesses (because of poor vascularity and the presence of pus and other material). When treating meningitis, two approaches may be used: (1) we can select a drug that readily crosses the blood-brain barrier, and (2) we can inject an antibiotic directly into the subarachnoid space. When pus and other fluids hinder drug access, surgical drainage is indicated.

Foreign materials (eg, cardiac pacemakers, prosthetic joints and heart valves, synthetic vascular shunts) present a special local problem. Phagocytes react to these objects and attempt to destroy them. Because of this behavior, the phagocytes are less able to attack bacteria, thereby allowing microbes to flourish. Treatment of these infections often results in failure or relapse. In many cases, the infection can be eliminated only by removing the foreign material.

83.5.3 Other Host Factors

83.5.3.1 Age.

Infants and the elderly are highly vulnerable to drug toxicity. In the elderly, heightened drug sensitivity is due in large part to reduced rates of drug metabolism and drug excretion, which can result in accumulation of antibiotics to toxic levels.

Multiple factors contribute to antibiotic sensitivity in infants. Because of poorly developed kidney and liver function, neonates eliminate drugs slowly. To avoid drug accumulation, many antibiotics must be used in low dosage. The very young are also subject to special toxicities. For example, use of sulfonamides in newborns can produce kernicterus, a severe neurologic disorder caused by displacement of bilirubin from plasma proteins (see [Chapter 87](#)). The tetracyclines provide another example of toxicity unique to the young: These antibiotics bind to developing teeth, causing discoloration.

83.5.3.2 Pregnancy and Lactation.

Antimicrobial drugs can cross the placenta, posing a risk to the developing fetus. For example, when gentamicin is used during pregnancy, irreversible hearing loss may result. Also, tetracyclines can stain immature teeth.

Antibiotic use during pregnancy may pose a risk to the expectant mother. It has been shown, for example, that during pregnancy there is an increased incidence of toxicity from tetracycline, characterized by hepatic necrosis, pancreatitis, renal damage, and, in extreme cases, death.

Antibiotics can enter breast milk, possibly affecting the nursing infant. Sulfonamides, for example, can reach levels in milk that are sufficient to cause kernicterus in nursing newborns. As a general guideline, antibiotics and all other drugs should be avoided by women who are breast-feeding.

83.5.3.3 Previous Allergic Reaction.

Severe allergic reactions are more common with the penicillins than with any other family of drugs. As a rule, patients with a history of allergy to the penicillins should not receive them again. The exception is treatment of a life-threatening infection for which no suitable alternative is available. In addition to the penicillins, other antibiotics (sulfonamides, trimethoprim, erythromycin) are associated with a high incidence of allergic responses. However, severe reactions to these agents are rare.

83.5.3.4 Genetic Factors.

As with other drugs, responses to antibiotics can be influenced by the patient's genetic heritage. For example, some antibiotics (eg, sulfonamides, nalidixic acid) can cause hemolysis in patients who, because of their genetic makeup, have red blood cells that are deficient in glucose-6-phosphate dehydrogenase. Clearly, people with this deficiency should not be given antibiotics that are likely to induce red cell lysis.

Genetic factors can also affect rates of metabolism. For example, hepatic inactivation of isoniazid is rapid in some people and slow in others. If the dosage is not adjusted accordingly, isoniazid may accumulate to toxic levels in the slow metabolizers, and may fail to achieve therapeutic levels in the rapid metabolizers.

83.6 DOSAGE SIZE AND DURATION OF TREATMENT

Success requires that the antibiotic be present at the site of infection in an effective concentration for a sufficient time. Dosages should be adjusted to produce drug concentrations that are equal to or greater than the MIC for the infection being treated. Drug levels 4 to 8 times the MIC are often desirable.

Duration of therapy depends on a number of variables, including the status of host defenses, the site of the infection, and the identity of the infecting organism. *It is imperative that antibiotics not be discontinued prematurely.* Accordingly, *patients should be instructed to take their medication for the entire prescribed course, even though symptoms may subside before the full course has been completed.* Early withdrawal is a common cause of recurrent infection, and the organisms responsible for relapse are likely to be more drug resistant than those present when therapy began.

83.7 THERAPY WITH ANTIBIOTIC COMBINATIONS

Therapy with a combination of antimicrobial agents is indicated only in specific situations. Under these well-defined conditions, use of multiple drugs may be lifesaving. However, it should be stressed that, although antibiotic combinations do have a valuable therapeutic role, routine use of two or more antibiotics should be discouraged. When an infection is caused by a single, identified microbe, treatment with just one drug is usually most appropriate.

980

83.7.1 Antimicrobial Effects of Antibiotic Combinations

981

When two antibiotics are used together, the result may be *additive*, *potentiative*, or, in certain cases, *antagonistic*. An *additive* response is one in which the antimicrobial effect of the

combination is equal to the sum of the effects of the two drugs alone. A *potentative* interaction (also called a *synergistic* interaction) is one in which the effect of the combination is greater than the sum of the effects of the individual agents. A classic example of potentiation is produced by trimethoprim plus sulfamethoxazole, drugs that inhibit sequential steps in the synthesis of tetrahydrofolic acid (see [Chapter 87](#)).

In certain cases, a combination of two antibiotics may be *less* effective than one of the agents by itself, indicating *antagonism* between the drugs. Antagonism is most likely when a *bacteriostatic* agent (eg, tetracycline) is combined with a *bactericidal* drug (eg, penicillin). Antagonism occurs because bactericidal drugs are usually effective only against organisms that are actively growing. Hence, when bacterial growth has been suppressed by a bacteriostatic drug, the effects of a bactericidal agent can be reduced. If host defenses are intact, antagonism between two antibiotics may have little clinical significance. However, if host defenses are compromised, the consequences can be dire.

83.7.2 Indications for Antibiotic Combinations

83.7.2.1 Initial Therapy of Severe Infection.

The most common indication for use of multiple antibiotics is initial therapy of severe infection of unknown etiology, especially in the neutropenic host. Until the infecting organism has been identified, wide antimicrobial coverage is appropriate. Just how broad the coverage should be depends on the clinician's skill in narrowing the field of potential pathogens. Once the identity of the infecting microbe is known, drug selection can be adjusted accordingly. As discussed above, samples for culture should be obtained before drug therapy starts.

83.7.2.2 Mixed Infections.

An infection may be caused by more than one microbe. Multiple infecting organisms are common in brain abscesses, pelvic infections, and infections resulting from perforation of abdominal organs. When the infecting microbes differ from one another in drug susceptibility, treatment with more than one antibiotic is required.

83.7.2.3 Prevention of Resistance.

Although use of multiple antibiotics is usually associated with *promoting* drug resistance, there is one infectious disease—tuberculosis—in which drug combinations are employed for the specific purpose of *suppressing* the emergence of resistant bacteria. Just why tuberculosis differs from other infections in this regard is discussed in [Chapter 89](#).

83.7.2.4 Decreased Toxicity.

In some situations, an antibiotic combination can reduce toxicity to the host. For example, by combining flucytosine with amphotericin B in the treatment of fungal meningitis, the dosage of amphotericin B can be reduced, thereby decreasing the risk of amphotericin-induced damage to the kidneys.

83.7.2.5 Enhanced Antibacterial Action.

In specific infections, a combination of antibiotics can have greater antibacterial action than a single agent. This is true of the combined use of penicillin plus an aminoglycoside in the treatment of enterococcal endocarditis. Penicillin acts to weaken the bacterial cell wall; the aminoglycoside acts to suppress protein synthesis. The combination has enhanced antibacterial action because, by weakening the cell wall, penicillin facilitates penetration of the aminoglycoside to its intracellular site of action.

83.7.3 Disadvantages of Antibiotic Combinations

Use of multiple antibiotics has several drawbacks, including (1) increased risk of toxic and allergic reactions, (2) possible antagonism of antimicrobial effects, (3) increased risk of suprainfection, (4) selection of drug-resistant bacteria, and (5) increased cost. Accordingly, antimicrobial combinations should be employed only when clearly indicated.

83.8 PROPHYLACTIC USE OF ANTIMICROBIAL DRUGS

Estimates indicate that between 30% and 50% of the antibiotics used in the United States are administered for prophylaxis. That is, these agents are given to prevent infection rather than to treat an established infection. Much of this prophylactic use is uncalled for. However, in certain situations, antimicrobial prophylaxis is both appropriate and effective. Whenever prophylaxis is attempted, the benefits must be weighed against the risks of toxicity, allergic reactions, suprainfection, and selection of drug-resistant organisms. Generally approved indications for prophylaxis are discussed below.

83.8.1 Surgery.

Prophylactic use of antibiotics can decrease the incidence of infection in certain kinds of surgery. Procedures in which prophylactic efficacy has been documented include cardiac surgery, peripheral vascular surgery, orthopedic surgery, and surgery on the GI tract (stomach, duodenum, colon, rectum, and appendix). Prophylaxis is also beneficial for women undergoing a

hysterectomy or an emergency cesarean section. In “dirty” surgery (operations performed on perforated abdominal organs, compound fractures, or lacerations from animal bites), the risk of infection is nearly 100%. Hence, for these operations, use of antibiotics is considered *treatment*, not prophylaxis. When antibiotics are given for prophylaxis, they should be administered before the surgery. If the procedure is unusually long, re-administration during surgery may be indicated. As a rule, postoperative antibiotics are unnecessary. For most operations, a first-generation cephalosporin (eg, cefazolin) will suffice.

83.8.2 Bacterial Endocarditis.

Individuals with congenital or valvular heart disease and those with prosthetic heart valves are unusually susceptible to bacterial endocarditis. For these people, endocarditis can develop following certain dental and medical procedures that dislodge bacteria into the bloodstream. Hence, prior to undergoing such procedures, these patients may need prophylactic antimicrobial medication. However, according to guidelines released by the American Heart Association in 2007, antibiotic prophylaxis is less necessary than previously believed, and hence should be done much less often than in the past.

83.8.3 Neutropenia.

Severe neutropenia puts individuals at high risk of infection. There is some evidence that the incidence of bacterial infection may be reduced through antibiotic prophylaxis. However, prophylaxis may increase the risk of infection with fungi: By killing normal flora, whose presence helps suppress fungal growth, antibiotics can encourage fungal invasion.

981

982

83.8.4 Other Indications for Antimicrobial Prophylaxis.

For young women with recurrent urinary tract infection, prophylaxis with trimethoprim/sulfamethoxazole may be helpful. Amantadine (an antiviral agent) may be employed for prophylaxis against type A influenza. For individuals who have had severe rheumatic endocarditis, lifelong prophylaxis with penicillin may be needed. Antimicrobial prophylaxis is indicated following exposure to organisms responsible for sexually transmitted diseases (eg, syphilis, gonorrhea).

83.9 MISUSES OF ANTIMICROBIAL DRUGS

Throughout this chapter, we have focused on the proper use of antimicrobial medications. In this section, we consider important ways in which these drugs are misused. The data in [Table 82-5](#) illustrate how common misuse can be.

83.9.1 Attempted Treatment of Untreatable Infection.

The majority of viral infections—including mumps, chickenpox, and the common cold—do not respond to currently available drugs. Hence, when drug therapy of these disorders is attempted, patients are exposed to all the risks of drug use without receiving any benefits.

Acute infections of the upper respiratory tract are a particular concern. When these infections are treated with antibiotics, only 1 patient out of 4000 is likely to benefit. However, the risks remain high: 1 in 4 patients will get diarrhea, 1 in 50 will get a rash, and 1 in 1000 will need to visit an emergency department, usually because of a severe allergic reaction.

83.9.2 Treatment of Fever of Unknown Origin.

Although fever can be a sign of infection, it can also signify other diseases, including hepatitis, arthritis, and cancer. Unless the cause of a fever is a proven infection, antibiotics should not be employed. Why? Because (1) if the fever is *not* due to an infection, antibiotics would not only be inappropriate, they would expose the patient to unnecessary toxicity and delay correct diagnosis of the fever's cause; and (2) if the fever *is* caused by infection, antibiotics could hamper later attempts to identify the infecting organism.

The only situation in which fever, by itself, constitutes a legitimate indication for antibiotic use is when fever occurs in the severely immunocompromised host. Since fever may indicate infection, and since infection can be lethal to the immunocompromised patient, these patients should be given antibiotics when fever occurs—even if fever is the only indication that an infection may be present.

83.9.3 Improper Dosage.

Like all other medications, antibiotics must be used in the right dosage. If the dosage is too low, the patient will be exposed to a risk of adverse effects without benefit of antibacterial effects. If the dosage is too high, the risks of suprainfection and adverse effects become unnecessarily high.

83.9.4 Treatment in the Absence of Adequate Bacteriologic Information.

As stressed earlier, proper antimicrobial therapy requires information on the identity and drug sensitivity of the infecting organism. Except in life-threatening situations, therapy should not be undertaken in the absence of bacteriologic information. This important guideline is often ignored.

83.9.5 Omission of Surgical Drainage.

Antibiotics may have limited efficacy in the presence of foreign material, necrotic tissue, or pus. Hence, when appropriate, surgical drainage and cleansing should be performed to promote antimicrobial effects.

83... MONITORING ANTIMICROBIAL THERAPY

Antimicrobial therapy is assessed by monitoring clinical responses and laboratory results. The frequency of monitoring is directly proportional to the severity of infection. Important clinical indicators of success are reduction of fever and resolution of signs and symptoms related to the affected organ system (eg, improvement of breath sounds in patients with pneumonia).

Various laboratory tests are used to monitor treatment. Serum drug levels may be monitored for two reasons: to ensure that levels are sufficient for antimicrobial effects and to avoid toxicity from excessive levels. Success of therapy is indicated by the disappearance of infectious organisms from post-treatment cultures. Cultures may become sterile within hours of the onset of treatment (as may happen with urinary tract infections), or they may not become sterile for weeks (as may happen with tuberculosis).

TABLE 82-5 Examples of Inappropriate Antibiotic Prescriptions

Type of Infection	Prescriptions per Year	Percent Inappropriate	Comment
Common cold	18 million	100	Antibiotics are ineffective against the common cold.
Bronchitis	16 million	80	Antibiotics are ineffective against bronchitis, except in a few infections or in patients with chronic severe lung disease.
Sore throat	13 million	50	Antibiotics should be used only in patients with confirmed strep infection.
Sinusitis	13 million	50	Most cases are viral, not bacterial. In the absence of facial pain or swelling, antibiotics should be withheld for about 10 days to see if symptoms improve without drugs.

982

83.10.1 KEY POINTS

- In antimicrobial therapy, the term *selective toxicity* refers to the ability of a drug to injure invading microbes without injuring cells of the host.

983

- Narrow-spectrum antibiotics are active against only a few microorganisms, whereas broad-spectrum antibiotics are active against a wide array of microbes.
- Bactericidal drugs kill bacteria, whereas bacteriostatic drugs only suppress growth.
- Emergence of resistance to antibiotics is a major concern in antimicrobial therapy.
- An important method by which bacteria acquire resistance is conjugation, a process in which DNA coding for drug resistance is transferred from one bacterium to another.
- Antibiotics do not cause the genetic changes that underlie resistance. Rather, antibiotics promote emergence of drug-resistant organisms by creating selection pressures that favor them.
- Broad-spectrum antibiotics promote the emergence of resistance more than do narrow-spectrum antibiotics.
- In the hospital, we can delay the emergence of antibiotic resistance in four basic ways: (1) preventing infection, (2) diagnosing and treating infection effectively, (3) using antimicrobial drugs wisely, and (4) preventing patient-to-patient transmission.
- Use of antibiotics to promote growth in livestock is a major force for promoting emergence of resistance.
- Effective antimicrobial therapy requires that we determine both the identity and drug sensitivity of the infecting organism.
- The minimum inhibitory concentration (MIC) of an antibiotic is defined as the lowest concentration needed to completely suppress bacterial growth.
- The minimum bactericidal concentration (MBC) is defined as the concentration that decreases the number of bacterial colonies by 99.9%.
- Host defenses—the immune system and phagocytic cells—are essential to the success of antimicrobial therapy.
- Patients should complete the prescribed course of antibiotic treatment, even though symptoms may abate before the full course is over.
- Although combinations of antibiotics should generally be avoided, they are appropriate in some situations, including (1) initial treatment of severe infections, (2) infection with

more than one organism, (3) treatment of tuberculosis, and (4) treatment of an infection in which combination therapy can greatly enhance antibacterial effects.

- Appropriate indications for prophylactic antimicrobial treatment include (1) certain surgeries, (2) neutropenia, (3) recurrent urinary tract infections, and (4) patients at risk of bacterial endocarditis (eg, those with prosthetic heart valves or congenital heart disease).
- Important misuses of antibiotics include (1) treatment of untreatable infections (eg, the common cold and most other viral infections), (2) treatment of fever of unknown origin (except in the immunocompromised host), (3) treatment in the absence of adequate bacteriologic information, and (4) treatment in the absence of appropriate surgical drainage.

⁸⁴CHAPTER 83 Drugs That Weaken the Bacterial Cell Wall I: Penicillins

^{84.1}INTRODUCTION TO THE PENICILLINS

The penicillins are practically ideal antibiotics. Why? Because they are active against a variety of bacteria and their direct toxicity is low. Allergic reactions are the principal adverse effect. Owing to their safety and efficacy, the penicillins are widely prescribed.

Because they have a beta-lactam ring in their structure ([Fig. 83-1](#)), the penicillins are known as *beta-lactam antibiotics*. The beta-lactam family also includes the cephalosporins, aztreonam, imipenem, meropenem, and ertapenem (see [Chapter 84](#)). All of the beta-lactam antibiotics share the same mechanism of action: disruption of the bacterial cell wall.

^{84.1.1} Mechanism of Action

To understand the actions of the penicillins, we must first understand the structure and function of the bacterial cell wall—a rigid, permeable, mesh-like structure that lies outside the cytoplasmic membrane. Inside the cytoplasmic membrane, osmotic pressure is very high. Hence, were it not for the rigid cell wall, which prevents expansion, bacteria would take up water, swell, and then burst.

Penicillins weaken the cell wall, causing bacteria to take up excessive amounts of water and rupture. As a result, penicillins are generally *bactericidal*. However, it is important to note that penicillins are active only against bacteria that are undergoing growth and division (see below).

Penicillins weaken the cell wall by two actions: (1) *inhibition of transpeptidases* and (2) *disinhibition (activation) of autolysins*. Transpeptidases are enzymes critical to cell wall synthesis. Specifically, they catalyze the formation of cross-bridges between the peptidoglycan polymer strands that form the cell wall, and thereby give the cell wall its strength ([Fig. 83-2](#)). Autolysins are bacterial enzymes that cleave bonds in the cell wall. Bacteria employ these enzymes to break down segments of the cell wall to permit growth and division. By simultaneously inhibiting transpeptidases and activating autolysins, the penicillins (1) disrupt synthesis of the cell wall and (2) promote its active destruction. These combined actions result in cell lysis and death.

The molecular targets of the penicillins (transpeptidases, autolysins, other bacterial enzymes) are known collectively as *penicillin-binding proteins* (PBPs). These molecules are so named because penicillins must bind to them to produce antibacterial effects. As indicated in [Figure 83-3](#), PBPs are located on the outer surface of the cytoplasmic membrane. More than eight different PBPs have been identified. Of these, PBP1 and PBP3 are most critical to penicillin's antibacterial

effects. Bacteria express PBPs only during growth and division. Accordingly, since PBPs must be present for penicillins to work, these drugs work only when bacteria are growing.

Since mammalian cells lack a cell wall, and since penicillins act specifically on enzymes that affect cell wall integrity, the penicillins have virtually no *direct* effects on cells of the host. As a result, the penicillins are among our safest antibiotics.

84.1.2 Mechanisms of Bacterial Resistance

Bacterial resistance to penicillins is determined primarily by three factors: (1) inability of penicillins to reach their targets (PBPs), (2) inactivation of penicillins by bacterial enzymes, and (3) production of PBPs that have a low affinity for penicillins.

84.1.2.1 The Gram-Negative Cell Envelope

All bacteria are surrounded by a cell envelope. However, the cell envelope of gram-negative organisms differs from that of gram-positive organisms. Because of this difference, some penicillins are ineffective against gram-negative bacteria.

As indicated in [Figure 83-3](#), the cell envelope of *gram-positive* bacteria has only two layers: the cytoplasmic membrane plus a relatively thick cell wall. Despite its thickness, the cell wall can be readily penetrated by penicillins, giving them easy access to PBPs on the cytoplasmic membrane. As a result, penicillins are generally very active against gram-positive organisms.

984

Figure 83-1 **Structural formulas of representative penicillins.**

The unique structure of individual penicillins is determined by the side chain coupled to the penicillin nucleus at the position labeled *R*. This side chain influences acid stability, pharmacokinetic properties, penicillinase resistance, and ability to bind specific penicillin-binding proteins.

The *gram-negative* cell envelope has three layers: the cytoplasmic membrane, a relatively thin cell wall, and an additional *outer membrane* (see [Fig. 83-3](#)). Like the gram-positive cell wall, the gram-negative cell wall can be easily penetrated by penicillins. The outer membrane, however, is difficult to penetrate. As a result, only certain penicillins (eg, ampicillin) are able to cross it and thereby reach PBPs on the cytoplasmic membrane.

84.1.2.2 Penicillinases (Beta-Lactamases)

Beta-lactamases are enzymes that cleave the beta-lactam ring, and thereby render penicillins and other beta-lactam antibiotics inactive ([Fig. 83-4](#)). Bacteria produce a large variety of beta-lactamases; some are specific for penicillins, some are specific for other beta-lactam antibiotics (eg, cephalosporins), and some act on several kinds of beta-lactam antibiotics. Beta-lactamases that act selectively on penicillins are known as *penicillinases*.

Figure 83-2 Inhibition of transpeptidase by penicillins. The bacterial cell wall is composed of long strands of a peptidoglycan polymer. As depicted, transpeptidase enzymes create cross-bridges between the peptidoglycan strands, giving the cell wall added strength. By inhibiting transpeptidases, penicillins prevent cross-bridge synthesis and thereby weaken the cell wall.

Penicillinases are synthesized by gram-positive and gram-negative bacteria. Gram-positive organisms produce large amounts of these enzymes, and then export them into the surrounding

medium. In contrast, gram-negative bacteria produce penicillinases in relatively small amounts, and, rather than exporting them to the environment, secrete them into the periplasmic space (see [Fig. 83-3](#)).

The genes that code for beta-lactamases are located on chromosomes and on plasmids (extrachromosomal DNA). The genes on plasmids may be transferred from one bacterium to another, thereby promoting the spread of penicillin resistance.

Transfer of resistance is of special importance with *Staphylococcus aureus*. When penicillin was first introduced in the early 1940s, all strains of *Staph. aureus* were sensitive. However, by 1960, as many as 80% of *Staph. aureus* isolates in hospitals displayed penicillin resistance. Fortunately, a penicillin derivative (methicillin) that has resistance to the actions of beta-lactamases was introduced at this time. To date, no known strains of *Staph. aureus* produce beta-lactamases capable of inactivating methicillin or related penicillinase-resistant penicillins (although some strains are resistant to these drugs for other reasons).

84.1.2.3 Altered Penicillin-Binding Proteins

Certain bacterial strains, known collectively as methicillin-resistant *Staphylococcus aureus* (MRSA), have a unique mechanism of resistance: production of PBPs with a low affinity for penicillins and all other beta-lactam antibiotics. How did MRSA develop this ability? By acquiring genes that code for low-affinity PBPs from other bacteria.

84.1.3 Chemistry

All of the penicillins are derived from a common nucleus: 6-aminopenicillanic acid. As shown in [Figure 83-1](#), this nucleus contains a beta-lactam ring joined to a second ring. The beta-lactam ring is essential for antibacterial actions. Properties of individual penicillins are determined by additions made to the basic nucleus, primarily at the site labeled *R*. These modifications determine (1) affinity for PBPs, (2) resistance to penicillinases, (3) ability to penetrate the gram-negative cell envelope, (4) resistance to stomach acid, and (5) pharmacokinetic properties.

985

Figure 83-3 **The bacterial cell envelope.** Note that the gram-negative cell envelope has an outer membrane, whereas the gram-positive envelope does not. The outer membrane of the gram-negative cell envelope prevents certain penicillins from reaching their target molecules. (PBP = penicillin-binding protein [transpeptidases and other penicillin target molecules], • = beta-lactamases.)

Figure 83-4 The effect of beta-lactamase on the penicillin nucleus.

84.1.4 Classification

The most useful classification of penicillins is based on antimicrobial spectrum. When classified this way, the penicillins fall into four major groups: (1) narrow-spectrum penicillins that are

penicillinase sensitive, (2) narrow-spectrum penicillins that are penicillinase resistant (antistaphylococcal penicillins), (3) broad-spectrum penicillins (aminopenicillins), and (4) extended-spectrum penicillins (antipseudomonal penicillins). [Table 83-1](#) lists the members of each group and their principal target organisms.

84.2 PROPERTIES OF INDIVIDUAL PENICILLINS

84.2.1 Penicillin G

Penicillin G (benzylpenicillin) was the first penicillin available and will serve as our prototype for the penicillin family. This drug is often referred to simply as *penicillin*. Penicillin G is bactericidal to a number of gram-positive bacteria as well as to some gram-negative bacteria. Despite the introduction of newer antibiotics, penicillin G remains a drug of choice for many infections. Its structure is shown in [Figure 83-1](#).

84.2.1.1 Antimicrobial Spectrum

Penicillin G is active against most *gram-positive bacteria* (except penicillinase-producing staphylococci), gram-negative cocci (*Neisseria meningitidis* and non-penicillinase-producing strains of *Neisseria gonorrhoeae*), anaerobic bacteria, and spirochetes (including *Treponema pallidum*). With few exceptions, gram-negative bacilli are resistant. Although many organisms respond to penicillin G, the drug is considered a narrow-spectrum agent (compared with other members of the penicillin family).

986

TABLE 83-1 Classification of the Penicillins

Penicillin Class	Drug	Clinically Useful Antimicrobial Spectrum
<i>Narrow-spectrum penicillins: penicillinase sensitive</i>	Penicillin G	<i>Streptococcus</i> species, <i>Neisseria</i> species, many anaerobes, spirochetes, others
	Penicillin V	
<i>Narrow-spectrum penicillins: penicillinase resistant (antistaphylococcal penicillins)</i>	Methicillin*	<i>Staphylococcus aureus</i>
	Nafcillin	
	Oxacillin	
	Cloxacillin*	
	Dicloxacillin	
<i>Broad-spectrum penicillins (aminopenicillins)</i>	Ampicillin	<i>Haemophilus influenzae</i> , <i>Escherichia coli</i> , <i>Proteus mirabilis</i> , enterococci, <i>Neisseria gonorrhoeae</i>
	Amoxicillin	
	Bacampicillin*	
<i>Extended-spectrum penicillins (antipseudomonal penicillins)</i>	Carbenicillin indanyl*	Same as broad-spectrum penicillins plus <i>Pseudomonas aeruginosa</i> , <i>Enterobacter</i> species, <i>Proteus</i> (indole positive), <i>Bacteroides fragilis</i> , many <i>Klebsiella</i>
	Ticarcillin	
	Mezlocillin*	
	Piperacillin	

* No longer used in the United States.

84.2.1.2 Therapeutic Uses

Penicillin G is a drug of first choice for infections caused by sensitive gram-positive cocci. Important among these are pneumonia and meningitis caused by *Streptococcus pneumoniae* (pneumococcus), pharyngitis caused by *Streptococcus pyogenes*, and infectious endocarditis caused by *Streptococcus viridans*. Penicillin is also the preferred drug for those few strains of *Staph. aureus* that do not produce penicillinase.

Penicillin is a preferred agent for infections caused by several gram-positive bacilli, specifically, gas gangrene (caused by *Clostridium perfringens*), tetanus (caused by *Clostridium tetani*), and anthrax (caused by *Bacillus anthracis*).

Penicillin is the drug of first choice for meningitis caused by *N. meningitidis* (meningococcus).

Although once the drug of choice for gonorrhea (caused by *N. gonorrhoeae*), penicillin has been replaced by ceftriaxone as the primary treatment. Penicillin is now limited to infections caused by non-penicillinase-producing strains of *N. gonorrhoeae*.

Penicillin is the drug of choice for syphilis, an infection caused by the spirochete *T. pallidum*.

In addition to treating active infections, penicillin G has important *prophylactic* applications. The drug is used to prevent syphilis in sexual partners of individuals who have this infection. Benzathine penicillin G (administered monthly for life) is employed for prophylaxis against recurrent attacks of rheumatic fever; treatment is recommended for patients with a history of recurrent rheumatic fever and for those with clear evidence of rheumatic heart disease. Penicillin is also employed for *prophylaxis of bacterial endocarditis*; candidates include individuals with (1) prosthetic heart valves, (2) most congenital heart diseases, (3) acquired valvular heart disease, (4) mitral valve prolapse, and (5) previous history of bacterial endocarditis. For prevention of endocarditis, penicillin is administered prior to dental procedures and other procedures that are likely to produce temporary bacteremia.

84.2.1.3 Pharmacokinetics

84.2.1.3.1 Absorption.

Penicillin G is available as three salts: (1) *potassium* penicillin G, (2) *procaine* penicillin G, and (3) *benzathine* penicillin G. These salts differ with respect to route of administration and time course of action. With all three forms, the salt dissociates to release penicillin G, the active component.

84.2.1.3.1.1 Oral.

Oral administration is obsolete. Penicillin G is unstable in acid, and the majority of an oral dose is destroyed in the stomach.

84.2.1.3.1.2 Intramuscular.

All forms of penicillin may be administered IM. However, it is important to note that the different salts are absorbed at very different rates. As indicated in [Figure 83-5](#), absorption of *potassium* penicillin G is rapid; blood levels peak about 15 minutes after injection. In contrast, the *procaine* and *benzathine* salts are absorbed slowly, and hence are considered

repository preparations. When benzathine penicillin is injected IM, penicillin G is absorbed for weeks, producing blood levels that are persistent but very low (see [Fig. 83-5](#)). Consequently, this preparation is useful only against highly sensitive organisms (eg, *T. pallidum*, the bacterium that causes syphilis).

84.2.1.3.1.3 Intravenous.

When high blood levels are needed rapidly, penicillin can be administered IV. Only the potassium salt should be used by this route. Owing to poor water solubility, *procaine and benzathine salts must never be administered IV*.

84.2.1.3.2 Distribution.

Penicillin distributes well to most tissues and body fluids. In the *absence* of inflammation, penetration of the meninges and into fluids of joints and the eye is poor. However, in the *presence* of inflammation, entry into cerebrospinal fluid, joints, and the eye is enhanced, permitting treatment of infections caused by susceptible organisms.

84.2.1.3.3 Metabolism and Excretion.

Penicillin undergoes minimal metabolism, and hence is eliminated by the kidneys, primarily as the unchanged drug. Renal excretion is accomplished mainly (90%) by active tubular secretion; the remaining 10% results from glomerular filtration. In older children and adults, the half-life is very short (about 30 minutes). Renal impairment causes the half-life to increase dramatically, and may necessitate a reduction in dosage. In patients at high risk of toxicity (those with renal impairment, the acutely ill, the elderly, the very young), kidney function should be monitored.

Renal excretion of penicillin can be delayed with *probenecid*, a compound that competes with penicillin for active tubular transport. In the past, when penicillin was both scarce and expensive, probenecid was employed routinely to prolong antibacterial effects. However, since penicillin is now available in abundance at low cost, concurrent use of probenecid is seldom indicated.

84.2.1.4 Side Effects and Toxicities

Penicillin G is the least toxic of all antibiotics, and among the safest of all medications. *Allergic reactions*, the principal concern with penicillin, are discussed separately below. Other reactions

include *pain at sites of IM injection*, prolonged (but reversible) *sensory and motor dysfunction* following accidental injection into a peripheral nerve, and *neurotoxicity* (sei

987

988

Figure 83-5 Blood levels of penicillin G following IM injection of three different penicillin G salts.

(Adapted from Pratt WB, Fekety R: The Antimicrobial Drugs. New York: Oxford University Press, 1986.)

zures, confusion, hallucinations) if blood levels are too high. Inadvertent *intra-arterial* injection can produce severe reactions—gangrene, necrosis, sloughing of tissue—and must be avoided.

Certain adverse effects may be caused by compounds coadministered with penicillin. For example, the procaine component of procaine penicillin G may cause bizarre behavioral effects when procaine penicillin is given in large doses. When large IV doses of potassium penicillin G are administered rapidly, hyperkalemia can result, possibly causing dysrhythmias and even cardiac arrest.

84.2.1.5 Penicillin Allergy

84.2.1.5.1 General Considerations.

Penicillins are the most common cause of drug allergy. Between 0.4% and 7% of patients who receive penicillins experience an allergic reaction. Severity can range from a minor rash to life-threatening anaphylaxis. As with most allergic reactions, there is no direct relationship between the size of the dose and the intensity of the response. Although prior exposure to penicillins is required for an allergic reaction, responses may occur in the absence of prior penicillin use. How can this be? Because patients may have been exposed to penicillins produced by fungi or to penicillins present in foods of animal origin.

Because of cross sensitivity, patients allergic to one penicillin should be considered allergic to all penicillins. In addition, a few patients (about 1%) display cross sensitivity to *cephalosporins*. If at all possible, patients with penicillin allergy should not be treated with any member of the penicillin family. Use of cephalosporins depends on the intensity of allergic response: If the penicillin allergy is mild, use of cephalosporins is probably safe; however, if the allergy is severe, cephalosporins should be avoided.

Individuals allergic to penicillin should be encouraged to wear a Medic Alert bracelet to alert healthcare personnel to their condition.

84.2.1.5.2 Types of Allergic Reactions.

Penicillin reactions are classified as *immediate*, *accelerated*, and *late*. Immediate reactions occur 2 to 30 minutes after drug administration; accelerated reactions occur within 1 to 72 hours; and late reactions occur within days to weeks.

Anaphylaxis (laryngeal edema, bronchoconstriction, severe hypotension) is an immediate hypersensitivity reaction, and the reaction of greatest concern. Anaphylactic reactions occur more frequently with penicillins than with any other drugs. However, even with penicillins, the incidence of anaphylaxis is extremely low (the estimated incidence is between 0.004% and 0.04%). Nonetheless, when these reactions do occur, the risk of mortality is high (about 10%). The primary treatment is *epinephrine* (subQ, IM, or IV) plus respiratory support. To ensure prompt treatment if anaphylaxis should develop, patients should remain in the prescriber's office for at least 30 minutes after drug injection (ie, until the risk of an anaphylactic reaction has passed).

84.2.1.5.3 Development of Penicillin Allergy.

Before discussing penicillin allergy further, we need to review development of allergy to small molecules as a class. Small molecules, such as penicillin and most other drugs, are unable to induce antibody formation directly. Therefore, in order to promote antibody formation, the small molecule must first bond covalently to a larger molecule (usually a protein). In these combinations, the small molecule is referred to as a *hapten*. The hapten-protein combination constitutes the complete *antigen* that stimulates antibody formation.

The hapten that stimulates production of penicillin antibodies is rarely intact penicillin itself. 988
Rather, compounds formed from the degradation of penicillin are the actual cause. As a result, 989
most “penicillin antibodies” are not directed at penicillin itself. Rather, they are directed at various penicillin degradation products.

84.2.1.5.4 Skin Tests for Penicillin Allergy.

Allergy to penicillin can decrease over time. Hence, an intense allergic reaction in the past does not necessarily mean that an intense reaction will occur again. In patients with a history of penicillin allergy, skin tests can be employed to assess the current risk. These tests are performed by injecting a tiny amount of allergen intradermally and observing for an allergic response.

Two reagents can be employed to assess penicillin allergy. One of these, *benzylpenicilloyl-polylysine* [Pre-Pen], tests primarily for *delayed* hypersensitivity. This reagent is referred to as a *major antigenic determinant*, a term indicating that the antibodies for which this reagent tests are relatively common. Benzylpenicilloyl-polylysine is a large polymeric molecule that is poorly absorbed. Hence, even in patients with severe penicillin allergy, a skin test carries little risk of a systemic reaction.

The second reagent, known as the *minor determinant mixture* (MDM), detects antibodies that mediate *immediate* allergic responses (eg, anaphylaxis). The term *minor* indicates that the antibodies being tested for are relatively uncommon and not that the allergic response mediated by these antibodies is of minor significance. It is important to note that skin testing with MDM can be dangerous: In patients with severe penicillin allergy, the skin test itself can precipitate an anaphylactic reaction. Accordingly, the test should be performed only if epinephrine and facilities for respiratory support are immediately available.

For two reasons, penicillin itself is rarely employed for skin tests. First, skin testing with penicillin can elicit an anaphylactic reaction in highly sensitized individuals. Second, use of penicillin can produce a false-negative result. This second point is paradoxical and requires explanation. Recall that most antibodies that mediate penicillin allergy are directed against degradation products of penicillin, and not against penicillin itself. Nonetheless, intact penicillin is able to bind to the active site of these antibodies—but that binding will not trigger an immune response. As a result, when small amounts of degradation products are formed following intradermal injection of penicillin, the presence of large amounts of intact penicillin can compete with those products for antibody-binding sites, thereby preventing the degradation products from triggering an allergic reaction.

84.2.1.5.5

Management of Patients with a History of Penicillin Allergy.

All patients who are candidates for penicillin therapy should be asked if they have penicillin allergy. For patients who answer “yes,” the general rule is to avoid penicillins. If the allergy is mild, a *cephalosporin* is often an appropriate alternative. However, if there is a history of anaphylaxis or some other severe allergic reaction, it is prudent to avoid cephalosporins as well (because there is about a 1% risk of cross sensitivity to cephalosporins). When a cephalosporin is indicated, an oral cephalosporin is preferred (because the risk of a severe reaction is lower than with parenteral therapy). For many infections, *vancomycin*, *erythromycin*, and *clindamycin* are effective and safe alternatives for patients with penicillin allergy.

Rarely, a patient with a history of anaphylaxis may have a life-threatening infection (eg, enterococcal endocarditis) for which alternatives to penicillins are ineffective. In these cases, the potential benefits of penicillin therapy outweigh the risks, and treatment should be instituted. To minimize the chances of an anaphylactic reaction, penicillin should be administered according to a desensitization schedule. In this procedure, an initial small dose is followed at 60-minute intervals by progressively larger doses until the full therapeutic dose has been achieved. It should be noted that the desensitization procedure is not without risk. Accordingly, epinephrine and facilities for respiratory support should be immediately available.

84.2.1.6 Drug Interactions

84.2.1.6.1 Aminoglycosides.

For some infections, penicillins are used in combination with an aminoglycoside (eg, gentamicin). By weakening the cell wall, the penicillin facilitates access of the aminoglycoside to its intracellular site of action, thereby increasing bactericidal effects. Unfortunately, when penicillins are present in high concentrations, they interact chemically with aminoglycosides and thereby inactivate the aminoglycoside. Accordingly, *penicillins and aminoglycosides should never be mixed in the same IV solution*. Rather, they should be administered separately. Once a penicillin has been diluted in body fluids, the potential for inactivating the aminoglycoside is minimal.

84.2.1.6.2 Probenecid.

As noted, probenecid can delay renal excretion of penicillin, thereby prolonging antibacterial effects.

84.2.1.6.3 Bacteriostatic Antibiotics.

Since penicillins are most effective against actively growing bacteria, concurrent use of a bacteriostatic antibiotic (eg, tetracycline) could, in theory, reduce the bactericidal effects of the penicillin. However, the clinical significance of such interactions is not known. Nonetheless, combined use of penicillin and bacteriostatic agents is generally avoided.

84.2.1.7 Preparations, Dosage, and Administration

84.2.1.7.1 Preparations and Routes of Administration.

Penicillin G is available as three different salts (potassium, procaine, and benzathine). These salts differ with respect to routes of administration: *potassium* penicillin G [Pfizerpen] is administered IM, IV, and by local infusion (eg, intrapleural); and *benzathine* penicillin G [Bicillin L-A, Permapen], *procaine* penicillin G [Wycillin], and a combination product [Bicillin C-R], composed of benzathine penicillin G plus procaine penicillin G, are all administered IM. Check to ensure that the penicillin salt to be administered is appropriate for the intended route.

84.2.1.7.2 Dosage.

Dosage of penicillin G is prescribed in units (1 unit equals 0.6 mg). Dosage ranges are summarized in [Table 83-2](#). For any particular patient, the specific dosage will depend on the type and severity of infection. Dosage should be reduced in patients with severe renal impairment.

84.2.1.7.3 Administration.

Solutions for parenteral administration should be prepared according to the manufacturer's instructions. During IM administration, take care to avoid inadvertent injection into an artery or peripheral nerve.

84.2.2 Penicillin V

Penicillin V [Veetids], also known as penicillin VK, is similar to penicillin G in most respects. The principal difference is acid stability: penicillin V is stable in stomach acid, whereas penicillin G is not. Because of its acid stability, penicillin V has replaced penicillin G for oral therapy. Penicillin V may be taken with meals. Dosages are summarized in [Table 83-2](#).

84.2.3 Penicillinase-Resistant Penicillins (Antistaphylococcal Penicillins)

By altering the penicillin side chain, pharmaceutical chemists have created a group of penicillins that are highly resistant to inactivation by beta-lactamases. In the United States, three such drugs are available: *nafcillin*, *oxacillin*, and *dicloxacillin*. These agents have a very narrow antimicrobial spectrum and are used only against penicillinase-producing strains of staphylococcus (*Staph. aureus* and *Staph. epidermidis*). Since most strains of staphylococci produce penicillinase, the penicillinase-resistant penicillins are drugs of choice for the majority of staphylococcal infections. It should be noted that these agents should not be used against infections caused by non-penicillinase-producing staphylococci, since they are less active than penicillin G against these bacteria.

989

990

TABLE 83-2 Dosages for Penicillin

				Total Daily Dosage ^a	
Generic Name	Trade Name	Usual Routes	Dosing Interval (hr)	Adults	Children
Narrow-Spectrum Penicillins: Penicillinase-Sensitive					
Penicillin G	Bicillin C-R, Bicillin L-A, Permapen, Pfizerpen, Wycillin	IM, IV	4	1.2–2.4 million units ^b	100,000–250,000 units/kg ^b
Penicillin V	Veetids	PO	4–6	0.5–2 gm	25–50 mg/kg
Narrow-Spectrum Penicillins: Penicillinase-Resistant (Antistaphylococcal Penicillins)					
Nafcillin		IV	4–6	2–12 gm	100–200 mg/kg
Oxacillin		IV	4–6	2–12 gm	100–200 mg/kg
Dicloxacillin		PO	6	1–4 gm	12.5–25 mg/kg
Broad-Spectrum Penicillins (Aminopenicillins)					
Ampicillin	Principen	PO	6–8	2–4 gm	50–100 mg/kg
		IV	6–8	2–12 gm	10–200 mg/kg
Ampicillin/sulbactam	Unasyn	IV	6	4–8 gm ^c	300 mg/kg ^c
Amoxicillin	Amoxil, DisperMox, Moxatag, Trimox	PO	8	0.75–1.5 gm	20–40 mg/kg
Amoxicillin/clavulanate	Augmentin	PO	8	250–500 mg ^d	20–40 mg/kg ^d
	Augmentin ES-600	PO	12	—	90 mg/kg
	Augmentin XR	PO	12	4000 mg	—
Extended-Spectrum Penicillins (Antipseudomonal Penicillins)					
Ticarcillin	Ticar	IV	4–6	200–300 mg/kg	200–300 mg/kg
Ticarcillin/clavulanate	Timentin	IV	4–6	200–300 mg/kg ^e	200 mg/kg ^e
Piperacillin		IV	4–6	12–24 gm	200–300 mg/kg
Piperacillin/tazobactam	Zosyn	IV	4–6	12 gm ^f	80–100 mg/kg ^f

- a Doses vary widely, depending upon the type and severity of infection; doses and dosing intervals presented here may not be appropriate for all patients.
- b 10,000 units = 6 mg.
- c Dose based on ampicillin content.
- d Dose based on amoxicillin content.
- e Dose based on ticarcillin content.
- f Dose based on piperacillin content.

An increasing clinical problem is the emergence of staphylococcal strains referred to as *methicillin-resistant Staphylococcus aureus* (MRSA), a term used to indicate lack of susceptibility to methicillin (an obsolete penicillinase-resistant penicillin) and all other penicillinase-resistant penicillins. Resistance appears to result from production of PBPs to which the penicillinase-resistant penicillins cannot bind. Currently, vancomycin (alone or combined with rifampin) is the treatment of choice. Infection with MRSA is discussed further in [Box 83-1](#).

84.2.3.1 Nafcillin

Nafcillin is usually administered IV. Intramuscular use is rare. Absorption from the GI tract is erratic and incomplete, and hence oral formulations have been discontinued. Dosage is summarized in [Table 83-2](#).

84.2.3.2 Oxacillin and Dicloxacillin

These drugs are similar in structure and pharmacokinetic properties: both are acid stable and available for oral administration. Oxacillin may also be administered IV. Oral dosing with both may be done with meals. Dosages are summarized in [Table 83-2](#).

84.2.3.3 Methicillin

Methicillin, the oldest penicillinase-resistant penicillin, is no longer available in the United States. In addition to causing allergic reactions typical of all penicillins, methicillin may produce interstitial nephritis, an adverse effect that is usually reversible but sometimes progresses to complete renal failure.

84.2.4 Broad-Spectrum Penicillins (Aminopenicillins)

Only two broad-spectrum penicillins are available: *ampicillin* and *amoxicillin*. Both have the same antimicrobial spectrum as penicillin G, *plus* increased activity against certain gram-negative

bacilli, including *Haemophilus influenzae*, *Escherichia coli*, *Salmonella*, and *Shigella*. This broadened spectrum is due in large part to an increased ability to penetrate the gram-negative cell envelope. Both drugs are readily inactivated by beta-lactamases, and hence are ineffective against most infections caused by *Staph. aureus*.

84.2.4.1 Ampicillin

Ampicillin [Principen] was the first broad-spectrum penicillin in clinical use. The drug is useful against infections caused by *Enterococcus faecalis*, *Proteus mirabilis*, *E. coli*, *Salmonella*, *Shigella*, and *H. influenzae*. The most common side effects are rash and diarrhea, both of which occur more frequently with ampicillin than with any other penicillin. Administration may be oral or IV. It should be noted, however, that for oral therapy, amoxicillin is preferred (see below). Dosages for patients with normal kidney function are summarized in [Table 83-2](#). For patients with renal impairment, dosage should be reduced.

990

992

84.2.4.1.1 BOX 83-1 Special Interest Topic

84.2.4.1.1.1 METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS*

Staphylococcus aureus is a gram-positive bacterium that often colonizes the skin and nostrils of healthy people. Infection usually involves the skin and soft tissues, causing abscesses, boils, cellulitis, and impetigo. However, more serious infections can also develop, including infections of the lungs and bloodstream, which can be fatal.

Like other pathogens, *Staph. aureus* has developed resistance over the years. When penicillins were introduced in the 1940s, all strains of *Staph. aureus* were susceptible. However, penicillin-resistant strains quickly emerged, owing to bacterial production of penicillinases. In 1959, this resistance was overcome with methicillin, the first penicillinase-resistant penicillin. Unfortunately, by 1968, strains resistant to methicillin had emerged. These highly resistant bacteria, known as *methicillin-resistant Staph. aureus* (MRSA), are resistant not only to methicillin (now obsolete), but to all penicillins and all cephalosporins as well. The basis of MRSA resistance is acquisition of genes that code for penicillin-binding proteins that have very low affinity for penicillins and cephalosporins. Resistant strains were initially limited to healthcare facilities, but are now found in the community as well.

In the United States, MRSA is a serious public health problem—and it's getting worse. Between 2000 and 2005, hospital stays for MRSA infection tripled, rising from 128,500

to 368,800. In 2005, MRSA caused an estimated 94,360 *severe* (ie, invasive) infections, resulting in 18,650 deaths—6150 *more* than were caused by HIV/AIDS. Not only does MRSA increase mortality, it increases costs: Treating hospitalized patients runs about \$35,000, compared with \$14,000 for patients with methicillin-sensitive infections. Fortunately, although MRSA infection is becoming more common and more invasive, it still remains treatable.

There are two distinct types of MRSA, referred to as *hospital-associated MRSA* (HA-MRSA) and *community-associated MRSA* (CA-MRSA). Of the two, HA-MRSA is more prevalent (85% vs. 15%) and emerged earlier (1968 vs. 1981). Also, HA-MRSA infection is generally more serious and harder to treat. Molecular typing indicates that HA-MRSA and CA-MRSA are genetically distinct strains, known as USA100 and USA300, respectively.

84.2.4.1.1....

Hospital-Associated MRSA

Methicillin resistance in *Staph. aureus* was first reported in isolates from hospitalized patients. The year was 1968. Since then, the prevalence of HA-MRSA among hospitalized patients has steadily climbed, reaching 2% of all *Staph. aureus* infections in 1974, 22% in 1995, and 63% in 2004. The prevalence of HA-MRSA in *invasive* infections (eg, bacteremia) is even higher, accounting for 85% of all invasive *Staph. aureus* infections. Although many infections with HA-MRSA *surface* in the community, nearly all occur in people who had been exposed to a healthcare facility within the prior year, indicating that acquisition of the infection probably occurred in a healthcare setting—not out in the community. Transmission of HA-MRSA is usually through person-to-person contact, very often between healthcare workers and patients. Risk factors for acquiring HA-MRSA include old age, recent surgery or hospitalization, dialysis, treatment in an ICU, prolonged antibiotic therapy, an indwelling catheter, and residence in a long-term care facility.

How do we treat HA-MRSA infection? Because most strains are multidrug resistant, many antibiotics are ineffective, including beta-lactam agents, tetracyclines, clindamycin, and trimethoprim/sulfamethoxazole. Fortunately, most isolates remain highly sensitive to IV vancomycin, the current treatment of choice. Alternatives include linezolid, daptomycin, tigecycline, and quinupristin/dalfopristin.

Community-Associated MRSA

Infection with CA-MRSA, first reported in 1981, is caused by staphylococcal strains that are genetically distinct from HA-MRSA. For example, most strains of CA-MRSA carry a gene for Panton-Valentine leukocidin (a cytotoxin that causes necrosis), whereas HA-MRSA strains do not. Many people are now asymptomatic carriers of CA-MRSA. In fact, between 20% and 30% of the population is colonized, typically on the skin and in the nostrils.

Infection with CA-MRSA is generally less dangerous than with HA-MRSA, but more dangerous than with methicillin-sensitive *Staph. aureus*. In most cases, CA-MRSA causes mild infections of the skin and soft tissues, manifesting as boils, impetigo, and so forth. However, CA-MRSA can also cause more serious infections, including necrotizing fasciitis, severe necrotizing pneumonia, and severe sepsis. Fortunately, these invasive infections are relatively rare. On the other hand, infections of the skin and soft tissues are now common, with CA-MRSA accounting for more than 50% of the *Staph. aureus* isolates from these sites.

How is CA-MRSA transmitted? And who is vulnerable? Transmission is by skin-to-skin contact, and by contact with contaminated objects, including frequently touched surfaces, sports equipment, and personal items (eg, razors). In contrast to HA-MRSA infection, CA-MRSA infection is seen primarily in young, healthy people with no recent exposure to healthcare facilities. Individuals at risk include athletes in contact sports (eg, wrestling), men who have sex with men, and people who live in close quarters, such as family members, day care clients, prison inmates, military personnel, and college students.

Several measures can reduce the risk of CA-MRSA transmission. Topping the list is good hand hygiene—washing with soap and water or applying an alcohol-based sanitizer. Other measures include showering after contact sports, cleaning frequently touched surfaces, keeping infected sites covered, and not sharing towels and personal items.

Treatment depends on infection severity. For boils, small abscesses, and other superficial infections, surgical drainage may be all that is needed. For more serious infections, drugs may be indicated. Preferred agents are trimethoprim/sulfamethoxazole, minocycline, doxycycline, and clindamycin. Alternative drugs—vancomycin, daptomycin, and linezolid—should be reserved for severe infections and

treatment failures. To eradicate the carrier state, intranasal application of a topical antibiotic—mupirocin or retapamulin—can be effective. Like HA-MRSA, CA-MRSA will not respond to beta-lactam antibiotics.

As discussed below, ampicillin is also available in a fixed-dose combination with sulbactam, an inhibitor of bacterial beta-lactamase. The combination is sold as *Unasyn*.

84.2.4.2 Amoxicillin

Amoxicillin [Amoxil, DisperMox, Moxatag, Trimox] is similar to ampicillin in structure and actions. The two drugs differ primarily in acid stability, amoxicillin being the more acid resistant. Hence, when the two are administered orally in equivalent doses, blood levels of amoxicillin are greater. Accordingly, when oral therapy is indicated, amoxicillin is preferred. Amoxicillin produces less diarrhea than ampicillin, perhaps because less amoxicillin remains unabsorbed in the intestine.

As discussed below, amoxicillin is also available in fixed-dose combinations with clavulanic acid, an inhibitor of bacterial beta-lactamases. The combination is marketed as *Augmentin*. Amoxicillin, by itself, is one of our most frequently prescribed antibiotics.

84.2.5 Extended-Spectrum Penicillins (Antipseudomonal Penicillins)

Two extended-spectrum penicillins are available: *ticarcillin* and *piperacillin*; a third drug—*carbenicillin indanyl* [Geocillin]—has been withdrawn. The antimicrobial spectrum of these drugs includes organisms that are susceptible to the aminopenicillins plus *Pseudomonas aeruginosa*, *Enterobacter* species, *Proteus* (indole positive), *Bacteroides fragilis*, and many *Klebsiella*. Both extended-spectrum penicillins are susceptible to beta-lactamases, and hence are ineffective against most strains of *Staph. aureus*.

The extended-spectrum penicillins are used primarily for infections with *P. aeruginosa*. These infections often occur in the immunocompromised host and can be very difficult to eradicate. To increase killing of *Pseudomonas*, an antipseudomonal aminoglycoside (gentamicin, tobramycin, amikacin, netilmicin) is almost always added to the regimen. When these combinations are employed, the penicillin and the aminoglycoside should not be mixed in the same IV solution. Why? Because high concentrations of penicillins can inactivate aminoglycosides.

84.2.5.1 Ticarcillin

84.2.5.1.1 Antimicrobial Spectrum and Therapeutic Use.

Ticarcillin [Ticar] has one of the broadest antimicrobial spectra of all penicillins. However, like other extended-spectrum penicillins, the drug is susceptible to destruction by penicillinase.

The primary indication for ticarcillin is infection with *P. aeruginosa*. When used against *Pseudomonas*, ticarcillin is usually combined with an aminoglycoside.

84.2.5.1.2 Adverse Effects.

In addition to promoting the allergic reactions typical of all penicillins, ticarcillin can cause unique effects. Since the drug is administered as the *disodium salt*, and since large IV doses are often required, symptoms of *sodium overload* (eg, congestive heart failure) may develop. Also, ticarcillin interferes with platelet function and can thereby promote *bleeding*.

84.2.5.1.3 Preparations and Administration.

Ticarcillin [Ticar] is unstable in acid, and hence must be given parenterally (almost always IV). When ticarcillin is used in combination with an aminoglycoside, the two drugs should be administered separately.

As discussed below, ticarcillin is available in a fixed-dose combination with clavulanic acid, a beta-lactamase inhibitor. The combination [Timentin] is administered IV.

Dosages for patients with normal kidney function are summarized in [Table 83-2](#). Dosages must be reduced in patients with renal impairment.

84.2.5.2 Piperacillin

Piperacillin has a broad antimicrobial spectrum. However, like other extended-spectrum penicillins, the drug is penicillinase sensitive. Piperacillin is highly active against *P. aeruginosa*, its principal target. Like ticarcillin, piperacillin can cause bleeding secondary to disrupting platelet function. The drug is acid labile and hence must be administered parenterally, usually IV. The risk of sodium overload is much less than with IV ticarcillin. When piperacillin is used in combination with an aminoglycoside, it should not be mixed in the same IV solution. Dosages for patients with normal kidney function are shown in [Table 83-2](#). Dosage should be

reduced in patients with renal impairment. As discussed below, piperacillin is also available in a fixed-dose combination with tazobactam, a beta-lactamase inhibitor. The combination is marketed as *Zosyn*.

84.2.6 Penicillins Combined with a Beta-Lactamase Inhibitor

As their name indicates, beta-lactamase inhibitors are drugs that inhibit bacterial beta-lactamases. By combining a beta-lactamase inhibitor with a penicillinase-sensitive penicillin, we can extend the antimicrobial spectrum of the penicillin. In the United States, three beta-lactamase inhibitors are used: *clavulanic acid*, *tazobactam*, and *sulbactam*. These drugs are not available alone. Rather, they are available only in fixed-dose combinations with a penicillin. Four such combination products are available:

- Ampicillin/sulbactam [Unasyn]
- Amoxicillin/clavulanic acid [Augmentin]
- Ticarcillin/clavulanic acid [Timentin]
- Piperacillin/tazobactam [Zosyn]

Because beta-lactamase inhibitors have minimal toxicity, any adverse effects that occur with the combination products are due to the penicillin. Routes of administration and dosages are summarized in [Table 83-2](#).

992

993

84.2.6.1

KEY POINTS

- Penicillins weaken the bacterial cell wall, causing lysis and death.
- Some bacteria resist penicillins by producing penicillinases (beta-lactamases), enzymes that inactivate penicillins.
- Gram-negative bacteria are resistant to penicillins that cannot penetrate the gram-negative cell envelope.
- Penicillins are the safest antibiotics available.
- The principal adverse effect of penicillins is allergic reaction, which can range in intensity from rash to lifethreatening anaphylaxis.

- Patients allergic to one penicillin should be considered cross-allergic to all other penicillins. In addition, they have about a 1% chance of cross-allergy to cephalosporins.
- Vancomycin, erythromycin, and clindamycin are safe and effective alternatives to penicillins for patients with penicillin allergy.
- Penicillins are normally eliminated rapidly by the kidney, but can accumulate to harmful levels if renal function is severely impaired.
- The principal differences among the penicillins relate to antibacterial spectrum, stability in stomach acid, and duration of action.
- Penicillin G has a narrow antibacterial spectrum and is unstable in stomach acid.
- Benzathine penicillin G is released very slowly following IM injection, and thereby produces prolonged antibacterial effects.
- The penicillinase-resistant penicillins (eg, nafcillin) are used primarily against penicillinase-producing strains of *Staph. aureus*.
- In contrast to penicillin G, the broad-spectrum penicillins, such as ampicillin and amoxicillin, have useful activity against gram-negative bacilli.
- Extended-spectrum penicillins, such as ticarcillin, are useful against *P. aeruginosa*.
- Beta-lactamase inhibitors, such as clavulanic acid, are combined with certain penicillins to increase their activity against beta-lactamase-producing bacteria.
- Penicillins should not be combined with aminoglycosides (eg, gentamicin) in the same IV solution.

84.2.6.2

Summary of Major Nursing Implications*

84.2.6.2.1

PENICILLINS

Amoxicillin

Ampicillin

Dicloxacillin

Nafcillin

Oxacillin

Penicillin G

Penicillin V

Piperacillin

Ticarcillin

Except where indicated otherwise, the implications summarized below apply to all members of the penicillin family.

84.2.6.2...

Preadministration Assessment

84.2.6.2...

Therapeutic Goal

Treatment of infections caused by sensitive bacteria.

84.2.6.2...

Baseline Data

The prescriber may order tests to identify the infecting organism and its drug sensitivity. Take samples for microbiologic culture prior to starting treatment.

In patients with a history of penicillin allergy, a skin test may be performed to determine current allergic status.

84.2.6.2...

Identifying High-Risk Patients

Penicillins should be used with *extreme caution*, if at all, in patients with a history of *severe* allergic reactions to penicillins, cephalosporins, or carbapenems.

84.2.6.2...	Implementation: Administration	
84.2.6.2...	Routes Penicillins are administered orally, IM, and IV. Routes for individual agents are summarized in Table 83-2. Before giving a penicillin, make sure the preparation is appropriate for the intended route.	
84.2.6.2...	Dosage Doses for penicillin G are prescribed in units (1 unit equals 0.6 mg). Doses for all other penicillins are prescribed by weight. Dosages for individual penicillins are summarized in Table 83-2.	
84.2.6.2...	Administration During IM injection, aspirate to avoid injection into an artery. Take care to avoid injection into a nerve. Instruct the patient to take oral penicillins with a full glass of water 1 hour before meals or 2 hours after. <i>Penicillin V, amoxicillin, and amoxicillin/clavulanic acid</i> may be taken with meals.	993 994
84.2.6.2...	Ongoing Evaluation and Interventions	
84.2.6.2...	Evaluating Therapeutic Effects Monitor the patient for indications of antimicrobial effects (eg, reduction in fever, pain, or inflammation; improved appetite or sense of well-being).	
84.2.6.2...	Monitoring Kidney Function Renal impairment can cause penicillins to accumulate to toxic levels, and hence monitoring kidney function can help avoid injury. Measuring intake and output is especially helpful in patients with kidney disease, acutely ill patients, and the very old	

and very young. Notify the prescriber if a significant change in intake/output ratio develops.

84.2.6.2...

Minimizing Adverse Effects

84.2.6.2...

Allergic Reactions.

Penicillin allergy is common. Very rarely, life-threatening anaphylaxis occurs. Interview the patient for a history of penicillin allergy.

For patients with prior allergic responses, a skin test may be ordered to assess current allergy status. Exercise caution: The skin test itself can cause a severe reaction. When skin tests are performed, epinephrine and facilities for respiratory support should be immediately available.

Advise patients with penicillin allergy to wear some form of identification (eg, Medic Alert bracelet) to alert emergency healthcare personnel.

Instruct outpatients to report any signs of an allergic response (eg, skin rash, itching, hives).

Whenever a parenteral penicillin is used, keep the patient under observation for at least 30 minutes. If anaphylaxis occurs, treatment consists of *epinephrine* (subQ, IM, or IV) plus respiratory support.

As a rule, patients with a history of penicillin allergy should not receive penicillins again. If previous reactions have been mild, a cephalosporin (preferably oral) may be an appropriate alternative. However, if severe immediate reactions have occurred, cephalosporins should be avoided too.

Rarely, a patient with a history of anaphylaxis nonetheless requires penicillin. To minimize the risk of a severe reaction, administer penicillin according to a desensitization schedule. Be aware, however, that the procedure does not guarantee that anaphylaxis will not occur. Accordingly, have epinephrine and facilities for respiratory support immediately available.

84.2.6.2...

Sodium Loading.

High IV doses of *ticarcillin* can produce sodium overload. Exercise caution in patients under sodium restriction (eg, cardiac patients, those with hypertension). Monitor electrolytes and cardiac status.

84.2.6.2...

Hyperkalemia.

High doses of IV *potassium penicillin G* may cause hyperkalemia, possibly resulting in dysrhythmias or cardiac arrest. Monitor electrolyte and cardiac status.

84.2.6.2...

Effects Resulting from Incorrect Injection.

Take care to avoid intra-arterial injection or injection into peripheral nerves, because serious injury can result.

84.2.6.2...

Minimizing Adverse Interactions

84.2.6.2...

Aminoglycosides.

When present in high concentration, penicillins can inactivate aminoglycosides (eg, gentamicin). Do not mix penicillins and aminoglycosides in the same IV solution.

* Patient education information is highlighted as **blue text**.

⁸⁵CHAPTER 84 Drugs That Weaken the Bacterial Cell Wall II: Cephalosporins, Carbapenems, Vancomycin, Aztreonam, Teicoplanin, and Fosfomycin

Like the penicillins, the drugs discussed in this chapter are inhibitors of cell wall synthesis. By disrupting the cell wall, these drugs produce bacterial lysis and death. Much of the chapter focuses on the cephalosporins, our most widely used antibacterial drugs. With only three exceptions—vancomycin, teicoplanin, and fosfomycin—the drugs addressed here are beta-lactam drugs.

^{85.1} CEPHALOSPORINS

The cephalosporins are beta-lactam antibiotics similar in structure and actions to the penicillins. These drugs are bactericidal, often resistant to beta-lactamases, and active against a broad spectrum of pathogens. Their toxicity is low. Because of these attributes, the cephalosporins are popular therapeutic agents and constitute our most widely used group of antibiotics. Hospitals in the United States spend more on cephalosporins than on all other antibiotics combined.

^{85.1.1} Chemistry

All cephalosporins are derived from the same nucleus. As shown in [Figure 84-1](#), this nucleus contains a *betalactam ring* fused to a second ring. The beta-lactam ring is required for antibacterial activity. Unique properties of individual cephalosporins are determined by additions made to the nucleus at the sites labeled R_1 and R_2 .

^{85.1.2} Mechanism of Action

The cephalosporins are bactericidal drugs with a mechanism like that of the penicillins. These agents bind to penicillinbinding proteins (PBPs) and thereby (1) disrupt cell wall synthesis and (2) activate autolysins (enzymes that cleave bonds in the cell wall). The resultant damage to the cell wall causes death by lysis. Like the penicillins, cephalosporins are most effective against cells undergoing active growth and division.

^{85.1.3} Resistance

The principal cause of cephalosporin resistance is production of beta-lactamases, enzymes that cleave the beta-lactam ring, and thereby render these drugs inactive. Beta-lactamases that act on

cephalosporins are sometimes referred to as *cephalosporinases*. Some of the beta-lactamases that act on cephalosporins can also cleave the beta-lactam ring of penicillins.

Not all cephalosporins are equally susceptible to betalactamases. Most *first-generation* cephalosporins are destroyed by beta-lactamases; *second-generation* cephalosporins are less sensitive to destruction; and *third-* and *fourth-generation* cephalosporins are highly resistant.

In some cases, bacterial resistance results from producing altered PBPs that have a low affinity for cephalosporins. Methicillin-resistant staphylococci produce these unusual PBPs and are resistant to cephalosporins as a result.

85.1.4 Classification and Antimicrobial Spectra

The cephalosporins can be grouped into four “generations” based on the order of their introduction to clinical use. The generations differ significantly with respect to antimicrobial spectrum and susceptibility to beta-lactamases. In general, *as we progress from first-generation agents to fourth-generation agents, there is (1) increasing activity against gram-negative bacteria and anaerobes, (2) increasing resistance to destruction by beta-lactamases, and (3) increasing ability to reach the cerebrospinal fluid (CSF)*. These differences are summarized in [Table 84-1](#).

85.1.4.1 First Generation.

First-generation cephalosporins, represented by cephalexin, are highly active against gram-positive bacteria. These drugs are the most active of all cephalosporins against staphylococci and nonenterococcal streptococci. However, staphylococci that are resistant to methicillin-like drugs are also resistant to first-generation cephalosporins (and to most other cephalosporins as well). The first-generation agents have only modest activity against gram-negative bacteria and do not reach effective concentrations in CSF.

85.1.4.2 Second Generation.

Second-generation cephalosporins (eg, cefoxitin) have enhanced activity against gram-negative bacteria. The increase is due to a combination of factors: (1) increased affinity for PBPs of gram-negative bacteria, (2) increased ability to penetrate the gram-negative cell envelope, and

995

Figure 84-1 Structural formulas of representative cephalosporins. The unique structure and pharmacologic properties of individual cephalosporins are determined by additions made to the cephalosporin nucleus at the positions labeled R_1 and R_2 .

(3) increased resistance to beta-lactamases produced by gram-negative organisms. However, none of the second-generation agents is active against *Pseudomonas aeruginosa*. These drugs do not reach effective concentrations in CSF.

TABLE 84-1 Major Differences Between Cephalosporin Generations

Class	Activity Against Gram-Negative Bacteria	Resistance to Beta-Lactamases	Distribution to Cerebrospinal Fluid
First generation (eg, cephalexin)	Low	Low	Poor
Second generation (eg, cefoxitin)	Higher	Higher	Poor
Third generation (eg, cefotaxime)	Higher	Higher	Good
Fourth generation (cefepime)	Highest	Highest	Good

85.1.4.3 Third Generation.

Third-generation cephalosporins (eg, cefotaxime) have a broad spectrum of antimicrobial activity. Because of increased resistance to beta-lactamases, these drugs are considerably more active against gram-negative aerobes than are the first- and second-generation agents. Some third-generation cephalosporins (eg, ceftazidime) have important activity against *P. aeruginosa*. Others (eg, cefixime) lack such activity. In contrast to first- and second-generation cephalosporins, the third-generation agents reach clinically effective concentrations in CSF.

85.1.4.4 Fourth Generation.

Cefepime, the only fourth-generation cephalosporin, is highly resistant to beta-lactamases and has a very broad antibacterial spectrum. Activity against *P. aeruginosa* equals that of ceftazidime. Penetration to CSF is good.

85.1.5 Pharmacokinetics

85.1.5.1 Absorption.

Because of poor absorption from the GI tract, *many cephalosporins must be administered parenterally* (IM or IV). Of the 18 cephalosporins used in the United States, only 10 can be administered by mouth ([Table 84-2](#)). Of these, only one—*cefuroxime*—can be administered orally *and* by injection.

85.1.5.2 Distribution.

Cephalosporins distribute well to most body fluids and tissues. Therapeutic concentrations are achieved in pleural, pericardial, and peritoneal fluids. However, concentrations in ocular fluids are generally low. Penetration to the CSF by first- and second-generation drugs is unreliable, and hence these drugs should not be used for bacterial meningitis. In contrast, CSF levels achieved with third- and fourth-generation drugs are generally sufficient for bactericidal effects.

85.1.5.3 Elimination.

Practically all cephalosporins are eliminated by the *kidney*; excretion is by a combination of glomerular filtration and active tubular secretion. Probenecid can decrease tubular secretion of some cephalosporins, thereby prolonging their effects. In patients with renal insufficiency, dosages of most cephalosporins must be reduced (to prevent accumulation to toxic levels).

One cephalosporin—*ceftriaxone*—is eliminated largely by the liver. Consequently, dosage reduction is unnecessary in patients with renal impairment.

85.1.6 Adverse Effects

Cephalosporins are generally well tolerated and constitute one of our safest groups of antimicrobial drugs. Serious adverse effects are rare.

85.1.6.1 Allergic Reactions.

Hypersensitivity reactions are the most frequent adverse events. Maculopapular rash that develops several days after the onset of treatment is most common. Severe, immediate

reactions (eg, bronchospasm, anaphylaxis) are rare. If, during the course of treatment, signs of allergy appear (eg, urticaria, rash, hypotension, difficulty in breathing), the cephalosporin should be discontinued immediately. Anaphylaxis is treated with respiratory support and parenteral epinephrine. Patients with a history of cephalosporin allergy should not be given these drugs.

Because of structural similarities between penicillins and cephalosporins, a few patients allergic to one type of drug may experience cross-reactivity with the other. In clinical practice, the incidence of cross-reactivity has been low: Only 1% of penicillin-allergic patients experience an allergic reaction if given a cephalosporin. For patients with mild penicillin allergy, cephalosporins can be used with minimal concern. However, because of the potential for fatal anaphylaxis, *cephalosporins should not be given to patients with a history of severe reactions to penicillins.*

TABLE 84-2 Pharmacokinetic Properties of the Cephalosporins

Class	Drug	Routes of Administration	Major Route of Elimination	Half-Life (hr)	
				Normal Renal Function	Severe Renal Impairment
First Generation	Cefadroxil	PO	Renal	1.2–1.3	20–25
	Cefazolin	IM, IV	Renal	1.5–2.2	24–50
	Cephalexin	PO	Renal	0.4–1	10–20
Second Generation	Cefaclor	PO	Renal	0.6–0.9	2–3
	Cefotetan	IM, IV	Renal	3–4.5	13–35
	Cefoxitin	IM, IV	Renal	0.7–1	13–22
	Cefprozil	PO	Renal	1.3	5–6
	Cefuroxime	PO, IM, IV	Renal	1–1.9	15–22
Third Generation	Cefdinir	PO	Renal	1.7	16
	Cefditoren	PO	Renal	1.6	—
	Cefixime	PO	Renal	3–4	11.5
	Cefotaxime	IM, IV	Renal	0.9–1.4	3–11
	Cefpodoxime	PO	Renal	2–3	9.8
	Ceftazidime	IM, IV	Renal	1.9–2	—
	Ceftibuten	PO	Renal	2	Increased
	Ceftizoxime	IM, IV	Renal	1.1–2.3	30
	Ceftriaxone	IM, IV	Hepatic	5.8–8.7	15.7
	Cefepime	IM, IV	Renal	2	Increased

997

85.1.6.2 Bleeding.

998

One cephalosporin—*cefotetan*—causes bleeding tendencies. The mechanism is reduction of prothrombin levels through interference with vitamin K metabolism.

Several measures can reduce the risk of hemorrhage. During prolonged treatment, patients should be monitored for prothrombin time, bleeding time, or both. Parenteral vitamin K can correct an abnormal prothrombin time. Patients should be observed for signs of bleeding, and, if bleeding develops, the cephalosporin should be withdrawn. Caution should be exercised during concurrent use of anticoagulants or thrombolytic agents. Because of their antiplatelet effects, aspirin and other nonsteroidal anti-inflammatory drugs should be used with care. Caution is needed in patients with a history of bleeding disorders.

85.1.6.3 Thrombophlebitis.

Thrombophlebitis may develop during IV infusion. This reaction can be minimized by rotating the infusion site and by administering cephalosporins slowly and in dilute solution. Patients should be observed for phlebitis. If it develops, the infusion site should be changed.

85.1.6.4 Other Adverse Effects.

Cephalosporins may cause *pain at sites of IM injection*; patients should be forewarned. Rarely, cephalosporins may be the cause of *antibiotic-associated pseudomembranous colitis* due to overgrowth with *Clostridium difficile*. If this suprainfection develops, the cephalosporin should be discontinued and, if necessary, oral vancomycin or metronidazole should be given.

With one cephalosporin—*cefditoren*—there are two unique concerns. First, the drug contains a milk protein (sodium caseinate), and hence should be avoided by patients with *milk-protein hypersensitivity* (as opposed to lactose intolerance). Second, cefditoren is excreted in combination with carnitine, and hence can cause *carnitine loss*. Accordingly, the drug is contraindicated for patients with existing carnitine deficiency or conditions that predispose to carnitine deficiency.

85.1.7 Drug Interactions

85.1.7.1 Probenecid.

Probenecid delays renal excretion of some cephalosporins and can thereby prolong their effects. This is the same interaction that occurs between probenecid and the penicillins.

85.1.7.2 Alcohol.

One cephalosporin—*cefotetan*—can induce a state of alcohol intolerance. If a patient taking this drug were to ingest alcohol, a disulfiram-like reaction could occur. (As discussed in [Chapter 38](#), the disulfiram effect is brought on by accumulation of acetaldehyde and can be extremely dangerous.) Accordingly, patients using cefotetan must not consume alcohol in any form.

85.1.7.3 Drugs That Promote Bleeding.

As noted, *cefotetan* promotes bleeding. Caution is needed if this drug is combined with other agents that promote bleeding (anticoagulants, thrombolytics, nonsteroidal anti-inflammatory drugs and other antiplatelet agents).

85.1.7.4 Calcium and Ceftriaxone.

Combining calcium with ceftriaxone can form potentially fatal precipitates. In neonates, the combination of IV calcium and IV ceftriaxone has caused death from depositing precipitates in the lungs and kidneys. Serious reactions in older patients have not been reported. Nonetheless, for *all* patients, the following rules apply:

- Don't reconstitute powdered ceftriaxone with calcium-containing diluents (eg, Ringer's solution).
- Don't mix reconstituted ceftriaxone with calcium-containing solutions.
- Don't give IV ceftriaxone and IV calcium by the same route or different routes within 48 hours of each other.
- If the patient must receive ceftriaxone and calcium, use *oral* calcium or *IM* ceftriaxone.

85.1.8 Therapeutic Uses

The therapeutic role of the cephalosporins is continually evolving as new agents are introduced and more experience is gained with older ones. Only general recommendations are considered here.

The cephalosporins are broad-spectrum, bactericidal drugs with a high therapeutic index. They have been employed widely and successfully against a variety of infections. Cephalosporins can be useful alternatives for patients with mild penicillin allergy.

The four generations of cephalosporins differ significantly in their applications. With one important exception—the use of first-generation agents for infections caused by sensitive staphylococci—the *first- and second-generation cephalosporins are rarely drugs of choice for active infections*. In most cases, equally effective and less expensive alternatives are available. In contrast, *the third-generation agents have qualities that make them the preferred therapy for several infections*. The role of *fourth-generation agents* is yet to be established.

85.1.8.1 First-Generation Cephalosporins.

When a cephalosporin is indicated for a *gram-positive infection*, a first-generation drug should be used; these agents are the most active of the cephalosporins against gram-positive organisms and are less expensive than other cephalosporins. First-generation agents are frequently employed as alternatives to penicillins to treat infections caused by staphylococci or streptococci (except enterococci) in patients with penicillin allergy. However, it is important to note that cephalosporins should be given only to patients with a history of *mild* penicillin allergy—not those who have experienced a severe, immediate hypersensitivity reaction.

The first-generation agents have been employed widely for *prophylaxis against infection in surgical patients*. First-generation agents are preferred to second- or third-generation cephalosporins for surgical prophylaxis. Why? Because they are as effective as the newer drugs, are less expensive, and have a more narrow antimicrobial spectrum.

85.1.8.2 Second-Generation Cephalosporins.

Specific indications for second-generation cephalosporins are limited. *Cefuroxime*, a prototype for the group, has been used with success against pneumonia caused by *Haemophilus influenzae*, *Klebsiella*, pneumococci, and staphylococci. Oral cefuroxime is useful for otitis, sinusitis, and respiratory tract infections. *Cefoxitin* is useful for abdominal and pelvic infections.

85.1.8.3 Third-Generation Cephalosporins.

Because they are highly active against gram-negative organisms, and because they penetrate to the CSF, third-generation cephalosporins are drugs of choice for meningitis caused by enteric, gram-negative bacilli. *Ceftazidime* is of special utility for treating meningitis caused by *P. aeruginosa*. Nosocomial infections caused by gram-negative bacilli, which are often resistant to first- and second-generation cephalosporins (and most other commonly used antibiotics), are appropriate indications for the third-generation drugs. Two third-generation agents—*ceftriaxone* and *cefotaxime*—are drugs of choice for infections caused by *Neisseria gonorrhoeae* (gonorrhea), *H. influenzae*, *Proteus*, *Salmonella*, *Klebsiella*, and *Serratia*; these drugs are also effective against meningitis caused by *Streptococcus pneumoniae*, a gram-positive bacterium.

The third-generation cephalosporins should not be used routinely. Rather, they should be given only when conditions demand, so as to delay emergence of resistance.

85.1.9 Drug Selection

Eighteen cephalosporins are currently employed in the United States, and selection among them can be a challenge. Within each generation, the similarities among cephalosporins are more pronounced than the differences. Hence, aside from cost, there is frequently no rational basis for choosing one drug over another. However, there are some differences between cephalosporins, and these differences may render one agent preferable to another for treating a specific infection in a specific host. The differences that do exist can be grouped into three main categories: (1) antimicrobial spectrum, (2) adverse effects, and (3) pharmacokinetics (eg, route of administration, penetration to the CSF, time course, mode of elimination). Drug selection based on these differences is discussed below.

998

999

85.1.9.1 Antimicrobial Spectrum.

A prime rule of antimicrobial therapy is to match the drug with the bug: The drug should be active against known or suspected pathogens, but its spectrum should be no broader than required. When a cephalosporin is appropriate, we should select from among those drugs known to have good activity against the causative pathogen. The third- and fourth-generation

agents, with their very broad antimicrobial spectra, should be avoided in situations where a narrower spectrum, first- or second-generation drug would suffice.

For some infections, one cephalosporin may be decidedly more effective than all others, and should be selected on this basis. For example, *ceftazidime* (a third-generation drug) is the most effective of all cephalosporins against *P. aeruginosa* and is clearly the preferred cephalosporin for treating infections caused by this microbe.

85.1.9.2 Adverse Effects.

Although most cephalosporins produce the same spectrum of adverse effects, a few can cause unique reactions. In particular, cefotetan can cause bleeding tendencies and intolerance to alcohol. When an equally effective alternative is available, it would be prudent to avoid these drugs.

85.1.9.3 Pharmacokinetics.

Four pharmacokinetic properties are of interest: (1) route of administration, (2) duration of action, (3) distribution to CSF, and (4) route of elimination. The relationship of these properties to drug selection is discussed below.

85.1.9.3.1 Route of Administration.

Ten cephalosporins can be administered orally. These drugs may be preferred for mild to moderate infections in patients who can't tolerate parenteral agents.

85.1.9.3.2 Duration of Action.

In patients with normal renal function, the half-lives of the cephalosporins range from about 30 minutes to 9 hours (see [Table 84-2](#)). Because they require fewer doses per day, drugs with a long half-life are frequently preferred. Cephalosporins with the longest half-lives in each generation are as follows: first generation, *cefazolin* (1.5 to 2 hours); second generation, *cefotetan* (3 to 4.5 hours); and third generation, *ceftriaxone* (6 to 9 hours).

85.1.9.3.3 Distribution to CSF.

Only the third- and fourth-generation agents achieve CSF concentrations sufficient for bactericidal effects. Hence, for meningitis caused by susceptible organisms, these drugs are preferred over first- and second-generation agents.

85.1.9.3.4 Route of Elimination.

Most cephalosporins are eliminated by the kidneys and, if dosage is not carefully adjusted, may accumulate to toxic levels in patients with renal impairment. Only one agent—*ceftriaxone*—is eliminated primarily by nonrenal routes, and hence can be used with relative safety in patients with bad kidneys.

85.1.10 Dosage and Administration

85.1.10.1 Routes.

Many cephalosporins cannot be absorbed from the GI tract and must therefore be administered parenterally (IM or IV). As shown in [Table 84-2](#), only 10 cephalosporins can be given orally. One drug—*cefuroxime*—can be administered both orally and by injection.

85.1.10.2 Dosage.

Dosages are summarized in [Table 84-3](#). For most cephalosporins (*ceftriaxone* excepted), dosage should be reduced in patients with significant renal impairment.

85.1.10.3 Administration.

Oral. If oral cephalosporins produce nausea, administration with food can reduce the response. Oral suspensions should be stored cold.

85.1.10.3.1 Intramuscular.

Intramuscular injections should be made deep into a large muscle. Intramuscular injection of cephalosporins is frequently painful; the patient should be forewarned. The injection site should be checked for induration, tenderness, and redness, and the prescriber informed if these occur.

999

1000

TABLE 84-3 Cephalosporin Dosages

				Total Daily Dosage*	
Drug	Trade Name	Route	Dosing Interval (hr)	Adults (gm)	Children (mg/kg)
First Generation					
Cefadroxil	Duricef	PO	12, 24	1–2	30
Cefazolin	generic only	IM, IV	6, 8	2–12	80–160
Cephalexin	Keflex	PO	6	1–4	25–50
Second Generation					
Cefaclor	Ceclor, Raniclor	PO	8	0.75–1.5	20–40
Cefotetan	Cefotan	IM, IV	12	2–6	—
Cefoxitin	Mefoxin	IM, IV	4, 8	3–12	80–160
Cefprozil	Cefzil	PO	12, 24	0.5–1	30
Cefuroxime	Ceftin	PO	12	0.5–1	250–500
	Zinacef	IM, IV	8	2.25–9	50–100
Third Generation					
Cefdinir	Omnicef	PO	12, 24	0.6	14
Cefditoren	Spectracef	PO	12	0.4–0.8	—
Cefixime	Suprax	PO	24	0.4	8
Cefotaxime	Claforan	IM, IV	4, 8	2–12	100–200
Cefpodoxime	Vantin	PO	12	0.2–0.4	10
Ceftazidime	Ceptaz, Fortaz, Tazicef, Tazidime	IM, IV	8, 12	0.5–6	90–150
Ceftibuten	Cedax	PO	24	0.4	9
Ceftizoxime	Cefizox	IM, IV	6, 12	2–12	150–200

Ceftriaxone	Rocephin	IM, IV	12, 24	1–4	50–100
Fourth Generation					
Cefepime	Maxipime	IM, IV	12	1–2	100

* With the exception of ceftriaxone, cephalosporins require a reduction of dosage for patients with severe renal impairment.

85.1.10.3.2 Intravenous.

For IV therapy, cephalosporins may be administered by three techniques: (1) bolus injection, (2) slow injection (over 3 to 5 minutes), and (3) continuous infusion. The prescriber's order should state which method to use. If there is uncertainty as to method, clarification should be requested. Solutions for parenteral administration should be prepared according to the manufacturer's recommendations.

85.2 CARBAPENEMS

Carbapenems are beta-lactam antibiotics that have very broad antimicrobial spectra—although none is active against methicillin-resistant *Staphylococcus aureus*. Four carbapenems are available: imipenem, meropenem, ertapenem, and doripenem. With all four, administration is parenteral. To delay emergence of resistance, these drugs should be reserved for patients who cannot be treated with more narrow-spectrum drugs.

85.2.1 Imipenem

Imipenem [Primaxin], a beta-lactam antibiotic ([Fig. 84-2](#)), has an extremely broad antimicrobial spectrum—broader, in fact, than nearly all other antimicrobial drugs. As a result, imipenem may be of special use for treating mixed infections in which anaerobes, *Staph. aureus*, and gram-negative bacilli may all be involved. Imipenem is supplied in fixed-dose combinations with cilastatin, a compound that inhibits destruction of imipenem by renal enzymes.

85.2.1.1 Mechanism of Action.

Imipenem binds to two PBPs (PBP1 and PBP2), causing weakening of the bacterial cell wall with subsequent lysis and death. Antimicrobial effects are enhanced by the drug's resistance to practically all beta-lactamases, and by its ability to penetrate the gram-negative cell envelope.

85.2.1.2 Antimicrobial Spectrum.

Imipenem is active against most bacterial pathogens, including organisms resistant to other antibiotics. The drug is highly active against gram-positive cocci and most gram-negative cocci and bacilli. In addition, imipenem is the most effective beta-lactam antibiotic for use against anaerobic bacteria.

85.2.1.3 Pharmacokinetics.

Imipenem is not absorbed from the GI tract and hence must be given parenterally (IV or IM). The drug is well distributed to body fluids and tissues. Imipenem penetrates the meninges to produce therapeutic concentrations in CSF.

Elimination is primarily renal. When employed alone, imipenem is inactivated by dipeptidase, an enzyme present in the kidney. As a result, drug levels in urine are low. To increase urinary concentrations, imipenem is administered in combination with *cilastatin*, a dipeptidase inhibitor. When the combination is used, about 70% of imipenem is excreted unchanged in the urine. The elimination half-life is about 1 hour.

85.2.1.4 Adverse Effects.

Imipenem is generally well tolerated. Gastrointestinal effects (nausea, vomiting, diarrhea) are most common. Hypersensitivity reactions (rashes, pruritus, drug fever) have occurred, and patients allergic to other beta-lactam antibiotics may be cross-allergic with imipenem. Suprainfections with bacteria or fungi develop in about 4% of patients. Rarely, seizures have occurred.

85.2.1.5 Therapeutic Use.

Because of its broad spectrum and low toxicity, imipenem is used widely. The drug has proved

Figure 84-2 Miscellaneous beta-lactam antibiotics.

effective for serious infections caused by gram-positive cocci, gram-negative cocci, gram-negative bacilli, and anaerobic bacteria. This broad antimicrobial spectrum gives imipenem special utility for chemotherapy of mixed infections (eg, simultaneous infection with aerobic and anaerobic bacteria). When imipenem has been given alone to treat infection with *P. aeruginosa*, resistant organisms have emerged. Consequently, imipenem should be combined with another anti-pseudomonal drug for use against this microbe.

85.2.1.6 Preparations, Dosage, and Administration.

Imipenem is formulated in 1:1 fixed-dose combinations with cilastatin. The combination products are marketed under the trade name *Primaxin*. Two formulations are available: *Primaxin I.V.* and *Primaxin I.M.*, for intravenous and intramuscular use, respectively. These products are supplied in powdered form and must be reconstituted in accord with the manufacturer's instructions. The usual adult dosage (based on imipenem content) is 250 to 500 mg every 6 hours. Dosage should be reduced in patients with renal impairment.

85.2.2 Other Carbapenems

85.2.2.1 Meropenem

85.2.2.1.1 Actions and Uses.

Meropenem [Merrem IV] is a beta-lactam antibiotic similar in structure and actions to imipenem. Meropenem is active against most clinically important gram-positive and gram-negative aerobes and anaerobes. Approved indications are (1) bacterial meningitis in children age 3 months or older, (2) complicated intra-abdominal infections in children and adults, and (3) skin and skin structure infections in children and adults. Meropenem may prove especially useful for nosocomial infections caused by organisms resistant to other antibiotics.

85.2.2.1.2 Pharmacokinetics.

Meropenem is administered IV and distributes to all body fluids and tissues. The drug has a plasma half-life of 1 hour and is eliminated primarily unchanged in the urine. In contrast to imipenem, meropenem is not degraded by renal dipeptidases, and hence is not combined with cilastatin.

85.2.2.1.3 Adverse Effects.

Like other beta-lactam antibiotics, meropenem is generally well tolerated. Principal adverse effects are rashes, diarrhea, nausea, and vomiting. As with imipenem, seizures occur rarely. The risk of seizures is highest in patients with central nervous system (CNS) disorders (eg, brain lesions, history of seizures) and bacterial meningitis.

1000

85.2.2.1.4 Preparations, Dosage, and Administration.

1001

Meropenem [Merrem IV] is supplied in powdered form to be reconstituted for IV administration. Depending on the volume employed, the drug may be (1) infused over 15 to 30 minutes or (2) injected as a bolus over 3 to 5 minutes. The dosage for adults is 1 gm every 8 hours. The dosage for pediatric patients is 20 mg/kg every 8 hours (for intra-abdominal infections) and 40 mg/kg every 8 hours (for bacterial meningitis). Adult and pediatric dosages must be reduced for patients with significant renal impairment (creatinine clearance less than 50 mL/min).

85.2.2.2 Ertapenem

85.2.2.2.1 Actions and Uses.

Like other carbapenems, ertapenem [Invanz] weakens the bacterial cell wall, and thereby causes cell lysis and death. Also like other carbapenems, ertapenem is highly resistant to beta-lactamases, and hence has a very broad antimicrobial spectrum—but less broad than that of imipenem or meropenem. Ertapenem is active against most gram-positive bacteria and most anaerobes. However, in contrast to imipenem and meropenem, the drug has little or no activity against *P. aeruginosa* or *Acinetobacter* species. In addition, ertapenem has minimal activity against pneumococci that are highly resistant to penicillin, and has no activity against methicillin-resistant staphylococci, *Enterococcus faecium*, *Enterococcus faecalis*, or atypical respiratory tract pathogens, including *Chlamydia* species, *Legionella* species, and *Mycoplasma pneumoniae*. Ertapenem is indicated for parenteral therapy of acute pelvic infections, community-acquired pneumonia, prophylaxis following elective colorectal surgery, and complicated infections of the urinary tract, abdomen, and skin and skin structures.

85.2.2.2.2 Pharmacokinetics.

Ertapenem may be administered by IM injection or IV infusion. Absorption following IM injection is complete. In the blood, ertapenem is highly bound to plasma proteins. The drug undergoes some hydrolysis of the beta-lactam ring prior to excretion in the urine (80%) and feces (10%). Its half-life is approximately 4 hours (compared with only 1 hour for imipenem or meropenem).

85.2.2.2.3 Adverse Effects.

Like other carbapenems, ertapenem is generally well tolerated. In clinical trials, the most common adverse effects were diarrhea (10.3%), nausea (8%), infused-vein complications (7.1%), headache (5.6%), vomiting (3.7%), and edema (3.4%). In addition, CNS effects (agitation, confusion, disorientation, decreased mental acuity, somnolence, stupor) were reported in 5.1% of patients. Like imipenem and meropenem, ertapenem can cause seizures, but the incidence is relatively low (0.5%).

85.2.2.2.4 Preparations, Dosage, and Administration.

Ertapenem [Invanz] is available as a powder to be reconstituted for IM or IV administration. For IV therapy, the drug is infused over 30 minutes, and should not be mixed with other drugs or with diluents that contain dextrose. The dosage (IM or IV) for *adults and children 13 years and older* is 1 gm once daily (for patients with good kidney function) or 500 mg once daily (for patients with significant renal impairment). The dosage for *children ages 3 months to 12 years* is 15 mg/kg twice daily (for children with good renal function); dosages for children with impaired renal function have not been established. For *adults and children*, the *duration* of treatment is 3 to 14 days, depending on the infection being treated.

85.2.2.3 Doripenem

85.2.2.3.1 Actions and Uses.

Doripenem [Doribax], approved in 2007, is active against a broad spectrum of gram-positive, gram-negative, and anaerobic bacteria. Activity against *P. aeruginosa* is greater than with other carbapenems. Cell kill results from disrupting cell wall synthesis. Doripenem has two approved indications: complicated intra-abdominal infections and complicated urinary tract

infections. To delay emergence of resistance, the drug should be reserved for seriously ill patients with mixed infections or infection with multidrug-resistant, gram-negative bacteria or *Pseudomonas*.

85.2.2.3.2 Pharmacokinetics.

Doripenem is administered by IV infusion. Binding to plasma proteins is low, and hepatic metabolism is minimal. Elimination is by renal excretion, primarily as unchanged drug. In patients with normal renal function, the half-life is about 1 hour. In patients with renal impairment, the half-life is longer, and hence these people require a reduced dosage to avoid accumulation of the drug to dangerous levels.

85.2.2.3.3 Adverse Effects and Interactions.

Like other carbapenems, doripenem is generally well tolerated. The most common side effects are headache (4% to 16%), nausea (4% to 12%), diarrhea (6% to 11%), rash (up to 3%), and injection-site phlebitis (4% to 8%). In contrast to other carbapenems, doripenem does not cause seizures. However, like other carbapenems, doripenem can reduce levels of valproic acid, and may thereby cause loss of seizure control.

85.2.2.3.4 Preparations, Dosage, and Administration.

Doripenem [Doribax] is supplied as a powder (500 mg) to be reconstituted in a total of 110 mL of normal saline or sterile water (to make 250 mg/55 mL). All doses are administered by IV infusion over a 1-hour span. Dosage depends on renal function as follows: *normal renal function*, 500 mg every 8 hours; *creatinine clearance 30 to 50 mL/min*, 250 mg every 8 hours; and *creatinine clearance 11 to 29 mL/min*, 250 mg every 12 hours.

85.3 OTHER INHIBITORS OF CELL WALL SYNTHESIS

85.3.1 Vancomycin

Vancomycin [Vancocin, Vancoled] is a potentially toxic drug used only for serious infections. Principal indications are antibiotic-associated pseudomembranous colitis (caused by *C. difficile*), infection with MRSA and treatment of serious infections with susceptible organisms in patients allergic to penicillins. Unlike most other drugs discussed in this chapter, vancomycin does not contain a beta-lactam ring.

85.3.1.1 Mechanism of Action.

Like the beta-lactam antibiotics, vancomycin inhibits cell wall synthesis and thereby promotes bacterial lysis and death. However, in contrast to the beta-lactams, vancomycin does not interact with PBPs. Instead, it disrupts the cell wall by binding to molecules that serve as precursors for cell wall biosynthesis.

85.3.1.2 Antimicrobial Spectrum.

Vancomycin is active only against gram-positive bacteria. The drug is especially active against *Staph. aureus* and *Staphylococcus epidermidis*, including strains of both species that are methicillin resistant. Other susceptible organisms include streptococci, penicillin-resistant pneumococci, and *C. difficile*.

85.3.1.3 Pharmacokinetics.

Absorption from the GI tract is poor. Hence, for most infections, vancomycin is given parenterally (by slow IV infusion). Oral administration is employed only for infections of the intestine.

Vancomycin is well distributed to most body fluids and tissues. Although it enters the CSF, levels may be insufficient to treat meningitis. Hence, if meningeal infection fails to respond to IV therapy, concurrent intrathecal administration may be required.

Vancomycin is eliminated unchanged by the kidneys. In patients with renal impairment, dosage must be reduced.

85.3.1.4 Therapeutic Use.

Vancomycin should be reserved for serious infections. This agent is the drug of choice for infections caused by MRSA or *Staph. epidermidis*; most strains of these bacteria remain vancomycin sensitive. The drug is also employed as an alternative to penicillins and cephalosporins to treat severe infections (eg, staphylococcal and streptococcal endocarditis) in patients allergic to beta-lactam antibiotics.

Until recently, oral vancomycin was considered the treatment of choice for antibiotic-associated pseudomembranous colitis caused by superinfection with *C. difficile*. However, to

delay emergence of resistance to vancomycin, metronidazole is now tried first. Vancomycin is used only in severely ill patients who have not responded to metronidazole.

85.3.1.5 Adverse Effects.

The most serious adverse effect is *ototoxicity*. Although hearing impairment is often reversible, permanent impairment can occur. Ototoxicity is most likely when plasma levels of vancomycin exceed 30 mcg/mL. The risk of hearing loss is increased by high dosage, prolonged treatment, renal impairment, and concurrent use of other ototoxic drugs (eg, aminoglycosides, ethacrynic acid).

Rapid infusion of vancomycin can cause a constellation of disturbing effects—flushing, rash, pruritus, urticaria, tachycardia, and hypotension—known collectively as *red man syndrome*, *red person syndrome*, or simply *red neck*. These effects, which may result from release of histamine, can usually be avoided by infusing vancomycin slowly (over 60 minutes or more).

Thrombophlebitis is common. The reaction can be minimized by administering vancomycin in dilute solution and by changing the infusion site frequently.

Rarely, vancomycin causes *immune-mediated thrombocytopenia*, a condition in which platelets are lost and spontaneous bleeding results. The underlying mechanism is development of unusual antibodies that bind to platelets—but only if the platelets first bind with vancomycin (forming a vancomycin-platelet complex). The resulting antibody-vancomycin-platelet complexes are then removed from the circulation by macrophages.

Patients allergic to penicillins do not show cross-reactivity with vancomycin. Accordingly, vancomycin is an alternative to penicillins in patients allergic to them.

85.3.1.6 Preparations, Dosage, and Administration.

For *systemic infection*, vancomycin is administered by intermittent infusion over 60 minutes or more. The usual adult dosage is 2 gm/day administered in divided doses at 12- or 24-hour intervals. The dosage for children is 44 mg/kg/day administered in divided doses at 6- or 12-hour intervals. In patients with renal impairment, dosages must be reduced. Serum drug levels should be monitored to ensure that dosage is appropriate. Blood for measuring peak drug levels should be drawn 1.5 to 2.5 hours after completing the IV infusion. Peak levels of 30 to 40 mcg/mL are generally acceptable.

For *antibiotic-associated pseudomembranous colitis*, vancomycin is given orally. The adult dosage is 125 to 500 mg every 6 hours. The dosage for children is 11 mg/kg every 6 hours. Because vancomycin is not absorbed from the GI tract, there is no need to decrease oral doses in patients with renal impairment.

85.3.2 Aztreonam

85.3.2.1 Chemistry.

Aztreonam [Azactam] belongs to a relatively new class of beta-lactam antibiotics known as *monobactams*. These agents contain a beta-lactam ring, but the ring is not fused with a second ring. The structure of aztreonam is shown in [Figure 84-2](#).

85.3.2.2 Mechanism of Action.

Aztreonam binds to PBP3. Hence, like most beta-lactam antibiotics, the drug inhibits bacterial cell wall synthesis, and thereby promotes cell lysis and death. The drug does not bind to PBPs produced by anaerobes or gram-positive bacteria.

85.3.2.3 Antimicrobial Spectrum and Therapeutic Use.

Aztreonam has a narrow antimicrobial spectrum, being active only against gram-negative aerobic bacteria. Susceptible organisms include *Neisseria* species, *H. influenzae*, *P. aeruginosa*, and Enterobacteriaceae (eg, *Escherichia coli*, *Klebsiella*, *Proteus*, *Serratia*, *Salmonella*, *Shigella*). Aztreonam is highly resistant to beta-lactamases, and therefore is active against many gram-negative aerobes that produce them. The drug is not active against gram-positive bacteria and anaerobes.

85.3.2.4 Pharmacokinetics.

Aztreonam is not absorbed from the GI tract and hence must be administered parenterally (IM or IV). Once in the blood, the drug distributes widely to most body fluids and tissues. Therapeutic concentrations can be achieved in the CSF. Aztreonam is eliminated by the kidneys, primarily unchanged.

85.3.2.5 Adverse Effects.

Aztreonam is generally well tolerated. Adverse effects are like those of other beta-lactam antibiotics. The most common effects are pain and thrombophlebitis at the site of injection. Because aztreonam differs greatly in structure from penicillins and cephalosporins, there is little cross-allergenicity with them. Hence, it appears that aztreonam is safe for patients with allergies to other beta-lactam antibiotics.

85.3.2.6 Preparations, Dosage, and Administration.

Aztreonam [Azactam] is supplied in powdered form to be reconstituted for IM or IV administration. The usual adult dosage is 1 to 2 gm every 8 to 12 hours. Dosage should be reduced in patients with renal impairment.

85.3.3 Teicoplanin

85.3.3.1 Chemistry and Actions.

Teicoplanin [Targocid] is similar in structure and actions to vancomycin. Both drugs disrupt cell wall synthesis to cause lysis and death, and both are active only against gram-positive bacteria. Sensitive organisms include MRSA, enterococci, and *C. difficile*. Like vancomycin—and unlike most other drugs discussed in the chapter—teicoplanin does not have a beta-lactam ring.

85.3.3.2 Pharmacokinetics.

The kinetics of teicoplanin are much like those of vancomycin—except that teicoplanin can be administered IM as well as IV. Neither drug is absorbed from the GI tract, so oral administration is reserved for infection of the intestine. Following parenteral administration, teicoplanin is well distributed to tissues and most body fluids, but not to the CSF. Teicoplanin has a long half-life (up to 100 hours) and is eliminated intact by the kidneys.

85.3.3.3 Therapeutic Use.

Teicoplanin is not approved in the United States, although it is approved in Japan and Europe. The drug has been used with success against an array of infections. Potential applications

include osteomyelitis and endocarditis caused by methicillin-resistant staphylococci, streptococci, and enterococci. Combining the drug with gentamicin can increase bactericidal effects.

Teicoplanin represents a safe and effective alternative to vancomycin, and offers several advantages, namely (1) the option of IM administration, (2) shorter infusion time with IV administration (30 vs. 60 minutes), (3) once-a-day dosing, and (4) the absence of serious adverse effects, including infusion-related reactions.

85.3.3.4 Adverse Effects.

Teicoplanin is largely devoid of adverse effects. In contrast to vancomycin, teicoplanin does not promote histamine release, and hence does not cause infusion-related reactions (eg, flushing, tachycardia, hypotension). Ototoxicity may occur but is rare. Not surprisingly, patients allergic to beta-lactam antibiotics are *not* cross-allergic to teicoplanin.

85.3.3.5 Dosage and Administration.

Teicoplanin may be given parenterally or orally. Parenteral administration is done by IM injection, IV injection, or 30-minute IV infusion. For parenteral therapy, the usual adult dosage is 6 mg/kg initially followed by 3 mg/kg every 24 hours. Dosage should be reduced in patients with renal impairment. As noted, oral therapy is used only for intestinal infections.

85.3.4 Fosfomycin

Fosfomycin [Monurol] is a unique antibiotic approved for single-dose therapy of women who have uncomplicated urinary tract infections (ie, acute cystitis) caused by *E. coli* or *Enterococcus faecalis*. The drug kills bacteria by disrupting synthesis of the peptidoglycan polymer strands that compose the cell wall. (As discussed in [Chapter 83](#), penicillins kill bacteria in part by preventing cross-linking of peptidoglycan strands.)

The most common adverse effects are diarrhea (10.4%), headache (10.3%), vaginitis (7.6%), and nausea (5.2%). Fosfomycin may also cause abdominal pain, rhinitis, drowsiness, dizziness, and rash.

Fosfomycin is supplied as a water-soluble powder in single-dose, 3-gm packets. Dosing may be done with or without food. Symptoms of cystitis should improve in 2 to 3 days. If symptoms fail to improve, additional doses will not help—but will increase the risk of side effects.

85.3.4.1

KEY POINTS

- Cephalosporins are beta-lactam antibiotics that weaken the bacterial cell wall, causing lysis and death.
- The major cause of cephalosporin resistance is production of beta-lactamases.
- Cephalosporins can be grouped into four “generations.” As we progress from first- to fourth-generation drugs, there is (1) increasing activity against gram-negative bacteria, (2) increasing resistance to destruction by betalactamases, and (3) increasing ability to reach the CSF.
- Except for ceftriaxone, all cephalosporins are eliminated by the kidneys, and therefore must be given in reduced dosage to patients with renal impairment.
- The most common adverse effects of cephalosporins are allergic reactions. Patients allergic to penicillins have about a 1% risk of cross-reactivity with cephalosporins.
- One cephalosporins—cefotetan—can cause bleeding tendencies and disulfiram-like reactions.
- Imipenem, a beta-lactam antibiotic, has an antimicrobial spectrum that is broader than that of practically all other antimicrobial drugs.
- Vancomycin is an important but potentially toxic drug generally reserved for (1) antibiotic-associated pseudomembranous colitis (caused by *C. difficile*), (2) infections with MRSA, and (3) serious infections by susceptible organisms in patients allergic to penicillins.

1002

85.3.4.2 Summary of Major Nursing Implications*

85.3.4.2.1 CEPHALOSPORINS

Cefaclor	Cefoxitin
Cefadroxil	Cefpodoxime
Cefazolin	Cefprozil
Cefdinir	Ceftazidime
Cefditoren	Ceftibuten
Cefepime	Ceftizoxime
Cefixime	Ceftriaxone
Cefotaxime	Cefuroxime
Cefotetan	Cephalexin

Except where indicated, the implications summarized below apply to all members of the cephalosporin family.

85.3.4.2... Preadministration Assessment

85.3.4.2... Therapeutic Goal

Treatment of infections caused by susceptible organisms.

85.3.4.2... Baseline Data

The prescriber may order tests to determine the identity and drug sensitivity of the infecting organism. Take samples for culture prior to initiating treatment.

85.3.4.2... Identifying High-Risk Patients

Cephalosporins are *contraindicated* for patients with a history of allergic reactions to cephalosporins or of severe allergic reactions to penicillins.

85.3.4.2...

Implementation: Administration

85.3.4.2...

Routes

Ten cephalosporins are given parenterally (IM or IV), 10 are given orally, and 1—*cefuroxime*—is given orally *and* parenterally (see [Table 84-3](#)).

85.3.4.2...

Dosage

Dosages are summarized in [Table 84-3](#). Dosages for all cephalosporins—except *ceftriaxone*—should be reduced in patients with significant renal impairment.

85.3.4.2...

Administration

85.3.4.2...

Oral.

Advise patients to take oral cephalosporins with food if gastric upset occurs. Instruct patients to refrigerate oral suspensions.

Instruct patients to complete the prescribed course of therapy even though symptoms may abate before the full course is over.

85.3.4.2...

Intramuscular.

Make IM injections deep into a large muscle. **Intramuscular injections are frequently painful; forewarn the patient.** Check the injection site for induration, tenderness, and redness—and notify the prescriber if these occur.

85.3.4.2...

Intravenous.

Techniques for IV administration are bolus injection, slow injection (over 3 to 5 minutes), and continuous infusion. The prescriber's order should specify which method to use; request clarification if the order is unclear.

85.3.4.2...

Ongoing Evaluation and Interventions

85.3.4.2...

Evaluating Therapeutic Effects

Monitor for indications of antimicrobial effects (eg, reduction in fever, pain, or inflammation; improved appetite or sense of well-being).

85.3.4.2...

Minimizing Adverse Effects

85.3.4.2...

Allergic Reactions.

Hypersensitivity reactions are relatively common. Rarely, life-threatening anaphylaxis occurs. Avoid cephalosporins in patients with a history of cephalosporin allergy or severe penicillin allergy. If penicillin allergy is *mild*, cephalosporins can be used with relative safety. **Instruct the patient to report any signs of allergy (eg, skin rash, itching, hives).** If anaphylaxis occurs, administer parenteral epinephrine and provide respiratory support.

85.3.4.2...

Bleeding.

Cefotetan can promote bleeding. Monitor prothrombin time, bleeding time, or both. Parenteral vitamin K can correct abnormal prothrombin time. Observe patients for signs of bleeding and, if bleeding develops, discontinue the drug. Exercise caution in patients with a history of bleeding disorders and in patients receiving drugs that can interfere with hemostasis (anticoagulants; thrombolytics; antiplatelet drugs, including aspirin and other nonsteroidal anti-inflammatory drugs).

85.3.4.2...

Thrombophlebitis.

Intravenous cephalosporins may cause thrombophlebitis. To minimize this reaction, rotate the injection site and inject cephalosporins slowly and in dilute solution. Observe the patient for phlebitis and change the infusion site if phlebitis develops.

85.3.4.2...

Antibiotic-Associated Pseudomembranous Colitis (AAPMC).

AAPMC may develop, especially with use of broad-spectrum cephalosporins. Notify the prescriber if diarrhea occurs (a possible indication of colitis). If AAPMC is

	diagnosed, discontinue the cephalosporin. Oral vancomycin or metronidazole may be needed.	
85.3.4.2...	Milk-Protein Hypersensitivity. <i>Cefditoren</i> tablets contain sodium caseinate, a milk protein. Do not give cefditoren to patients with milk-protein allergy. (The drug is safe in patients with lactose intolerance.)	
85.3.4.2...	Carnitine Deficiency. <i>Cefditoren</i> is excreted in combination with carnitine, and can thereby lower carnitine levels. Do not give cefditoren to patients with pre-existing carnitine deficiency or conditions that predispose to carnitine deficiency.	
85.3.4.2...	Minimizing Adverse Interactions	
85.3.4.2...	Alcohol. <i>Cefotetan</i> can cause alcohol intolerance. A serious disulfiram-like reaction may occur if alcohol is consumed. Inform patients about alcohol intolerance and warn them not to drink alcoholic beverages.	
85.3.4.2...	Drugs That Promote Bleeding. Drugs that interfere with hemostasis—anticoagulants, thrombolytics, and antiplatelet drugs (including aspirin and other nonsteroidal anti-inflammatory drugs)—can intensify bleeding tendencies caused by <i>cefotetan</i>. Do not combine these drugs.	1003 1004
85.3.4.2...	Calcium and Ceftriaxone. Combining calcium with ceftriaxone can form potentially fatal precipitates. To avoid harm, don't reconstitute powdered ceftriaxone with calcium-containing diluents; don't mix reconstituted ceftriaxone with calcium-containing solutions; and don't give IV ceftriaxone and IV calcium by the same or different routes within 48 hours of each other.	

* Patient education information is highlighted as **blue text**.

⁸⁶CHAPTER 85 Bacteriostatic Inhibitors of Protein Synthesis: Tetracyclines, Macrolides, and Others

All of the drugs discussed in this chapter inhibit bacterial protein synthesis. Unlike the aminoglycosides, whose effects on protein synthesis produce microbial death, the drugs considered here are usually bacteriostatic. That is, they suppress bacterial growth and replication but do not produce outright kill. In general, the drugs presented here are second-line agents, used primarily for infections resistant to first-line agents.

^{86.1}TETRACYCLINES

The tetracyclines are *broad-spectrum* antibiotics. Four members of the family are available for systemic therapy in the United States. All four—tetracycline, demeclocycline, doxycycline, and minocycline—are similar in structure, antimicrobial actions, and adverse effects. Principal differences among them are pharmacokinetic. Because the similarities among these drugs are more pronounced than their differences, we will discuss the tetracyclines as a group, rather than focusing on a prototype. Unique properties of individual tetracyclines are indicated as appropriate.

^{86.1.1} Mechanism of Action

The tetracyclines suppress bacterial growth by inhibiting protein synthesis. These drugs bind to the 30S ribosomal subunit, and thereby inhibit binding of transfer RNA to the messenger RNA–ribosome complex.* As a result, addition of amino acids to the growing peptide chain is prevented. At the concentrations achieved clinically, the tetracyclines are bacteriostatic.

Selective toxicity of the tetracyclines results from their poor ability to cross mammalian cell membranes. In order to influence protein synthesis, tetracyclines must first gain access to the cell interior. These drugs enter bacteria by way of an energy-dependent transport system. Mammalian cells lack this transport system, and hence do not actively accumulate the drug. Consequently, although tetracyclines are inherently capable of inhibiting protein synthesis in mammalian cells, their levels within host cells remain too low to be harmful.

* [Figure 86-2](#) in [Chapter 86](#) depicts the role of the 30S ribosomal subunit in bacterial protein synthesis.

^{86.1.2} Microbial Resistance

Bacterial resistance results from reduced drug accumulation, increased drug inactivation, and decreased access of drug to ribosomes (owing to the presence of ribosome protection proteins).

Regarding reduced accumulation, two mechanisms are involved: (1) decreased uptake and (2) increased ability to actively extrude tetracyclines.

86.1.3 Antimicrobial Spectrum

The tetracyclines are broad-spectrum antibiotics, active against a wide variety of gram-positive and gram-negative bacteria. Sensitive organisms include *Rickettsia*, spirochetes, *Brucella*, *Chlamydia*, *Mycoplasma*, *Helicobacter pylori*, *Borrelia burgdorferi*, *Bacillus anthracis*, and *Vibrio cholerae*.

86.1.4 Therapeutic Uses

86.1.4.1 Treatment of Infectious Diseases.

Extensive use of tetracyclines has resulted in increasing bacterial resistance. Because of resistance, and because antibiotics with greater selectivity and less toxicity are now available, use of tetracyclines has declined. Today, tetracyclines are rarely drugs of first choice. Disorders for which they *are* first-line drugs include (1) rickettsial diseases (eg, Rocky Mountain spotted fever, typhus fever, Q fever); (2) infections caused by *Chlamydia trachomatis* (trachoma, lymphogranuloma venereum, urethritis, cervicitis); (3) brucellosis; (4) cholera; (5) pneumonia caused by *Mycoplasma pneumoniae*; (6) Lyme disease; (7) anthrax; and (8) gastric infection with *H. pylori*.

86.1.4.2 Treatment of Acne.

Tetracyclines are used topically and orally for severe acne vulgaris. Beneficial effects derive from suppressing the growth and metabolic activity of *Propionibacterium acnes*, an organism that secretes inflammatory chemicals. Oral doses for acne are relatively low. As a result, adverse effects are minimal. Treatment of acne is discussed further in [Chapter 104](#) (Drugs for the Skin).

1005

TABLE 85-1 Pharmacokinetic Properties of the Tetracyclines

Class	Drug	Lipid Solubility	Percent of Oral Dose Absorbed	Effect of Food on Absorption	Route of Elimination	Half-Life	
						Normal (hr)	Anuric (hr)
Short Acting	Tetracycline	Low	60–80	Decrease	Renal	8	57–108*
Intermediate Acting	Demeclocycline	Moderate	60–80	Decrease	Renal	12	40–60*
Long Acting	Doxycycline	High	90–100	No change	Hepatic	18	12–22
	Minocycline	High	90–100	No change	Hepatic	16	11–23

* Do not use in patients with renal impairment because the drug could accumulate to toxic levels.

86.1.4.3 Peptic Ulcer Disease.

Helicobacter pylori, a bacterium that lives in the stomach, is a major contributing factor to peptic ulcer disease. Tetracyclines, in combination with metronidazole and bismuth subsalicylate, are a treatment of choice for eradicating this bug. The role of *H. pylori* in ulcer formation is discussed in [Chapter 77](#) (Drugs for Peptic Ulcer Disease).

86.1.4.4 Periodontal Disease.

Two tetracyclines—*doxycycline* and *minocycline*—are used for periodontal disease. Doxycycline is used orally *and* topically, whereas minocycline is only used topically.

86.1.4.4.1 Oral Therapy.

Benefits of oral doxycycline [Periostat] result from inhibiting collagenase, an enzyme that destroys connective tissue in the gums. The small doses employed— 20 mg twice daily—are too low to harm bacteria.

86.1.4.4.2 Topical Therapy.

Topical minocycline [Arestin] and doxy–cycline [Atridox] are employed as adjuncts to scaling and root planing. The objective is to reduce pocket depth and bleeding in adults with

periodontitis. Benefits derive from suppressing bacterial growth. Both products are applied directly to the site of periodontal disease.

86.1.4.5 Rheumatoid Arthritis

Minocycline can reduce symptoms in patients with rheumatoid arthritis, suggesting a possible infectious component to the disease.

86.1.5 Pharmacokinetics

Individual tetracyclines differ significantly in their pharmacokinetic properties. Of particular significance are differences in half-life and route of elimination. Also important is the degree to which food decreases absorption. The pharmacokinetic properties of individual tetracyclines are summarized in [Table 85-1](#).

86.1.5.1 Duration of Action.

The tetracyclines can be divided into three groups: short acting, intermediate acting, and long acting (see [Table 85-1](#)). These differences are related to differences in lipid solubility: The only short-acting tetracycline (tetracycline) has relatively low lipid solubility, whereas the long-acting agents (doxycycline, minocycline) have relatively high lipid solubility.

86.1.5.2 Absorption.

All of the tetracyclines are orally effective, although the extent of absorption differs among individual agents (see [Table 85-1](#)). Absorption of the short- and intermediate-acting tetracyclines is reduced by food; in contrast, absorption of the long-acting agents is not.

The tetracyclines form insoluble chelates with calcium, iron, magnesium, aluminum, and zinc. The result is decreased absorption. Accordingly, *tetracyclines should not be administered together with* (1) *calcium supplements*, (2) *milk products* (because they contain calcium), (3) *iron supplements*, (4) *magnesium-containing laxatives*, and (5) *most antacids* (because they contain magnesium, aluminum, or both).

86.1.5.3 Distribution.

Tetracyclines are widely distributed to most tissues and body fluids. However, penetration to the cerebrospinal fluid (CSF) is poor, and hence levels in the CSF are too low to treat meningeal infections. Tetracyclines readily cross the placenta and enter the fetal circulation.

86.1.5.4 Elimination.

Tetracyclines are eliminated by the kidneys and liver. All tetracyclines are excreted by the liver into the bile. After the bile enters the intestine, most tetracyclines are reabsorbed.

Ultimate elimination of short- and intermediate-acting tetracyclines—tetracycline and demeclocycline—is in the urine, largely as the unchanged drug (see [Table 85-1](#)). Because these agents undergo renal excretion, they can accumulate to toxic levels if the kidneys fail. Consequently, *tetracycline and demeclocycline should not be given to patients with renal failure.*

Long-acting tetracyclines are eliminated by the liver, primarily as metabolites. Because these agents are excreted by the liver, their half-lives are unaffected by kidney dysfunction. Accordingly, *the long-acting agents (doxycycline and minocycline) are drugs of choice for tetracycline-responsive infections in patients with renal impairment.*

86.1.6 Adverse Effects

86.1.6.1 Gastrointestinal Irritation.

Tetracyclines irritate the GI tract. As a result, oral therapy is frequently associated with epigastric burning, cramps, nausea, vomiting, and diarrhea. These reactions can be reduced by giving tetracyclines with meals—although food may decrease absorption. Occasionally, tetracyclines cause esophageal ulceration. Risk can be minimized by avoiding dosing at bedtime. Because diarrhea may result from suprainfection of the bowel (in addition to nonspecific irritation), it is important that the cause of diarrhea be determined.

86.1.6.2 Effects on Bones and Teeth.

Tetracyclines bind to calcium in developing teeth, resulting in yellow or brown discoloration; hypoplasia of the enamel may also occur. The intensity of tooth discoloration is related to the total cumulative dose: Staining is darker with prolonged and repeated treatment. When taken after the fourth month of gestation, tetracyclines can cause staining of *deciduous* teeth. However, use during pregnancy will not affect *permanent* teeth. Discoloration of permanent teeth occurs when tetracyclines are taken by patients ages 4 months to 8 years, the interval during which tooth enamel is being formed. Accordingly, these drugs should be avoided by children under 8 years old. The risk of tooth discoloration with *doxycycline* may be less than with other tetracyclines.

1006

1007

Tetracyclines can suppress long-bone growth in premature infants. This effect is reversible upon discontinuation of treatment.

86.1.6.3 Suprainfection.

As discussed in [Chapter 82](#), a suprainfection is an overgrowth with drug-resistant microbes, which occurs secondary to suppression of drug-sensitive organisms. Because the tetracyclines are broad-spectrum agents, and therefore can decrease viability of a wide variety of microbes, the risk of suprainfection is greater than with antibiotics that have a more narrow spectrum.

Suprainfection of the bowel with staphylococci or with *Clostridium difficile* produces severe diarrhea and can be life threatening. The infection caused by *C. difficile* is known as *antibiotic-associated pseudomembranous colitis* (AAPMC). Patients should notify the prescriber if significant diarrhea occurs, so that the possibility of bacterial suprainfection can be evaluated. If a diagnosis of suprainfection with staphylococci or *C. difficile* is made, tetracyclines should be discontinued immediately. Treatment consists of oral *vancomycin* or *metronidazole* plus vigorous fluid and electrolyte replacement.

Overgrowth with fungi (commonly *Candida albicans*) may occur in the mouth, pharynx, vagina, and bowel. Symptoms include vaginal or anal itching; inflammatory lesions of the anogenital region; and a black, furry appearance of the tongue. Suprainfection with *Candida* can be managed by discontinuing tetracyclines. When this is not possible, antifungal therapy is indicated.

86.1.6.4 Hepatotoxicity.

Tetracyclines can cause fatty infiltration of the liver. Hepatotoxicity manifests clinically as lethargy and jaundice. Rarely, the condition progresses to massive liver failure. Liver damage is most likely when tetracyclines are administered intravenously in high doses (greater than 2 gm/day). Pregnant and postpartum women with kidney disease are at especially high risk.

86.1.6.5 Renal Toxicity.

Tetracyclines may exacerbate renal impairment in patients with pre-existing kidney disease. Because most tetracyclines are excreted by the kidneys, these agents should not be given to patients with renal impairment. Exceptions to this rule are *doxycycline* and perhaps *minocycline*, because both are eliminated primarily by the liver.

86.1.6.6 Photosensitivity.

All tetracyclines can increase the sensitivity of the skin to ultraviolet light. The most common result is exaggerated sunburn. Advise patients to avoid prolonged exposure to sunlight, wear protective clothing, and apply a sunscreen to exposed skin.

86.1.6.7 Other Adverse Effects.

Vestibular toxicity—manifesting as dizziness, lightheadedness, and unsteadiness—has occurred with minocycline. Rarely, tetracyclines have produced pseudotumor cerebri (a benign elevation in intracranial pressure). In a few patients, demeclocycline has produced nephrogenic diabetes insipidus, a syndrome characterized by thirst, increased frequency of urination, and unusual weakness or tiredness. Because of their irritant properties, tetracyclines can cause pain at sites of IM injection and thrombophlebitis when administered intravenously.

86.1.7 Drug and Food Interactions

As noted, tetracyclines can form nonabsorbable chelates with certain metal ions (calcium, iron, magnesium, aluminum, zinc). Substances that contain these ions include *milk products, calcium supplements, iron supplements, magnesium-containing laxatives, and most antacids*. If a tetracycline is administered with these agents, its absorption will be decreased. To minimize interference with absorption, tetracyclines should be *administered at least 2 hours before or 2 hours after ingestion of chelating agents*.

86.1.8 Dosage and Administration

86.1.8.1 Administration.

For systemic therapy, tetracyclines may be administered orally, intravenously, and by IM injection. Oral administration is preferred, and all tetracyclines are available in oral formulations. As a rule, oral tetracyclines should be taken on an empty stomach (1 hour before meals or 2 hours after) and with a full glass of water. An interval of at least 2 hours should separate tetracycline ingestion and ingestion of products that can chelate these drugs (eg, milk, calcium or iron supplements, antacids). Three tetracyclines can be given IV ([Table 85-2](#)), but this route should be employed only when oral therapy cannot be tolerated or has proved inadequate. Intramuscular injection is extremely painful and used rarely.

In addition to their systemic use, two agents—doxycycline and minocycline—are available in formulations for topical therapy of periodontal disease (see above).

86.1.8.2 Dosage.

Dosage is determined by the nature and intensity of the infection. Typical systemic doses for adults and children are summarized in [Table 85-2](#).

86.1.9 Summary of Major Precautions

Two tetracyclines—tetracycline and demeclocycline—are eliminated primarily in the urine, and hence will accumulate to toxic levels in patients with kidney disease. Accordingly, patients with kidney disease should not use these drugs.

Tetracyclines can cause discoloration of deciduous and permanent teeth. Tooth discoloration can be avoided by withholding these drugs from pregnant women and from children under 8 years of age.

Diarrhea may indicate a potentially life-threatening suprainfection of the bowel. Advise patients to notify the prescriber if diarrhea occurs.

High-dose IV therapy has been associated with severe liver damage, particularly in pregnant and postpartum women with kidney disease. As a rule, these women should not receive tetracyclines.

86.1.10 Summary of Unique Properties of Individual Tetracyclines

86.1.10.1 Tetracycline.

Tetracycline hydrochloride [Sumycin] is the least expensive and most widely used member of the family. When employed systemically, the drug has the indications, pharmacokinetics, adverse effects, and drug interactions described for the tetracyclines as a group. Like most tetracyclines, tetracycline hydrochloride should not be administered with food, and is contraindicated for patients with kidney dysfunction. This agent and all other tetracyclines should not be given to pregnant women or to children less than 8 years old.

86.1.10.2 Demeclocycline.

Demeclocycline [Declomycin] shares the actions, indications, and adverse effects described above for the tetracyclines as a group. Because of its intermediate duration of action, demeclocycline can be administered at dosing intervals that are longer than those used for tetracycline.

Demeclocycline is unique among the tetracyclines in that it stimulates urine flow. This side effect can lead to excessive urination, thirst, and tiredness. Interestingly, because of its effect on renal function, demeclocycline has been employed therapeutically to promote urine production in patients suffering from the syndrome of inappropriate (excessive) secretion of antidiuretic hormone.

86.1.10.3 Doxycycline.

Doxycycline [Vibramycin, others] is a long-acting agent that shares the actions and adverse effects described for the tetracyclines as a group. Because of its extended half-life, doxycycline can be administered once daily. Absorption of oral doxycycline is greater than that of tetracycline, and is not diminished by food or milk, and hence the drug may be administered with meals. Doxycycline is eliminated primarily by nonrenal mechanisms. As a result, it is safe for patients with renal failure. Doxycycline is a first-line drug for Lyme disease, anthrax, chlamydial infections (urethritis, cervicitis, and lymphogranuloma venereum), and sexually acquired proctitis (in combination with ceftriaxone). A topical formulation [Atridox] is used for periodontal disease, as is a low-dose oral formulation [Periostat]. Another low-dose oral formulation [Oracea] is used for acne (see [Chapter 104](#)).

1007

1008

TABLE 85-2 Tetracyclines: Routes of Administration, Dosing Interval, and Dosage

Class	Drug	Trade Name	Route	Usual Dosing Interval (hr)	Total Daily Dose	
					Adult (mg)	Pediatric (mg/kg) ^a
Short Acting	Tetracycline	Sumycin	PO	6	1000–2000	25–50
			IV ^b	12	500–1000	10–20
			IM ^c	12	300	15–25
Intermediate Acting	Demeclocycline	Declomycin	PO	12	600	6–12
Long Acting	Doxycycline	Vibramycin, others	PO	24	100 ^d	2.2 ^e
			IV ^b	24	100–200 ^f	2.2–4.4 ^g
	Minocycline	Minocin, Dynacin	PO	12	200 ^h	4 ⁱ
			IV ^b	12	200 ^h	4 ⁱ

a Doses presented are for children over the age of 8 years; use in children below this age may cause permanent staining of teeth.

b The intravenous route is used only if oral therapy cannot be tolerated or is inadequate.

c Intramuscular injection is extremely painful and used only rarely.

d First-day regimen is 100 mg initially, followed by 100 mg 12 hours later.

e First-day regimen is 2.2 mg/kg initially, followed by 2.2 mg/kg 12 hours later.

f First-day regimen is 200 mg in one or two slow infusions (1 to 4 hours).

g First-day regimen is 4.4 mg/kg in one or two slow infusions (1 to 4 hours).

h First-day regimen is 200 mg initially, followed by 100 mg 12 hours later.

i First-day regimen is 4 mg/kg initially, followed by 2 mg/kg 12 hours later.

86.1.10.4 Minocycline.

Minocycline [Minocin, Dynacin] is a long-acting agent similar to doxycycline. Like doxycycline, minocycline can be taken with food, and is safe for patients with kidney disease.

The drug is unique among the tetracyclines in that it can damage the vestibular system, causing unsteadiness, lightheadedness, and dizziness. This toxicity limits its use. Minocycline is expensive, costing significantly more than tetracycline. In addition to fighting systemic infection, minocycline can reduce symptoms of arthritis (see [Chapter 72](#)), and is available in an extended-release formulation [Solodyn] for acne, and a topical formulation [Arestin] for periodontal disease.

86.2 MACROLIDES

The macrolides are broad-spectrum antibiotics that inhibit bacterial protein synthesis. Why are they called macrolides? Because they are very big molecules. Erythromycin is the oldest member of the family. All of the newer macrolides—azithromycin, clarithromycin, dirithromycin, and troleandomycin—are derivatives of erythromycin.

86.2.1 Erythromycin

Erythromycin has a relatively broad antimicrobial spectrum and is a preferred or alternative treatment for a number of infections. The drug is one of our safest antibiotics and will serve as our prototype for the macrolide family.

86.2.1.1 Mechanism of Action

Antibacterial effects result from inhibition of protein synthesis: Erythromycin binds to the 50S ribosomal subunit and thereby blocks addition of new amino acids to the growing peptide chain. The drug is usually bacteriostatic, but can be bactericidal against highly susceptible organisms, or when present in high concentration. Erythromycin is selectively toxic to bacteria because ribosomes in the cytoplasm of mammalian cells do not bind the drug. Also, in contrast to chloramphenicol (see below), erythromycin cannot cross the mitochondrial membrane, and therefore does not inhibit protein synthesis in host mitochondria.

86.2.1.2 Acquired Resistance

Bacteria can become resistant by two mechanisms: (1) production of a pump that exports the drug and (2) modification (by methylation) of target ribosomes so that binding of erythromycin is impaired.

86.2.1.3 Antimicrobial Spectrum

Erythromycin has an antibacterial spectrum similar to that of penicillin. The drug is active against most gram-positive bacteria as well as some gram-negative bacteria. Bacterial

sensitivity is determined in large part by the ability of erythromycin to gain access to the cell interior.

86.2.1.4 Therapeutic Uses

Erythromycin is a commonly used antibiotic. *The drug is a treatment of first choice for several infections and may be used as an alternative to penicillin G in patients with penicillin allergy.*

Erythromycin is a preferred treatment for pneumonia caused by *Legionella pneumophila* (legionnaires' disease).

Erythromycin is considered the drug of first choice for individuals infected with *Bordetella pertussis*, the causative agent of *whooping cough*. Because symptoms are caused by a toxin produced by *B. pertussis*, erythromycin does little to alter the course of the disease. However, by eliminating *B. pertussis* from the nasopharynx, treatment does lower infectivity.

Corynebacterium diphtheriae is highly sensitive to erythromycin. Accordingly, erythromycin is the treatment of choice for *acute diphtheria* and eliminating the diphtheria carrier state.

Several infections respond equally well to erythromycin and tetracyclines. Both are drugs of first choice for certain chlamydial infections (urethritis, cervicitis) and for pneumonia caused by *M. pneumoniae*.

1008

1009

Erythromycin may be employed as an alternative to penicillin G in patients with penicillin allergy. The drug is used most frequently as a substitute for penicillin to treat respiratory tract infections caused by *Streptococcus pneumoniae* and by group A *Streptococcus pyogenes*. Erythromycin can also be employed as an alternative to penicillin for preventing recurrences of rheumatic fever and bacterial endocarditis.

86.2.1.5 Pharmacokinetics

86.2.1.5.1 Absorption and Bioavailability.

Erythromycin for oral administration is available in three forms: *erythromycin base* and two derivatives of the base: *erythromycin stearate* and *erythromycin ethylsuccinate*. The base is unstable in stomach acid, and its absorption can be variable; the derivatives were synthesized to improve bioavailability. Bioavailability has also been enhanced by use of acid-resistant coatings, which protect erythromycin while in the stomach and then dissolve in the duodenum, thereby permitting absorption from the small intestine. As a rule, *food decreases the absorption of erythromycin base and erythromycin stearate*, whereas absorption of

erythromycin ethylsuccinate is not affected. Only erythromycin base is biologically active; the derivatives must be converted to the base (either in the intestine or following absorption) in order to work. When used properly (ie, when dosage is correct and the effects of food are accounted for), all of the oral erythromycins produce equivalent responses.

In addition to its oral forms, erythromycin is available as *erythromycin lactobionate* for IV use. Intravenous dosing produces drug levels that are higher than those achieved with oral dosing.

86.2.1.5.2 Distribution.

Erythromycin readily distributes to most tissues and body fluids. Penetration to the CSF, however, is poor. Erythromycin crosses the placenta, but adverse effects on the fetus have not been observed.

86.2.1.5.3 Elimination.

Erythromycin is eliminated primarily by hepatic mechanisms, including metabolism by CYP3A4 (the 3A4 isozyme of cytochrome P450). Erythromycin is concentrated in the liver and then excreted in the bile. A small amount (10% to 15%) is excreted unchanged in the urine.

86.2.1.6 Adverse Effects

Erythromycin is generally free of serious toxicity and is considered one of our safest antibiotics. However, the drug does carry a very small risk of sudden cardiac death.

86.2.1.6.1 Gastrointestinal Effects.

Gastrointestinal disturbances (epigastric pain, nausea, vomiting, diarrhea) are the most common adverse effects. These can be reduced by administering erythromycin with meals. However, this should be done only when using erythromycin products whose absorption is unaffected by food (erythromycin estolate, erythromycin ethylsuccinate, certain enteric-coated formulations of erythromycin base). Patients who experience persistent or severe GI reactions should notify the prescriber.

86.2.1.6.2 QT Prolongation and Sudden Cardiac Death.

A study published in 2004 has raised concerns about cardiotoxicity, especially when erythromycin is combined with drugs that can raise its plasma level. When present in high

concentrations, erythromycin can prolong the QT interval, thereby posing a risk of torsades de pointes, a potentially fatal ventricular dysrhythmia. Sudden death can result. The 2004 study revealed that, when erythromycin is combined with a CYP3A4 inhibitor, there is a fivefold increase in the risk of sudden cardiac death—or 6 extra deaths for every 100,000 patients using the drug. To minimize risk, erythromycin should be avoided by patients with congenital QT prolongation and by those taking class IA or class III antidysrhythmic drugs. Also, the drug should be avoided by patients taking CYP3A4 inhibitors, including certain calcium channel blockers (verapamil and diltiazem), azole antifungal drugs (eg, ketoconazole, itraconazole), HIV protease inhibitors (eg, ritonavir, saquinavir), and nefazodone (an antidepressant).

86.2.1.6.3 Other Adverse Effects.

By killing off sensitive gut flora, erythromycin can promote suprainfection of the bowel. Thrombophlebitis can occur with IV administration; this reaction can be minimized by infusing the drug slowly in dilute solution. *Transient hearing loss* occurs rarely with high-dose therapy. There is evidence that erythromycin may cause *hypertrophic pyloric stenosis in infants*, especially those under 2 weeks of age.

86.2.1.7 Drug Interactions

Erythromycin can increase the plasma levels and half-lives of several drugs, thereby posing a risk of toxicity. The mechanism is inhibition of hepatic P450 drug-metabolizing enzymes. Elevated levels are a concern with *theophylline* (used for asthma), *carbamazepine* (used for seizures and bipolar disorder), and *warfarin* (an anticoagulant). Accordingly, when these agents are combined with erythromycin, the patient should be monitored closely for signs of toxicity.

Erythromycin prevents binding of *chloramphenicol* and *clindamycin* to bacterial ribosomes, thereby antagonizing the effects of these antibiotics. Accordingly, concurrent use of erythromycin with these two drugs is not recommended.

As noted, erythromycin should not be combined with drugs that can inhibit erythromycin metabolism. Among these are verapamil, diltiazem, HIV protease inhibitors, and azole antifungal drugs.

86.2.1.8 Preparations, Dosage, and Administration

86.2.1.8.1 Preparations.

For treating systemic infections, erythromycin is available in oral and IV formulations. All preparations have the same indications, antimicrobial spectrum, and adverse effects. Erythromycin is also available in topical formulations [Eryderm, others] to treat acne (see [Chapter 104](#)).

86.2.1.8.2 Oral Dosage and Administration.

Oral erythromycin should be administered on an empty stomach and with a full glass of water. If necessary, some preparations (erythromycin ethylsuccinate, certain enteric-coated preparations of erythromycin base) can be administered with food to decrease GI reactions. The usual *adult* dosage for *erythromycin base* and *erythromycin stearate* is 250 to 500 mg every 6 hours; the adult dosage for *erythromycin ethylsuccinate* is 400 to 800 mg every 6 hours. The usual *pediatric* dosage for all oral erythromycins is 7.5 to 12.5 mg/kg every 6 hours.

Trade names for oral erythromycins are Ery-Tab, PCE Dispertab, and Erythromycin Filmtabs (for erythromycin base) and E.E.S. and EryPed (for erythromycin ethylsuccinate). Erythromycin stearate is available only as a generic product.

86.2.1.8.3 Intravenous Dosage and Administration.

Intravenous administration is reserved for severe infections and is used rarely. Continuous infusion is preferred to intermittent dosing. Only *erythromycin lactobionate* [Erythrocin Lactobionate] is given IV. The usual *adult* dosage is 1 to 4 gm daily. The usual *pediatric* dosage is 15 to 50 mg/kg/day. Erythromycin should be infused slowly and in dilute solution (to minimize the risk of thrombophlebitis). For instruction on preparation and storage of IV solutions, consult the manufacturer's literature.

86.2.2 Other Macrolides

All of the macrolides are similar to erythromycin with respect to mechanism of action, antimicrobial spectrum, and resistance. Major differences among these drugs are pharmacokinetic.

1009

86.2.2.1 Clarithromycin**86.2.2.1.1 Actions and Therapeutic Uses.**

Like erythromycin, clarithromycin [Biaxin, Biaxin XL] binds the 50S subunit of bacterial ribosomes, causing inhibition of protein synthesis. The drug is approved for respiratory tract infections, uncomplicated infections of the skin and skin structures, and prevention of disseminated *Mycobacterium avium* complex infections in patients with advanced HIV infection. It is also used for *H. pylori* infection and as a substitute for penicillin G in penicillin-allergic patients.

86.2.2.1.2 Pharmacokinetics.

Clarithromycin is available in three oral formulations: standard tablets, extended-release tablets, and granules. The standard tablets and granules are well absorbed, even in the presence of food. In contrast, the extended-release tablets are absorbed poorly if food is absent. Following absorption, clarithromycin is widely distributed and readily penetrates cells. Elimination is by hepatic metabolism and renal excretion. A reduction in dosage may be needed for patients with severe renal impairment.

86.2.2.1.3 Adverse Effects and Interactions.

Clarithromycin is well tolerated and does not produce the intense nausea seen with erythromycin. The most common reactions (3%) have been diarrhea, nausea, and distorted taste—all described as mild to moderate. In clinical trials, only 3% of patients withdrew because of side effects, compared with 20% of those taking erythromycin. High doses of clarithromycin have caused fetal abnormalities in laboratory animals; possible effects on the human fetus are unknown. Like erythromycin, clarithromycin may prolong the QT interval, and hence may pose a risk of serious dysrhythmias.

Like erythromycin, clarithromycin can inhibit hepatic metabolism of other drugs, and can thereby elevate their levels. Affected drugs include *warfarin*, *carbamazepine*, and *theophylline*; dosages of these drugs may need to be reduced.

86.2.2.1.4 Preparations, Dosage, and Administration.

Clarithromycin is available in standard tablets (250 and 500 mg), sold as Biaxin; extended-release tablets (500 mg), sold as Biaxin XL; and granules for oral suspension (25 and 50 mg/mL), sold as Biaxin. With the standard tablets and granules, the recommended

dosage is 250 or 500 mg every 12 hours for 7 to 14 days; the exact dosage size and duration depend on the infection being treated. With the extended-release tablets, the recommended dosage is 500 mg once a day for 7 to 14 days. The standard tablets and granules may be taken without regard to meals, but the extended-release tablets should be taken with food.

86.2.2.2 Azithromycin

86.2.2.2.1 Actions and Therapeutic Uses.

Like erythromycin, azithromycin [Zithromax, Zmax] binds the 50S subunit of bacterial ribosomes, causing inhibition of protein synthesis. The drug is used for respiratory tract infections, cholera, chancroid, otitis media, uncomplicated infections of the skin and skin structures, disseminated *M. avium* complex disease, and infections caused by *Chlamydia trachomatis*, for which it is a drug of choice. It may also be used as a substitute for penicillin G in penicillin-allergic patients.

86.2.2.2.2 Pharmacokinetics.

Absorption of azithromycin is increased by food, and hence dosing may be done with meals. Following absorption, azithromycin is widely distributed to tissues and becomes concentrated in cells. Elimination is via the bile, as both metabolites and parent drug.

86.2.2.2.3 Adverse Effects and Interactions.

Like clarithromycin, azithromycin is well tolerated and does not produce the intense nausea seen with erythromycin. The most common reactions are diarrhea (5%), and nausea and abdominal pain (3%). In one clinical trial, only 0.7% of patients withdrew because of side effects. Aluminum- and magnesium-containing antacids reduce the rate (but not the extent) of absorption. In contrast to erythromycin and clarithromycin, azithromycin does not inhibit the metabolism of other drugs.

86.2.2.2.4 Preparations, Dosage, and Administration.

Oral, Immediate Release. Azithromycin [Zithromax] is available in two immediate-release oral formulations: tablets (250, 500, and 600 mg) and a suspension (20 and 40 mg/mL). The usual dosing schedule is 500 mg once on the first day, followed by 250 mg once daily on the following 4 days. Dosing may be done with or without food, but *not* with aluminum- or magnesium-containing antacids.

86.2.2.2.4.1 Oral, Extended Release.

Extended-release azithromycin [Zmax] is formulated as a powder composed of extended-release microspheres, designed to dissolve in the small intestine. The rationale is to reduce GI upset. The powder, sold in 2-gm, single-dose bottles, must be suspended in 60 mL of water before ingestion. Dosing is done just once a day.

86.2.2.2.4.2 Intravenous.

Azithromycin is supplied as powder (500 mg) to be reconstituted for IV infusion. The usual dosage is 500 mg infused slowly (over 60 minutes or more) on 2 or more days. Intravenous therapy is followed by oral therapy. A complete course of treatment takes 7 days.

86.2.2.3 Dirithromycin

86.2.2.3.1 Actions and Therapeutic Uses.

Dirithromycin [Dynabac] is similar to erythromycin with respect to mechanism of action, antimicrobial spectrum, and clinical effects. Approved indications include bronchitis caused by *Strep. pneumoniae* (but not *Haemophilus influenzae*); community-acquired pneumonia caused by pneumococci, *M. pneumoniae*, or *L. pneumophila*; and skin and soft tissue infections caused by *Staphylococcus aureus*. *In 2009, dirithromycin was withdrawn from the United States market.*

86.2.2.3.2 Pharmacokinetics.

Following oral administration, dirithromycin is absorbed from the GI tract and converted by nonenzymatic hydrolysis into erythromycylamine, an active metabolite. The drug reaches high concentrations in tissues, although serum concentrations may be low. Dirithromycin and its metabolite are eliminated slowly in the bile, with a half-life of 40 hours. Because of this extended half-life, once-daily dosing is sufficient.

86.2.2.3.3 Adverse Effects and Interactions.

As with erythromycin, nausea and abdominal pain are common; the reported incidence is about 10%, but the actual incidence may be higher. In contrast to erythromycin and clarithromycin, dirithromycin does not inhibit the metabolism of other drugs.

86.2.2.3.4 Dosage and Administration.

The usual dosage is 500 mg once daily for 7 to 14 days. Dirithromycin should be taken with meals or within 1 hour after eating. Food does not reduce absorption.

86.2.2.4 Troleandomycin

Troleandomycin [Tao], the newest macrolide, is no longer available in the United States. Like other macrolides, the drug suppresses bacterial growth by inhibiting protein synthesis. At this time, troleandomycin has only two approved indications: pneumococcal pneumonia and upper respiratory tract infections caused by group A beta-hemolytic streptococci. Some patients have developed jaundice while taking the drug. Accordingly, liver function should be monitored.

Troleandomycin inhibits cytochrome P450, and hence can suppress metabolism of other drugs, causing their levels to rise. The usual adult dosage is 250 to 500 mg 4 times a day for 10 days.

86.3 OTHER BACTERIOSTATIC INHIBITORS OF PROTEIN SYNTHESIS

86.3.1 Clindamycin

Clindamycin [Cleocin] can promote severe antibiotic-associated pseudomembranous colitis, a condition that can be fatal. Because of the risk of colitis, indications for clindamycin are limited. Currently, systemic use is indicated only for certain anaerobic infections located outside the central nervous system (CNS).

86.3.1.1 Mechanism of Action

Clindamycin binds to the 50S subunit of bacterial ribosomes and thereby inhibits protein synthesis. The site at which clindamycin binds overlaps the binding sites for erythromycin and chloramphenicol. As a result, these agents may antagonize each other's effects. Accordingly, there are no indications for concurrent use of clindamycin with these other antibiotics.

86.3.1.2 Antimicrobial Spectrum

Clindamycin is active against most anaerobic bacteria (gram positive and gram negative) and most gram-positive aerobes. Gram-negative aerobes are generally resistant. Susceptible anaerobes include *Bacteroides fragilis*, *Fusobacterium*, *Clostridium perfringens*, and anaerobic streptococci. Clindamycin is usually bacteriostatic. However, it can be bactericidal if the target organism is especially sensitive. Resistance can be a significant problem with *B. fragilis*.

86.3.1.3 Therapeutic Use

Because of its efficacy against gram-positive cocci, clindamycin has been used widely as an alternative to penicillin. The drug is employed primarily for anaerobic infections outside the CNS (it doesn't cross the blood-brain barrier). Clindamycin is the drug of choice for severe group A streptococcal infection and for gas gangrene (an infection caused by *C. perfringens*), owing to its ability to rapidly suppress synthesis of bacterial toxins. In addition, clindamycin is a preferred drug for abdominal and pelvic infections caused by *B. fragilis*.

1010

1011

86.3.1.4 Pharmacokinetics

86.3.1.4.1 Absorption and Distribution.

Clindamycin may be administered orally, IM, or IV. Absorption from the GI tract is nearly complete and not affected by food. The drug is widely distributed to most body fluids and tissues, including synovial fluid and bone. However, penetration to the CSF is poor.

86.3.1.4.2 Elimination.

Clindamycin undergoes hepatic metabolism to active and inactive products, which are then excreted in the urine and bile. Only 10% of the drug is eliminated unchanged by the kidneys. The half-life is approximately 3 hours. In patients with substantial reductions in liver function *or* kidney function, the half-life increases slightly, but adjustments in dosage are not needed. However, in patients with *combined* hepatic and renal disease, the half-life increases significantly, and hence the drug may accumulate to toxic levels if dosage is not reduced.

86.3.1.5 Adverse Effects

86.3.1.5.1 Antibiotic-Associated Pseudomembranous Colitis.

AAPMC is the most severe toxicity. The cause is suprainfection of the bowel with *C. difficile*, an anaerobic gram-positive bacillus. AAPMC is characterized by profuse, watery diarrhea (10 to 20 watery stools per day), abdominal pain, fever, and leukocytosis. Stools often contain mucus and blood. Symptoms usually begin during the first week of treatment, but may develop as long as 4 to 6 weeks after clindamycin withdrawal. Left untreated, the condition can be fatal. AAPMC occurs with parenteral and oral therapy. Because of the risk of colitis, patients should be instructed to report significant diarrhea (more than five watery stools per day). If suprainfection with *C. difficile* is diagnosed, clindamycin should be

discontinued and the patient given oral vancomycin or metronidazole, which are drugs of choice for eliminating *C. difficile* from the bowel. Diarrhea usually ceases 3 to 5 days after starting vancomycin. Vigorous replacement therapy with fluids and electrolytes is usually indicated. Drugs that decrease bowel motility (eg, opioids, anticholinergics) may worsen symptoms and should not be used.

86.3.1.5.2 Other Adverse Effects.

Diarrhea (unrelated to AAPMC) is relatively common. Hypersensitivity reactions (especially rashes) occur frequently. Hepatotoxicity and blood dyscrasias (agranulocytosis, leukopenia, thrombocytopenia) develop rarely. Rapid IV administration can cause electrocardiographic changes, hypotension, and cardiac arrest.

86.3.1.6 Preparations, Dosage, and Administration

86.3.1.6.1 Preparations.

Clindamycin is available as *clindamycin hydrochloride* and *clindamycin palmitate* for oral dosing, and as *clindamycin phosphate* for IM, IV, or topical (vaginal) dosing. Clindamycin hydrochloride [Cleocin] is supplied in capsules (75, 150, and 300 mg). Clindamycin palmitate [Cleocin Pediatric] is supplied in flavored granules, which are reconstituted with fluid to make an oral solution containing 15 mg of clindamycin per milliliter. Clindamycin phosphate [Cleocin, Cleocin Phosphate, others] is supplied in solution (150 mg/mL) for parenteral therapy, and in a 2% cream and 100-mg suppositories for intravaginal dosing.

86.3.1.6.2 Oral Dosage and Administration.

For *clindamycin hydrochloride*, the adult dosage range is 150 to 450 mg every 6 hours; the pediatric dosage range is 8 to 20 mg/kg daily in three or four divided doses. For *clindamycin palmitate*, adult and pediatric dosages range from 8 to 25 mg/kg/day administered in three or four divided doses. Oral clindamycin should be taken with a full glass of water. The drug may be administered with meals.

86.3.1.6.3 Parenteral Dosage and Administration.

For parenteral (IM or IV) therapy, *clindamycin phosphate* is employed. Intramuscular and IV dosages are the same. The usual adult dosage is 0.6 to 3.6 gm/day administered in three or four divided doses. The usual pediatric dosage is 15 to 40 mg/kg/day in three or four divided doses.

86.3.1.6.4 Intravaginal Administration.

Intravaginal clindamycin (suppositories or cream) is indicated for bacterial vaginosis. The suppositories are approved only for nonpregnant women; the cream can be used by pregnant women, but only during the second and third trimesters. Women using clindamycin cream should apply 1 applicatorful (5 gm containing 100 mg clindamycin) nightly for 7 days (if pregnant) or for 3 to 7 days (if nonpregnant). Women using clindamycin suppositories should insert 1 suppository (100 mg) on three consecutive evenings.

86.3.2 Linezolid

Linezolid [Zyvox] is the first member of a new class of antibiotics, the *oxazolidinones*. The drug is important because it has activity against multidrug-resistant gram-positive pathogens, including vancomycin-resistant enterococci (VRE) and methicillin-resistant *Staph. aureus* (MRSA). For treatment of MRSA, the drug is at least as effective as vancomycin. To delay the emergence of resistance, linezolid should generally be reserved for infections caused by VRE or MRSA, even though it has additional approved uses.

86.3.2.1 Mechanism, Resistance, and Antimicrobial Spectrum

Linezolid is a bacteriostatic inhibitor of protein synthesis. The drug binds to the 23S portion of the 50S ribosomal subunit, and thereby blocks formation of the initiation complex. No other antibiotic works quite this way. As a result, cross-resistance with other agents is unlikely. In clinical trials, development of resistance to linezolid was rare, and occurred only in association with prolonged treatment of VRE infections and the presence of a prosthetic implant or undrained abscess.

Linezolid is active primarily against aerobic and facultative gram-positive bacteria. Susceptible pathogens include *Enterococcus faecium* (vancomycin-sensitive and vancomycin-resistant strains), *Enterococcus faecalis* (vancomycin-resistant strains), *Staph. aureus* (methicillin-sensitive and methicillin-resistant strains), *Staphylococcus epidermidis* (including methicillin-resistant strains), and *Strep. pneumoniae* (penicillin-sensitive and penicillin-resistant strains). Linezolid is not active against gram-negative bacteria, which readily export the drug.

86.3.2.2 Pharmacokinetics

Oral linezolid is rapidly and completely absorbed. Food decreases the rate of absorption but not the extent. Linezolid is eliminated by hepatic metabolism and renal excretion. Its half-life is about 5 hours.

86.3.2.3 Adverse Effects

Linezolid is generally well tolerated. The most common side effects are diarrhea (5.3%), nausea (3.5%), and headache (2.7%). Linezolid oral suspension contains phenylalanine, and hence must not be used by patients with phenylketonuria.

Linezolid can cause reversible *myelosuppression*, manifesting as anemia, leukopenia, thrombocytopenia, or even pancytopenia. Risk is related to duration of use. Complete blood counts should be done weekly. Special caution is needed in patients with pre-existing myelosuppression, those taking other myelosuppressive drugs, and those receiving linezolid for more than 2 weeks. If existing myelosuppression worsens or new myelosuppression develops, discontinuing linezolid should be considered.

1011

Rarely, prolonged therapy has been associated with *neuropathy*. Patients taking the drug for more than 5 months have developed reversible optic neuropathy and irreversible peripheral neuropathy.

1012

86.3.2.4 Drug Interactions

Linezolid is a weak inhibitor of monoamine oxidase (MAO), and hence poses a risk of hypertensive crisis. As discussed in [Chapter 32](#), MAO inhibitors can cause severe hypertension if combined with *indirect-acting sympathomimetics* (eg, ephedrine, pseudoephedrine, methylphenidate, cocaine) or with foods that contain large amounts of *tyramine*. Accordingly, patients using linezolid should be warned to avoid these agents.

In theory, combining linezolid with a *selective serotonin reuptake inhibitor* (eg, fluoxetine [Prozac]) can increase the risk of serotonin syndrome (because inhibition of MAO increases the serotonin content of CNS neurons). However, serotonin syndrome has not been reported.

86.3.2.5 Preparations, Dosage, and Administration

Linezolid is available in three formulations: (1) 600-mg *tablets*, (2) a powder for reconstitution to a 20-mg/mL *oral suspension*, and (3) a 2-mg/mL *intravenous solution* supplied in 100-, and

300-mL single-use bags. Oral linezolid can be taken with or without food. Intravenous linezolid is infused over 30 to 120 minutes, and should not be combined with additives or other drugs. Adult dosages for specific infections are as follows:

- *VRE infections*—600 mg PO or IV every 12 hours for 14 to 28 days
- *Pneumonia (nosocomial or community acquired)*—600 mg PO or IV every 12 hours for 10 to 14 days
- *Complicated skin and skin structure infections (including MRSA infections)*—same as pneumonia
- *Uncomplicated skin and skin structure infections*—400 mg PO every 12 hours for 10 to 14 days

86.3.3 Telithromycin

86.3.3.1 Therapeutic Use.

Telithromycin [Ketek], a close relative of erythromycin and other macrolides, is the first representative of a new class of antibiotics, the *ketolides*. Antibacterial activity is similar to that of the macrolides, with one important exception: telithromycin has significant activity against strains of *Strep. pneumoniae* that are penicillin and macrolide resistant. The Food and Drug Administration (FDA) initially approved the drug for three indications, but has since withdrawn approval for two of them. Currently, the only approved indication is community-acquired pneumonia (CAP) caused by *Strep. pneumoniae* (including multidrug-resistant isolates [MDRSP]), *H. influenzae*, *M. catarrhalis*, *Chlamydia pneumoniae*, or *Mycoplasma pneumoniae*.

Unfortunately, although telithromycin is an effective antibiotic, it carries a significant risk of adverse effects (especially severe liver injury) and drug interactions. As a result, it should be reserved for infections caused by MDRSP that cannot be treated with other agents.

86.3.3.2 Mechanism of Action.

Like the macrolides, telithromycin binds to the 50S ribosomal subunit, and thereby inhibits bacterial protein synthesis. However, in contrast to the macrolides, telithromycin has properties that give it activity against bacteria that are macrolide resistant. Among respiratory tract pathogens, macrolide resistance occurs by two mechanisms: (1) removal of the macrolide with export pumps and (2) modification (by methylation) of the bacterial ribosome in a way that

decreases macrolide binding. Because telithromycin differs in structure from the macrolides, the drug is less subject to removal by bacterial export pumps, and can bind strongly to bacterial ribosomes even if they are methylated.

86.3.3.3 Pharmacokinetics.

Telithromycin undergoes rapid but incomplete absorption following oral administration. Bioavailability is about 57%, both in the presence and absence of food. Once in the blood, telithromycin becomes concentrated in white cells. About 70% of absorbed drug is metabolized in the liver—half by CYP3A4 (the 3A4 isozyme of cytochrome P450) and half by P450-independent pathways. Excretion of parent drug and metabolites occurs in the urine and feces. The half-life is 10 hours.

86.3.3.4 Adverse Effects.

Although telithromycin is generally well tolerated, the drug can cause serious adverse effects, especially injury to the liver (see below). As a result, the drug should be used only when absolutely necessary.

In clinical trials, most adverse effects were mild to moderate. Furthermore, the rate of discontinuation because of adverse effects was nearly the same as with patients taking a comparator antibiotic (4.4% vs. 4.3%). The most common adverse effects are *gastrointestinal disturbances*, including diarrhea (10% vs. 8% with a comparator antibiotic), nausea (7% vs. 4.1%), vomiting (2.4% vs. 1.4%), and loose stools (2.1% vs. 1.4%).

Telithromycin can cause *severe liver injury* (fulminant hepatitis, hepatic necrosis) and acute hepatic failure. Liver transplants have been required and deaths have occurred. Liver damage can develop early in telithromycin treatment and can progress rapidly. Patients should be monitored for signs of hepatitis (eg, jaundice, fatigue, abdominal pain, dark urine). If liver injury is diagnosed, telithromycin should be discontinued and never used again.

In patients with *myasthenia gravis*, telithromycin can make muscle weakness much worse, sometimes within hours of taking the first dose. Some patients have died from respiratory failure. Accordingly, telithromycin is contraindicated for patients with this disorder.

About 1% of patients experience *visual disturbances*, including blurred vision, double vision, and difficulty focusing. Females and patients under 40 years old are at highest risk. These disturbances usually develop after the first or second dose, and can persist for several hours. Symptoms may or may not recur with subsequent doses.

Like erythromycin and clarithromycin, telithromycin can *prolong the QT interval*, and hence may pose a risk of adverse cardiac events. However, QT prolongation was not observed in clinical trials, and there have been no reports of torsades de pointes or other ventricular dysrhythmias. Nonetheless, telithromycin should be avoided by patients with congenital QT prolongation and by those taking class IA or class III antidysrhythmics.

86.3.3.5 Drug Interactions.

Telithromycin is both a substrate for and inhibitor of CYP3A4, and hence has the potential for numerous drug interactions.

Because telithromycin is a substrate for CYP3A4, agents that inhibit the enzyme (eg, itraconazole, ketoconazole) can elevate telithromycin levels. Conversely, agents that induce CYP3A4 (eg, rifampin, phenytoin, carbamazepine, phenobarbital) can decrease telithromycin levels, possibly resulting in therapeutic failure.

By inhibiting CYP3A4, telithromycin can increase levels of many drugs that are substrates for the enzyme, thereby posing a risk of toxicity. Two such substrates—cisapride [Propulsid] and pimozide [Orap]—are contraindicated for use with telithromycin. Similarly, use of three statin-type cholesterol-lowering agents—simvastatin [Zocor], lovastatin [Mevacor], and atorvastatin [Lipitor]—should be interrupted during telithromycin therapy. However, use of two other statins—pravastatin [Pravachol] and fluvastatin [Lescol]—may continue. Telithromycin is likely to increase levels of ergotamine and dihydroergotamine (ergot alkaloids used for migraine), and may thereby cause severe peripheral vasospasm. Accordingly, use of these alkaloids must be avoided. Telithromycin increases peak levels of digoxin [Lanoxin] by 73%. Accordingly, digoxin levels and side effects should be monitored closely. Other CYP3A4 substrates whose levels can be increased include midazolam [Versed], ritonavir [Norvir], sirolimus [Rapamune], and tacrolimus [Prograf]. Finally, telithromycin can increase levels of metoprolol [Lopressor], a substrate for CYP2D6. Patients with heart failure who are using metoprolol should be monitored closely.

86.3.3.6 Preparations, Dosage, and Administration.

Telithromycin [Ketek] is available in 300 and 400 mg tablets for oral dosing, with or without food. The dosage for CAP is 800 mg once a day for 7 to 10 days. A dosage reduction may be needed for patients with severe renal impairment, but not for patients with mild to moderate renal impairment or those with hepatic impairment.

86.3.4 Dalfopristin/Quinupristin

Dalfopristin and quinupristin are the first members of a new class of antibiotics known as *streptogramins*. The two drugs are available in a fixed-dose combination (70 parts dalfopristin/30 parts quinupristin) under the trade name *Synercid*.

86.3.4.1 Mechanism of Action.

Dalfopristin and quinupristin inhibit bacterial protein synthesis. When used separately, dalfopristin and quinupristin are bacteriostatic. However, in combination they are bactericidal.

86.3.4.2 Therapeutic Use.

The principal indication for dalfopristin/quinupristin is vancomycin-resistant *E. faecium*. (The drugs are not active against *E. faecalis*.) To delay emergence of resistance, dalfopristin/quinupristin should be reserved for infections that have not responded to vancomycin. Other indications include MRSA, methicillin-resistant *Staph. epidermidis*, and drug-resistant *Strep. pneumoniae*. Dalfopristin/quinupristin is safe for patients who are allergic to penicillins and cephalosporins.

86.3.4.3 Adverse Effects

Hepatotoxicity is the major concern. Blood should be tested for liver enzymes and bilirubin at least twice during the first week of therapy and weekly thereafter. About 50% of patients develop infusion-related thrombophlebitis. When this occurs, administration must be switched to a central venous line. Other adverse effects include joint and muscle pain, rash, pruritus, vomiting, and diarrhea.

1012

1013

86.3.4.4 Drug Interactions.

Dalfopristin and quinupristin inhibit hepatic drug-metabolizing enzymes, specifically CYP3A4. Accordingly, the combination is likely to inhibit the metabolism of many other drugs, including cyclosporine, tacrolimus, and cisapride.

86.3.4.5 Preparations, Dosage, and Administration.

Dalfopristin/quinupristin [Synercid] is supplied as a powder in 500-mg vials to be reconstituted for IV administration. The usual dosage is 7.5 mg/kg infused slowly (over 1 hour) 2 or 3 times a day. To minimize venous irritation, flush the vein with 0.5% dextrose after the infusion. If

irritation occurs despite flushing, the drug should be infused through a central venous line.

Because dalbopristin and quinupristin are eliminated by hepatic metabolism, dosage should be reduced in patients with liver impairment.

86.3.5 Chloramphenicol

Chloramphenicol [Chloromycetin] is a broad-spectrum antibiotic with the potential for causing *fatal aplastic anemia* and other blood dyscrasias. Because of the risk of severe blood disorders, use of chloramphenicol is limited to serious infections for which less toxic drugs are not effective.

86.3.5.1 Mechanism of Action

Chloramphenicol inhibits bacterial protein synthesis. The drug binds reversibly to the 50S subunit of bacterial ribosomes and thereby prevents addition of new amino acids to the growing peptide chain. Chloramphenicol is usually bacteriostatic, but can be bactericidal against highly susceptible organisms or when its concentration is high.

Since most protein synthesis in mammalian cells is carried out in the cytoplasm employing ribosomes that are insensitive to chloramphenicol, toxic effects are restricted largely to bacteria. However, because the ribosomes of mammalian *mitochondria* are very similar to those of bacteria, chloramphenicol can decrease mitochondrial protein synthesis in the host. This action may underlie certain adverse effects (eg, dose-dependent bone marrow suppression, gray syndrome in infants).

86.3.5.2 Antimicrobial Spectrum

Chloramphenicol is active against a broad spectrum of bacteria. A large number of gram-positive and gram-negative aerobic organisms are sensitive. Among these are *Salmonella typhi*, *H. influenzae*, *Neisseria meningitidis*, and *Strep. pneumoniae*. Most anaerobic bacteria (eg, *B. fragilis*) are also susceptible. In addition, chloramphenicol is active against rickettsiae, chlamydiae, mycoplasmas, and treponemes.

86.3.5.3 Resistance

Resistance among gram-negative bacteria results from acquisition of an R factor that codes for acetyltransferase, an enzyme that inactivates chloramphenicol. This same R factor also codes for resistance to tetracyclines, and frequently confers resistance to penicillins too.

86.3.5.4 Pharmacokinetics

Chloramphenicol is available in two forms: *chloramphenicol base* (administered PO), and *chloramphenicol succinate* (administered IV). Chloramphenicol base is active as administered. In contrast, chloramphenicol succinate is a prodrug that must be hydrolyzed to free chloramphenicol before it can act.

86.3.5.4.1 Availability of Active Drug.

Chloramphenicol base is absorbed rapidly following oral administration, and bioavailability is high (between 75% and 90%). In contrast, when the drug is administered IV as chloramphenicol succinate, conversion to the active form (free chloramphenicol) is variable and incomplete. Production of active drug is especially erratic in newborns, infants, and young children.

86.3.5.4.2 Distribution.

Chloramphenicol is highly lipid soluble and widely distributed to body tissues and fluids. Therapeutic concentrations are readily achieved in the CSF, and drug levels in the brain may be as much as 9 times those in plasma. As a result, chloramphenicol is of special value for treating meningitis and brain abscesses caused by susceptible bacteria. The drug crosses the placenta and is secreted in breast milk.

86.3.5.4.3 Metabolism and Excretion.

Chloramphenicol is eliminated primarily by hepatic metabolism. Inactive metabolites are excreted in the urine. In patients with liver dysfunction, the half-life is prolonged and accumulation can occur. Accordingly, dosage should be reduced. Because the kidneys serve only to excrete inactive metabolites, there is no need for dosage reduction in patients with renal dysfunction. In neonates, hepatic metabolism is not fully developed and hence the half-life of chloramphenicol is prolonged.

86.3.5.4.4 Monitoring Chloramphenicol Serum Levels.

Because chloramphenicol has a low therapeutic index, and because serum levels of the drug can vary substantially among patients, monitoring drug levels is frequently indicated. Monitoring is especially important for neonates, infants, and young children because chloramphenicol levels in these patients can be highly variable. For most infections, effective therapy is achieved with peak serum drug levels of 10 to 20 mcg/mL and trough levels of 5

to 10 mcg/mL. The risk of dose-dependent bone marrow suppression is significantly increased when peak levels rise above 25 mcg/mL.

86.3.5.5 Therapeutic Use

When first introduced, chloramphenicol was employed widely. However, use dropped sharply when its ability to cause fatal aplastic anemia became evident. Today, chloramphenicol is indicated only for life-threatening infections for which safer drugs are ineffective or contraindicated.

86.3.5.6 Adverse Effects

The most important adverse effects are gray syndrome and toxicities related to the blood. Because of these toxicities, indications for chloramphenicol are limited.

86.3.5.6.1 Gray Syndrome.

Gray syndrome, originally known as gray baby syndrome, is a potentially fatal toxicity observed most commonly in newborns. Initial symptoms are vomiting, abdominal distention, cyanosis, and gray discoloration of the skin. These may be followed by vasomotor collapse and death. The syndrome results from accumulation of chloramphenicol to high levels. Newborns are especially vulnerable to gray syndrome because (1) hepatic function is insufficient to detoxify chloramphenicol and (2) renal function is insufficient to excrete active drug. Although gray syndrome is usually observed in neonates, it can occur in older children and adults if dosage is excessive. If drug use is discontinued immediately when early symptoms appear, the syndrome is usually reversible. The risk of gray syndrome in infants can be reduced by using low doses and by monitoring chloramphenicol levels in serum.

86.3.5.6.2 Reversible Bone Marrow Suppression.

Chloramphenicol can produce dose-related suppression of the bone marrow, resulting in anemia, and sometimes leukopenia and thrombocytopenia. Marrow suppression is dose related, occurring most commonly when plasma drug levels exceed 25 mcg/mL. The cause of bone marrow suppression appears to be inhibition of protein synthesis in host mitochondria. To promote early detection of bone marrow suppression, complete blood counts should be performed prior to therapy and every 2 days thereafter. Advise patients to notify the physician if signs of blood disorders develop (eg, sore throat, fever, unusual bleeding or bruising). Chloramphenicol should be withdrawn if evidence of bone marrow

suppression is detected. Suppression of bone marrow usually reverses within 1 to 3 weeks following drug withdrawal. The anemia associated with toxic bone marrow suppression is not related to aplastic anemia (discussed next).

86.3.5.6.3 Aplastic Anemia.

Rarely, chloramphenicol produces aplastic anemia, a condition characterized by pancytopenia and bone marrow aplasia. The reaction is usually fatal. Aplastic anemia develops in 1 of 35,000 patients, and is not related to dosage. As a rule, the reaction develops weeks or months after termination of treatment. Aplastic anemia can occur with oral, IV, or even topical (ophthalmic) use of the drug. The mechanism underlying aplastic anemia has not been determined, but toxicity may result from a genetic predisposition. Unfortunately, aplastic anemia cannot be predicted by monitoring the blood.

86.3.5.6.4 Other Adverse Effects.

Gastrointestinal effects (vomiting, diarrhea, glossitis) occur occasionally. Herxheimer reactions have occurred during treatment of typhoid fever. Neurologic effects (peripheral neuropathy, optic neuritis, confusion, delirium) develop rarely, usually in association with prolonged treatment. Other rare toxicities include suprainfection of the bowel, allergic reactions, and fever.

86.3.5.7 Drug Interactions

Chloramphenicol can inhibit hepatic drug-metabolizing enzymes, thereby prolonging the half-lives of other drugs. Agents that may be affected include *phenytoin* (an anticonvulsant), *warfarin* (an anticoagulant), and two oral hypoglycemics: *tolbutamide* and *chlorpropamide*. If any of these drugs are taken concurrently with chloramphenicol, their dosages should be reduced.

86.3.5.8 Preparations, Dosage, and Administration

86.3.5.8.1 General Considerations Regarding Route and Dosage.

For treatment of systemic infections, chloramphenicol is administered IV. The oral formulation is no longer available.

As a rule, the dosing objective is to produce peak chloramphenicol plasma levels that range between 10 and 20 mcg/mL.

1013

86.3.5.8.2 Preparations.

For *intravenous* therapy, chloramphenicol is available in powdered form as *chloramphenicol sodium succinate* [Chloromycetin Sodium Succinate], which must be reconstituted to a 100-mg/mL solution.

86.3.5.8.3 Dosage and Administration.

The usual IV dosage for adults and children is 12.5 to 25 mg/kg every 6 hours. For infants 7 days old or younger, the usual dosage is 25 mg/kg once a day. For infants more than 7 days old, the recommended dosage is 25 mg/kg every 12 hours. Dosage should be reduced for patients with liver dysfunction.

86.3.6 Spectinomycin

86.3.6.1 Mechanism of Action and Antimicrobial Spectrum.

Spectinomycin [Trobicin] binds to the 30S ribosomal subunit and thereby suppresses bacterial protein synthesis. The drug is active against a number of gram-negative bacteria. Resistance develops frequently.

86.3.6.2 Therapeutic Use.

Because resistant organisms emerge rapidly, use of spectinomycin is limited. Its principal indication is anogenital *gonorrhea* in patients who cannot tolerate preferred drugs (eg, ceftriaxone, cefixime).

86.3.6.3 Pharmacokinetics.

Spectinomycin is administered by IM injection. (The drug is not absorbed from the GI tract.) Most of each dose is excreted unchanged in the urine. The plasma half-life is approximately 2 hours.

86.3.6.4 Adverse Effects.

Spectinomycin is generally well tolerated. Adverse effects seen occasionally include soreness at the site of injection, dizziness, nausea, urticaria, pruritus, chills, fever, and insomnia.

86.3.6.5 Preparations, Dosage, and Administration.

Spectinomycin [Trobicin] is supplied as a sterile powder together with sufficient diluent to produce a 400-mg/mL solution. For treatment of uncomplicated gonorrhea of the rectum or genitalia, the usual adult dose is 2 gm administered as a single IM (intragluteal) injection. For children weighing less than 45 kg, a single injection of 40 mg/kg is given. For disseminated gonococcal infection, the adult dosage is 2 gm twice a day for 3 days.

86.3.7 Tigecycline

Tigecycline [Tygacil], approved in 2005, is the first representative of a new class of antibiotics, the *glycylcyclines*. The drug is a tetracycline derivative designed to overcome drug resistance. Tigecycline is active against a broad spectrum of bacteria, including many drug-resistant strains. Adverse effects may be similar to those of the tetracyclines.

86.3.7.1 Mechanism of Action and Resistance.

Tigecycline is a bacteriostatic inhibitor of protein synthesis. Like the tetracyclines, tigecycline binds to the 30S ribosomal subunit and thereby inhibits binding of transfer RNA to the messenger RNA–ribosome complex. As a result, addition of amino acids to the growing peptide chain is stopped.

Bacterial resistance to tigecycline is much less than with the tetracyclines. Why? First, because bacteria are unable to extrude tigecycline. Second, they cannot block binding of tigecycline to ribosomes.

86.3.7.2 Antimicrobial Spectrum.

Tigecycline is a broad-spectrum antibiotic with activity against gram-positive and gram-negative bacteria, including many strains that are drug resistant. Susceptible gram-positive organisms include *Staph. aureus* (vancomycin sensitive, methicillin sensitive, and methicillin resistant), vancomycin-resistant enterococci, penicillin-resistant *Strep. pneumoniae*, *C. perfringens*, and *C. difficile*. Susceptible gram-negative organisms include *Acinetobacter baumannii*, *Stenotrophomonas maltophilia*, *B. fragilis*, *Escherichia coli*, and *Enterobacter* species. Of note, tigecycline is *not* active against *Pseudomonas aeruginosa* or *Proteus* species.

86.3.7.3 Therapeutic Use.

Tigecycline is approved for treating complicated intra-abdominal infections and complicated skin infections that need broad empiric coverage. To delay emergence of resistance, tigecycline should be used only when other drugs are considered likely to fail.

86.3.7.4 Pharmacokinetics.

Tigecycline is administered IV and undergoes moderate binding to plasma proteins (about 80%). Very little of the drug is metabolized. Excretion occurs in the bile (59%) and urine (33%), mainly as unchanged drug. The plasma half-life is 42 hours.

86.3.7.5 Adverse Effects.

Because tigecycline is a tetracycline analog, adverse effects may be like those of the tetracyclines. In clinical trials, the most common reactions were nausea (30%) and vomiting (20%). Like the tetracyclines, tigecycline may pose a risk of pseudotumor cerebri (a benign elevation of intracranial pressure) and may increase sensitivity to ultraviolet light (thereby increasing the risk of sunburn). Tigecycline may stain developing teeth, and hence should not be used by children under 8 years old. Being a broadspectrum antibiotic, tigecycline may pose a risk of suprainfection, including antibiotic-associated pseudomembranous colitis. Tigecycline is in FDA Pregnancy Risk Category D, and hence should be avoided by pregnant women.

86.3.7.6 Drug Interactions.

Drug interactions appear minimal. Tigecycline does not affect the cytochrome P450 system, and hence will not alter the kinetics of drugs metabolized by P450. Similarly, because tigecycline undergoes very little metabolism, drugs that alter P450 activity should not alter the kinetics of tigecycline. Tigecycline can delay the clearance of warfarin (an anticoagulant). Accordingly, if the drugs are used concurrently, coagulation status should be monitored.

86.3.7.7 Preparations, Dosage, and Administration.

Tigecycline [Tygacil] is supplied as a lyophilized powder in single-dose 50-mg vials, to be reconstituted for IV infusion. The powder should be dissolved in 5.3 mL of sodium chloride injection or 5% dextrose injection, to produce a 10-mg/mL solution. This concentrated solution is then added to a 100-mL IV bag for infusion over 30 to 60 minutes. For adults, treatment consists of a 100-mg initial dose followed by 50 mg every 12 hours for 5 to 14 days. No adjustment in dosage is needed for patients with renal impairment or with mild to moderate

hepatic impairment. For patients with *severe* hepatic impairment, the initial dose is unchanged, but maintenance dosing should be reduced to 25 mg every 12 hours.

86.3.8 Retapamulin and Mupirocin

Retapamulin and mupirocin are new topical antibiotics. Both drugs are indicated for impetigo; mupirocin is also indicated for clearing the nostrils of methicillin-resistant *Staph. aureus* (MRSA). For impetigo therapy, retapamulin is more convenient than mupirocin, but generic mupirocin is cheaper.

86.3.8.1 Retapamulin

Retapamulin [Altabax] is the first representative of a new class of antibiotics, the *pleuromutalins*. The drug binds the 50S bacterial ribosomal subunit, and thereby inhibits protein synthesis. However, the 50S binding site is different from that of other antibiotics, and hence cross-resistance with other antibiotics is not expected. Retapamulin is bacteriostatic at therapeutic concentrations. At this time, the drug is approved only for *topical* therapy of impetigo caused by *Strep. pyogenes* or methicillin-susceptible *Staph. aureus*. However, *in vitro* data indicate that the drug may be effective against methicillin- and mupirocin-resistant *Staph. aureus*. Significant resistance among *Staph. aureus* has not been observed, and is considered unlikely. The principal adverse effect is local irritation, which only 2% of users experience. Systemic toxicity does not occur, owing to minimal absorption from topical sites. Retapamulin is available as a 1% ointment in 5-, 10-, and 15-gm tubes. Application is done twice daily for 5 days.

86.3.8.2 Mupirocin

Mupirocin [Bactroban, Bactroban Nasal] is a topical antibiotic with two indications: (1) impetigo caused by *Staph. aureus*, *Strep. pyogenes*, or beta-hemolytic streptococci; and (2) elimination of nasal colonization by MRSA. Mupirocin has a unique mechanism: The drug binds with bacterial isoleucyl transfer-RNA synthetase, and thereby blocks protein synthesis. The drug is bactericidal at therapeutic concentrations. Resistance has developed owing to production of a modified form of isoleucyl transfer-RNA synthetase, but cross-resistance with other antibiotics has not been seen.

Adverse effects depend on the application site. With application to the *skin*, local irritation can occur, but systemic effects occur rarely, if at all. (Absorption from intact skin is minimal, and any absorbed drug undergoes rapid conversion to inactive products.) With *intranasal*

application, the most common side effects are headache (9%), rhinitis (6%), upper respiratory congestion (5%), and pharyngitis (4%).

Mupirocin is available as a 2% cream and a 2% ointment. For *impetigo*, the cream or ointment is applied 3 times a day for 10 to 12 days. To eradicate *MRSA nasal colonization*, the ointment is applied twice daily for 5 days.

1014

1015

86.3.8.2.1

KEY POINTS

- Tetracyclines are broad-spectrum, bacteriostatic antibiotics that inhibit bacterial protein synthesis.
- Tetracyclines are first-choice drugs for just a few infections, including those caused by *Chlamydia trachomatis*, rickettsia (eg, Rocky Mountain spotted fever), *H. pylori* (ie, peptic ulcer disease), *B. anthracis* (anthrax), *Borrelia burgdorferi* (Lyme disease), and *M. pneumoniae*.
- Tetracyclines form insoluble chelates with calcium, iron, magnesium, aluminum, and zinc. Accordingly, they must not be administered with calcium supplements, milk products, iron supplements, magnesium-containing laxatives, and most antacids.
- Tetracycline and demeclocycline should not be given to patients with renal failure.
- Tetracyclines can stain developing teeth, and therefore should not be given to pregnant women or children under 8 years old.
- Because they are broad-spectrum antibiotics, tetracyclines can cause suprainfections, especially antibiotic-associated pseudomembranous colitis (AAPMC) and overgrowth of the mouth, pharynx, vagina, or bowel with *Candida albicans*.
- High doses of tetracyclines can cause severe liver damage, especially in pregnant and postpartum women who have renal impairment.
- Erythromycin, the prototype of the macrolide antibiotics, is a bacteriostatic drug that inhibits bacterial protein synthesis.
- Erythromycin has an antimicrobial spectrum similar to that of penicillin G, and hence can be used in place of penicillin G in patients with penicillin allergy.

- Erythromycin is generally very safe. However, combined use of erythromycin with inhibitors of CYP3A4 increases the risk of QT prolongation and sudden cardiac death.
- Clindamycin is used primarily as an alternative to penicillin for serious gram-positive anaerobic infections.
- Clindamycin causes a high incidence of AAPMC.
- Linezolid is important because it can suppress multidrug-resistant gram-positive pathogens, including vancomycin-resistant enterococci (VRE) and methicillin-resistant *Staph. aureus* (MRSA).

86.3.8.2.2

Summary of Major Nursing Implications*

86.3.8.2.2.1

TETRACYCLINES

Demeclocycline

Doxycycline

Minocycline

Tetracycline

Except where stated otherwise, the implications summarized below pertain to all tetracyclines.

86.3.8.2.2....

Preadministration Assessment

86.3.8.2.2....

Therapeutic Goal

Treatment of tetracycline-sensitive infections, acne, and periodontal disease.

86.3.8.2.2....

Identifying High-Risk Patients

Tetracyclines are *contraindicated* in pregnant women and children under 8 years of age.

Tetracycline and *demeclocycline* must be used with great *caution* in patients with significant renal impairment.

Implementation: Administration

Routes

Systemic.

All tetracyclines are used systemically. Specific routes for individual agents are shown in [Table 85-2](#).

Topical.

Doxycycline and *minocycline* are used topically to treat periodontal disease.

Administration

Oral.

Advise patients to take oral tetracyclines on an empty stomach (1 hour before meals or 2 hours after) and with a full glass of water. *Doxycycline* and *minocycline* may be taken with food.

Absorption of tetracyclines is reduced by certain chelating agents: *milk products*, *calcium supplements*, *iron supplements*, *magnesium-containing laxatives*, and *most antacids*. **Instruct patients to allow at least 2 hours between ingestion of tetracyclines and these chelators.**

Instruct patients to complete the prescribed course of treatment, even though symptoms may abate before the full course is over.

Parenteral.

Intravenous administration is performed only when oral administration is ineffective or cannot be tolerated. *Intramuscular* injection is painful and used rarely.

86.3.8.2.2....	Ongoing Evaluation and Interventions	
86.3.8.2.2....	Minimizing Adverse Effects	
86.3.8.2.2....	Gastrointestinal Irritation.	
	Inform patients that GI distress (epigastric burning, cramps, nausea, vomiting, diarrhea) can be reduced by taking tetracyclines with meals, although absorption may be reduced.	
86.3.8.2.2....	Effects on Teeth.	
	Tetracyclines can discolor developing teeth. To prevent this, avoid tetracyclines in pregnant women and children under 8 years of age.	
86.3.8.2.2....	Suprainfection.	
	Tetracyclines can promote bacterial suprainfection of the bowel, resulting in severe diarrhea. Instruct patients to notify the prescriber if significant diarrhea develops. If suprainfection is diagnosed, discontinue tetracyclines immediately; treatment consists of oral vancomycin or metronidazole, plus fluid and electrolyte replacement.	
	Fungal overgrowth may occur in the mouth, pharynx, vagina, and bowel. Inform patients about symptoms of fungal infection (vaginal or anal itching; inflammatory lesions of the anogenital region; black, furry appearance of the tongue), and advise them to notify the prescriber if these occur. Suprainfection caused by <i>Candida</i> can be managed by discontinuing the tetracycline or by giving an antifungal drug.	1015
86.3.8.2.2....	Hepatotoxicity.	1016
	Tetracyclines can cause fatty infiltration of the liver, resulting in jaundice and, rarely, massive liver failure. The risk of liver injury can be reduced by avoiding high-dose IV therapy and by withholding tetracyclines from pregnant and postpartum women who have kidney disease.	

86.3.8.2.2....

Renal Toxicity.

Tetracyclines can exacerbate pre-existing renal impairment. *Tetracycline* and *demeclocycline* should not be used by patients with kidney disease.

86.3.8.2.2....

Photosensitivity.

Tetracyclines can increase the sensitivity of the skin to ultraviolet light, thereby increasing the risk of sunburn. **Advise patients to avoid prolonged exposure to sunlight, wear protective clothing, and apply a sunscreen to exposed skin.**

86.3.8.2.2.2

ERYTHROMYCIN

The implications summarized below apply to all forms of erythromycin, except where noted otherwise.

86.3.8.2.2....

Preadministration Assessment

86.3.8.2.2....

Therapeutic Goal

Erythromycin is indicated for legionnaires' disease, whooping cough, diphtheria, chancroid, chlamydial infections, and other infections caused by erythromycin-sensitive organisms. The drug is also used as a substitute for penicillin G in penicillin-allergic patients.

86.3.8.2.2....

Identifying High-Risk Patients

All forms of erythromycin should be avoided by patients with QT prolongation and by those taking inhibitors of CYP3A4.

86.3.8.2.2....

Implementation: Administration

86.3.8.2.2....

Routes

86.3.8.2.2....

Oral.

Erythromycin base, erythromycin ethylsuccinate, and erythromycin stearate.

86.3.8.2.2....

Intravenous.

Erythromycin lactobionate.

86.3.8.2.2....

Administration

86.3.8.2.2....

Oral.

Advise patients to take oral preparations on an empty stomach (1 hour before meals or 2 hours after) and with a full glass of water. However, if GI upset occurs, administration may be done with meals.

Inform patients using erythromycin ethylsuccinate and enteric-coated formulations of erythromycin base that they make take these drugs without regard to meals.

Instruct patients to complete the prescribed course of treatment, even though symptoms may abate before the full course is over.

86.3.8.2.2....

Intravenous.

Administer by slow infusion and in dilute solution to minimize thrombophlebitis.

86.3.8.2.2....

Ongoing Evaluation and Interventions

86.3.8.2.2....

Minimizing Adverse Effects

86.3.8.2.2....

Gastrointestinal Effects.

Gastrointestinal disturbances (epigastric pain, nausea, vomiting, diarrhea) can be reduced by administering erythromycin with meals. **Advise patients to notify the prescriber if GI reactions are severe or persistent.**

86.3.8.2.2....

QT Prolongation and Sudden Cardiac Death.

High levels of erythromycin can prolong the QT interval, thereby posing a risk of a potentially fatal cardiac dysrhythmia. Avoid erythromycin in patients with pre-existing QT prolongation, and in those taking drugs that can increase erythromycin levels.

86.3.8.2.2....

Minimizing Adverse Interactions

Erythromycin can increase the half-lives and plasma levels of several drugs. When erythromycin is combined with *theophylline*, *carbamazepine*, or *warfarin*, patients should be monitored closely for toxicity.

Erythromycin can antagonize the antibacterial actions of *clindamycin* and *chloramphenicol*. Concurrent use of erythromycin with these agents is not recommended.

Drugs that inhibit CYP3A4 (eg, verapamil, diltiazem, HIV protease inhibitors, azole antifungal drugs) can increase erythromycin levels, thereby posing a risk of QT prolongation and sudden cardiac death. People using these drugs should not use erythromycin.

86.3.8.2.2.3

CLINDAMYCIN

86.3.8.2.2....

Preadministration Assessment

86.3.8.2.2....

Therapeutic Goal

Treatment of anaerobic infections outside the CNS.

86.3.8.2.2....

Implementation: Administration

86.3.8.2.2....

Routes

Oral, IM, IV, intravaginal.

86.3.8.2.2....

Administration

Instruct patients to take oral clindamycin with a full glass of water.

Instruct patients to complete the prescribed course of treatment, even though symptoms may abate before the full course is over.

86.3.8.2.2....

Ongoing Evaluation and Interventions

86.3.8.2.2....

Minimizing Adverse Effects

86.3.8.2.2....

Antibiotic-Associated Pseudomembranous Colitis.

Clindamycin can promote AAPMC, a potentially fatal suprainfection. Prominent symptoms are profuse watery diarrhea, abdominal pain, fever, and leukocytosis. Stools often contain mucus and blood. **Instruct patients to report significant diarrhea (more than five watery stools per day).** If AAPMC is diagnosed, discontinue clindamycin. Treat with oral vancomycin or metronidazole and vigorous replacement of fluids and electrolytes. Drugs that decrease bowel motility (eg, opioids, anticholinergics) may worsen symptoms and should be avoided.

* Patient education information is highlighted as **blue text**.

⁸⁷CHAPTER 86 Aminoglycosides: Bactericidal Inhibitors of Protein Synthesis

The aminoglycosides are narrow-spectrum antibiotics, used primarily against aerobic gram-negative bacilli. These drugs disrupt protein synthesis, resulting in rapid bacterial death. The aminoglycosides can cause serious injury to the inner ear and kidney. Because of these toxicities, indications for these drugs are limited. All of the aminoglycosides carry multiple positive charges. As a result, the drugs are not absorbed from the GI tract, and hence must be administered parenterally to treat systemic infections. In the United States, seven aminoglycosides are approved for clinical use. The agents employed most commonly are gentamicin, tobramycin, and amikacin.

^{87.1}BASIC PHARMACOLOGY OF THE AMINOGLYCOSIDES**^{87.1.1} Chemistry**

The aminoglycosides are composed of two or more amino sugars connected by a glycoside linkage, hence the family name. At physiologic pH, these drugs are highly polar polycations (ie, they carry several positive charges), and therefore cannot readily cross membranes. As a result, aminoglycosides are not absorbed from the GI tract, do not enter the cerebrospinal fluid, and are rapidly excreted by the kidneys. Structural formulas for the three major aminoglycosides are shown in [Figure 86-1](#).

^{87.1.2} Mechanism of Action

The aminoglycosides disrupt bacterial protein synthesis. As indicated in [Figure 86-2](#), these drugs bind to the 30S ribosomal subunit, and thereby cause (1) inhibition of protein synthesis, (2) premature termination of protein synthesis, and (3) production of abnormal proteins (secondary to misreading of the genetic code).

The aminoglycosides are *bactericidal*. Cell kill is concentration dependent. Hence, the higher the concentration, the more rapidly the infection will clear. Of note, bactericidal activity persists for several hours *after* serum levels have dropped below the minimal bactericidal concentration, a phenomenon known as the *postantibiotic effect*.

Bacterial kill appears to result from production of abnormal proteins rather than from simple inhibition of protein synthesis. Studies suggest that abnormal proteins become inserted in the bacterial cell membrane, causing it to leak. The resultant loss of cell contents causes death. Inhibition of protein synthesis per se does not seem the likely cause of bacterial death. Why?

Because complete blockade of protein synthesis by other antibiotics (eg, tetracyclines, chloramphenicol) is usually bacteriostatic—not bactericidal.

87.1.3 Microbial Resistance

The principal cause for bacterial resistance is production of enzymes that can inactivate aminoglycosides. Among gram-negative bacteria, the genetic information needed to synthesize these enzymes is acquired through transfer of R factors. To date, more than 20 different aminoglycoside-inactivating enzymes have been identified. Since each of the aminoglycosides can be modified by more than one of these enzymes, and since each enzyme can act on more than one aminoglycoside, patterns of bacterial resistance can be complex.

Of all the aminoglycosides, *amikacin* is least susceptible to inactivation by bacterial enzymes. As a result, resistance to amikacin is uncommon. To minimize emergence of resistant bacteria, amikacin should be reserved for infections that are unresponsive to other aminoglycosides.

87.1.4 Antimicrobial Spectrum

Bactericidal effects of the aminoglycosides are limited almost exclusively to *aerobic gram-negative bacilli*. Sensitive organisms include *Escherichia coli*, *Klebsiella pneumoniae*, *Serratia marcescens*, *Proteus mirabilis*, and *Pseudomonas aeruginosa*. Aminoglycosides are inactive against most gram-positive bacteria.

Aminoglycosides *cannot kill anaerobes*. To produce antibacterial effects, aminoglycosides must be transported across the bacterial cell membrane, a process that is oxygen dependent. Since, by definition, anaerobic organisms live in the absence of oxygen, these microbes cannot take up aminoglycosides, and hence are resistant. For the same reason, aminoglycosides are inactive against facultative bacteria when these organisms are living under anaerobic conditions.

87.1.5 Therapeutic Use

87.1.5.1 Parenteral Therapy.

The principal use for parenteral aminoglycosides is treatment of *serious infections due to aerobic gram-negative bacilli*. Primary target organisms are

1017

Figure 86-1 Structural formulas of the major aminoglycosides.

Pseudomonas aeruginosa and the Enterobacteriaceae (eg, *E. coli*, *Klebsiella*, *Serratia*, *Proteus mirabilis*).

One aminoglycoside—gentamicin—is now commonly used in combination with either vancomycin or a beta-lactam antibiotic to treat *serious infections with certain gram-positive cocci*, specifically *Enterococcus* species, some streptococci, and *Staphylococcus aureus*.

The aminoglycosides used most commonly for parenteral therapy are gentamicin, tobramycin, and amikacin. Selection among the three depends in large part on patterns of resistance in a given community or hospital. In settings where resistance to aminoglycosides is uncommon, either gentamicin or tobramycin is usually preferred. Of the two, gentamicin is less expensive and may be selected on this basis. Organisms resistant to both gentamicin and tobramycin are usually sensitive to amikacin. Accordingly, in settings where resistance to gentamicin and tobramycin is common, amikacin may be preferred for initial therapy.

87.1.5.2 Oral Therapy.

Aminoglycosides are not absorbed from the GI tract, and hence oral therapy is used only for local effects within the intestine. In patients anticipating elective colorectal surgery, oral aminoglycosides have been given prophylactically to suppress bacterial growth in the bowel. One aminoglycoside—*paromomycin*—is used to treat intestinal amebiasis.

87.1.5.3 Topical Therapy.

Neomycin is available in formulations for application to the eyes, ears, and skin. Topical preparations of *gentamicin* and *tobramycin* are used to treat conjunctivitis caused by susceptible gram-negative bacilli.

87.1.6 Pharmacokinetics

All of the aminoglycosides have similar pharmacokinetic profiles. Pharmacokinetic properties of the principal aminoglycosides are summarized in [Table 86-1](#).

87.1.6.1 Absorption.

Because they are polycations, the aminoglycosides cross membranes poorly. As a result, very little (about 1%) of an oral dose is absorbed. Hence, for treatment of systemic infections, aminoglycosides must be given parenterally (IM or IV). Absorption following application to the intact skin is minimal. However, when used for wound irrigation, aminoglycosides may be absorbed in amounts sufficient to produce systemic toxicity.

87.1.6.2 Distribution.

Distribution of aminoglycosides is limited largely to extracellular fluid. Entry into the cerebrospinal fluid is insufficient to treat meningitis in adults. Aminoglycosides bind tightly to renal tissue, achieving levels in the kidney up to 50 times higher than levels in serum. These high levels are responsible for nephrotoxicity (see below). Aminoglycosides penetrate readily to the perilymph and endolymph of the inner ear, and can thereby cause ototoxicity (see below). Aminoglycosides can cross the placenta and may be toxic to the fetus.

87.1.6.3 Elimination.

The aminoglycosides are eliminated primarily by the kidney. These drugs are not metabolized. In patients with normal renal function, half-lives of the aminoglycosides range from 2 to 3

hours. However, because elimination is almost exclusively renal, half-lives increase dramatically in patients with renal impairment (see [Table 86-1](#)). *Accordingly, to avoid serious toxicity, we must reduce dosage size or increase the dosing interval in patients with kidney disease.*

87.1.6.4 Interpatient Variation.

Different patients receiving the same aminoglycoside dosage (in milligrams per kilogram of body weight) can achieve widely different serum levels of drug. This interpatient variation is caused by several factors,

1018

1019

Figure 86-2 Mechanism of action of aminoglycosides.**A,** Protein synthesis begins with binding of the 50S and 30S ribosomal subunits to messenger RNA (mRNA), followed by attachment of the first amino acid of the new protein to the 50S subunit. As the ribosome moves down the mRNA strand, additional amino acids are added to the growing peptide chain. When the new protein is complete, it separates from the ribosome and the ribosomal subunits separate from the mRNA.
B, Aminoglycosides bind to the 30S ribosomal subunit and can thereby (1) block initiation, (2) terminate synthesis before the new protein is complete, and (3) cause misreading of the genetic code, which causes synthesis of faulty proteins.

including age, percent body fat, and pathophysiology (eg, renal impairment, fever, edema, dehydration). Because of variability among patients, aminoglycoside dosage must be individualized. As dramatic evidence of this need, in one clinical study it was observed that, in order to produce equivalent serum drug levels, the doses required ranged from as little as 0.5 mg/kg in one patient to a high of 25.8 mg/kg in another—a difference of more than 50-fold.

87.1.7 Adverse Effects

The aminoglycosides can produce serious toxicity, especially to the inner ear and kidney. The inner ear and kidney are vulnerable because aminoglycosides become concentrated within cells of these structures.

87.1.7.1 Ototoxicity.

All aminoglycosides can accumulate within the inner ear, causing cellular injury that can impair both hearing and balance. *Impairment of hearing* is caused by damage to sensory hair cells in the *cochlea*. *Disruption of balance* is caused by damage to sensory hair cells of the *vestibular apparatus*.

TABLE 86-1 Dosages and Pharmacokinetics of Systemic Aminoglycosides

Generic Name	Trade Name	Total Daily Dose (mg/kg) ^{a,b}		Half-Life in Adults (hr)		Therapeutic (Peak) Level ^{c,d} (mcg/mL)	Safe Trough Level ^{e,f} (mcg/mL)
		Adults	Children	Normal	Anuric		
Amikacin	Amikin	15	15	2–3	24–60	15–30	Less than 5–10
Gentamicin	generic only ^g	3–5 ^h	6–7.5 ^h	2	24–60	4–10 ⁱ	Less than 1–2 ^j
Tobramycin	generic only ^{i,k}	3–6	6–7.5	2–2.5	24–60	4–10	Less than 1–2 ^j

a The total daily dose may be administered as one large dose each day, or as two or three divided doses given at equally spaced intervals around-the-clock.

- b Because of interpatient variability, standard doses cannot be relied upon to produce appropriate serum drug levels, and hence dosage should be adjusted on the basis of serum drug measurements.
- c Measured 30 minutes after IM injection or a 30-minute IV infusion.
- d The peak values presented refer to levels obtained when the total daily dosage is given in *divided* doses, rather than as a single large daily dose.
- e Measured just prior to the next dose.
- f To minimize ototoxicity, drug levels should drop *below* the listed values between doses.
- g Formerly available as Garamycin.
- h When gentamicin is combined with either vancomycin or a beta-lactam antibiotic to treat certain gram-positive infections, the total daily dose is much lower (eg, about 1 mg/kg for adults).
- i These peak values apply when gentamicin is used to treat gram-negative infections, not when gentamicin is combined with vancomycin or a beta-lactam antibiotic to treat gram-positive infections.
- j For severe infections, the trough may be less than 2-4 mcg/mL.
- k Formerly available as Nebcin.

The risk of ototoxicity is related primarily to excessive *trough levels*^{*} of drug—rather than to excessive *peak* levels. Why? Because, when trough levels remain persistently elevated, aminoglycosides are unable to diffuse out of inner ear cells, and hence the cells are exposed to the drug continuously for an extended time. It is this prolonged exposure, rather than brief exposure to high levels, that underlies cellular injury. In addition to high trough levels, the risk of ototoxicity is increased by (1) renal impairment (which can cause accumulation of aminoglycosides); (2) concurrent use of ethacrynic acid (a drug that has ototoxic properties of its own); and (3) administering aminoglycosides in excessive doses or for more than 10 days.

Patients should be monitored for ototoxicity. The first sign of impending *cochlear* damage is high-pitched tinnitus (ringing in the ears). As injury to cochlear hair cells proceeds, hearing in the high-frequency range begins to decline. Loss of low-frequency hearing develops with continued drug use. Because the initial decline in high-frequency hearing is subtle, audiometric testing is needed to detect it. The first sign of impending *vestibular* damage is headache, which may last for 1 or 2 days. After that, nausea, unsteadiness, dizziness, and vertigo begin to

appear. Patients should be informed about the symptoms of vestibular and cochlear damage and instructed to report them.

Ototoxicity is largely irreversible. Accordingly, if permanent injury is to be avoided, aminoglycosides should be withdrawn at the first sign of damage (ie, tinnitus, persistent headache, or both).

The risk of ototoxicity can be minimized in several ways. Dosages should be adjusted so that trough serum drug levels do not exceed recommended values. (Aminoglycosides diffuse out of the endolymph and perilymph during the trough time, thereby decreasing exposure of sensory hair cells.) Special care should be taken to ensure safe trough levels in patients with renal impairment. When possible, aminoglycosides should be used for no more than 10 days. Concurrent use of ethacrynic acid should be avoided.

* The trough serum level is defined as the lowest level between doses, and occurs just prior to administering the next dose.

87.1.7.2 Nephrotoxicity.

Aminoglycosides can injure cells of the proximal renal tubules. These drugs are taken up by tubular cells and achieve high intracellular concentrations. Nephrotoxicity correlates with the *total cumulative dose* of aminoglycosides and *with high trough levels*. High *peak levels* do not seem to increase toxicity. Aminoglycoside-induced nephrotoxicity usually manifests as *acute* tubular necrosis. Prominent symptoms are proteinuria, casts in the urine, production of dilute urine, and elevations in serum creatinine and blood urea nitrogen (BUN). Serum creatinine and BUN should be monitored. The risk of nephrotoxicity is especially high in the elderly, in patients with pre-existing kidney disease, and in patients receiving other nephrotoxic drugs (eg, amphotericin B, cephalothin, cyclosporine). Fortunately, cells of the proximal tubule readily regenerate. As a result, injury to the kidney usually reverses following cessation of aminoglycoside use.* The most significant consequence of renal damage is accumulation of aminoglycosides themselves, which can lead to ototoxicity and even more kidney damage.

* If interstitial fibrosis or renal tubular necrosis develop, damage to the kidney may be permanent.

87.1.7.3 Neuromuscular Blockade.

Aminoglycosides can inhibit neuromuscular transmission, causing flaccid paralysis and potentially fatal respiratory depression. Most episodes of neuromuscular blockade have occurred following intraperitoneal or intrapleural instillation of aminoglycosides. However,

neuromuscular blockade has also occurred with IV, IM, and oral administration. The risk of paralysis is increased by concurrent use of neuromuscular blocking agents and general anesthetics. Myasthenia gravis is an additional risk. Neuromuscular blockade can be reversed with calcium; IV infusion of a calcium salt (eg, calcium gluconate) is the treatment of choice. Because of increased prescriber awareness, aminoglycoside-induced neuromuscular blockade is now rare.

87.1.7.4 Other Adverse Effects.

Hypersensitivity reactions (eg, rash, pruritus, urticaria) occur occasionally. Blood dyscrasias (neutropenia, agranulocytosis, aplastic anemia) are rare. *Streptomycin* has been associated with neurologic disorders (optic nerve dysfunction, peripheral neuritis, paresthesias of the face and hands). *Oral neomycin* has caused suprainfection of the bowel and intestinal malabsorption. *Topical neomycin* can cause contact dermatitis.

1020

87.1.8 Drug Interactions

1021

87.1.8.1 Penicillins.

Penicillins and aminoglycosides are frequently employed in combination to enhance bacterial kill. The combination is effective because penicillins disrupt the cell wall, and thereby facilitate access of aminoglycosides to their site of action. Unfortunately, when present in high concentrations, penicillins can inactivate aminoglycosides by direct chemical interaction. Therefore, *penicillins and aminoglycosides should not be mixed together in the same IV solution*. (Inactivation is not likely to occur once the drugs are in the body, because drug concentrations are usually too low for significant chemical interaction.)

87.1.8.2 Cephalosporins and Vancomycin.

Like the penicillins, cephalosporins and vancomycin weaken the bacterial cell wall, and can thereby act in concert with aminoglycosides to enhance bacterial kill.

87.1.8.3 Ototoxic Drugs.

The risk of injury to the inner ear is significantly increased by concurrent use of *ethacrynic acid*, a loop diuretic that has ototoxic actions of its own. Combining aminoglycosides with two other loop diuretics—furosemide and bumetanide—appears to cause no more ototoxicity than aminoglycosides alone.

87.1.8.4 Nephrotoxic Drugs.

The risk of renal damage is increased by concurrent therapy with other nephrotoxic agents. Additive or potentiative nephrotoxicity can occur with *amphotericin B*, *cephalosporins*, *polymyxins*, *vancomycin*, and *cyclosporine*, as well as with *aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs)*.

87.1.8.5 Skeletal Muscle Relaxants.

Aminoglycosides can intensify neuromuscular blockade induced by pancuronium and other skeletal muscle relaxants. If aminoglycosides are used with these agents, caution must be exercised to avoid respiratory arrest.

87.1.9 Dosing Schedules

Systemic aminoglycosides may be administered as a single large dose each day, or as two or three smaller doses. Traditionally, these drugs have been administered in divided doses, given at equally spaced intervals around-the-clock (eg, every 8 hours). Today, however, it is common to administer the total daily dose all at once, rather than dividing it up. Several studies have shown that once-daily doses are just as effective as divided doses, and may be safer. Because once-daily dosing is both safe and effective, and because it's easier and cheaper than giving divided doses, once-daily dosing has become the preferred schedule. Keep in mind, however, that this schedule is not appropriate for some patients, including neonates and women who are pregnant.

How can it be that giving one large daily dose is just as safe and effective as giving divided doses? The answer lies in the hypothetical data for gentamicin levels plotted in [Figure 86-3](#). As indicated, when we give one large dose (4.5 mg/kg) once a day, we achieve a very high peak plasma level—much higher than when we give the same daily total in the form of three smaller doses (1.5 mg/kg) every 8 hours. Because of this high peak concentration, and because aminoglycosides exhibit a postantibiotic effect (see *Mechanism of Action* above), bacterial kill using a single daily dose is just as great as when we use divided doses—even though, with once-daily dosing, plasma drug levels are subtherapeutic for a prolonged time between doses. This prolonged period of low drug levels also explains why once-daily dosing is very safe: Because levels

Figure 86-3 **Plasma gentamicin levels produced with once-daily doses versus divided doses.** The curves depict plasma levels of gentamicin produced with (1) a single large dose administered once a day versus (2) the same daily total given as three smaller doses spaced 8 hours apart. Plasma levels with both regimens are high enough to produce good bactericidal effects. The shaded area indicates levels that are low enough to permit washout of the drug from vulnerable cells in the inner ear. Note that, with once-daily dosing, levels are in the washout range for over 12 hours, versus a total of only 6 hours when divided doses are used. As a result, ototoxicity is lower with the once-a-day schedule.

are low for a long time, aminoglycosides are able to wash out from vulnerable cells, thereby reducing injury. In contrast, when we use divided doses, the time during which drug levels are low enough to permit washout is quite short, and hence the risk of toxicity is high.

87.1.10 Monitoring Serum Drug Levels

Monitoring serum drug levels provides the best basis for adjusting aminoglycoside dosage. To produce bacterial kill, peak levels must be sufficiently high. To minimize ototoxicity, trough levels must be sufficiently low. Therapeutic levels and trough levels for the major systemic aminoglycosides are listed in [Table 86-1](#).

How monitoring is done depends on the dosing schedule employed (ie, once-daily dosing or use of divided doses). When once-daily dosing is employed, we only need to measure trough levels. As a rule, there is no need to measure peak levels. Why? Because, when the entire daily dose is given at once, high peak levels are guaranteed. (They're typically 3 to 4 times those achieved with divided doses.) In contrast, when divided doses are employed, we need to measure both the peak and the trough.

When drawing blood samples for aminoglycoside levels, timing is important. Samples for *peak* levels should be taken 30 minutes after giving an IM injection or after completing a 30-minute IV infusion. Sampling for *trough* levels depends on the dosing schedule. For patients receiving *divided doses*, trough samples should be taken just prior to the next dose. For patients receiving *once-daily doses*, a single sample can be drawn 1 hour before the next dose. The value should be very low, preferably close to zero.

1021

87.2 PROPERTIES OF INDIVIDUAL AMINOGLYCOSIDES

1022

87.2.1 Gentamicin

87.2.1.1 Therapeutic Use

Gentamicin (formerly available as Garamycin) is used primarily to treat serious infections caused by aerobic gram-negative bacilli. Primary targets are *Pseudomonas aeruginosa* and the Enterobacteriaceae (eg, *E. coli*, *Klebsiella*, *Serratia*, *Proteus mirabilis*). In hospitals where resistance is not a problem, gentamicin is often the preferred aminoglycoside for use against these bacteria. Why? Because gentamicin is cheaper than the alternatives (tobramycin and amikacin). Unfortunately, resistance to gentamicin is increasing, and crossresistance to tobramycin is common. For infections that are resistant to gentamicin and tobramycin, amikacin is usually effective.

In addition to its use against gram-negative bacilli, gentamicin can be combined with vancomycin, a cephalosporin, or a penicillin to treat serious infections caused by certain gram-positive cocci, namely, *Enterococcus* species, some streptococci, and *Staphylococcus aureus*.

87.2.1.2 Adverse Effects and Interactions

Like all other aminoglycosides, gentamicin is toxic to the kidney and inner ear. Caution must be exercised when combining gentamicin with other nephrotoxic or ototoxic drugs. Gentamicin is inactivated by penicillins and should not be mixed with these drugs in the same IV solution.

87.2.1.3 Preparations, Dosage, and Administration

87.2.1.3.1 Treatment of Gram-Negative Infections.

87.2.1.3.1.1 Intravenous and Intramuscular.

Gentamicin sulfate (formerly available as Garamycin) is supplied in solution (0.8, 0.9, 1, 1.2, 1.4, 1.6, 10 and 40 mg/mL) for IM and IV administration. The dosage for both routes is the same. For adults, the traditional dosing scheme consists of a loading dose (2 mg/kg) followed by doses of 1 to 1.7 mg/kg every 8 hours—for a total of 3 to approximately 5 mg/kg/day. When once-daily dosing is employed, the dosage is 5 mg/kg every 24 hours; no loading dose is needed. For children, the traditional maintenance dosage is 2 to 2.5 mg/kg every 8 hours. In patients with renal impairment, the total daily dosage should be reduced. Duration of treatment is usually 7 to 10 days.

Because of substantial interpatient variation, it is desirable to monitor serum drug levels and to adjust dosage accordingly. Peak levels should range between 4 and 10 mcg/mL (for traditional dosing) or between 16 and 24 mcg/mL (for once-daily dosing). The trough should not exceed 2 mcg/mL.

For IV administration, gentamicin should be diluted in either 0.9 sodium chloride injection or 5% dextrose and infused over 30 minutes or longer. The drug should not be mixed with penicillins in the same IV solution.

87.2.1.3.1.2 Intrathecal.

Intrathecal therapy is done with a 2-mg/mL solution devoid of preservatives. The usual dosage for children under 3 months old is 1 to 2 mg once daily. The usual dosage for adults

is 4 to 8 mg once daily. For all patients, treatment should continue for 1 day after samples of cerebrospinal fluid become negative for the infecting organism.

87.2.1.3.2 Treatment of Gram-Positive Infections.

As noted, gentamicin may be combined with vancomycin, a penicillin, or a cephalosporin to treat serious infections caused by *Enterococcus* species, certain streptococci, and *S. aureus*. When gentamicin is used in this way, dosages are much lower than when the drug is used against gram-negative infections. For combination therapy, a typical dosage for adults is 1 mg/kg/day, compared with 3 to 5 mg/kg/day when the drug is used by itself.

87.2.2 Tobramycin

87.2.2.1 Uses, Adverse Effects, and Interactions.

Tobramycin (formerly available as Nebcin) is similar to gentamicin with respect to uses, adverse effects, and interactions. The drug is more active than gentamicin against *Pseudomonas aeruginosa*, but less active against enterococci and *Serratia*. Inhaled tobramycin is used for patients with cystic fibrosis (see [Chapter 106](#)). Like all other aminoglycosides, tobramycin can injure the inner ear and kidney. If possible, concurrent therapy with other ototoxic or nephrotoxic drugs should be avoided.

87.2.2.2 Preparations, Dosage, and Administration.

87.2.2.2.1 Intravenous and Intramuscular.

Tobramycin sulfate (formerly available as Nebcin) is supplied in solution (0.8, 1.2, 10 and 40 mg/mL) for IM and IV administration. Dosages and serum levels are the same as those given for gentamicin. Ideally, dosages should be individualized to produce peak and trough levels within the ranges indicated in [Table 86-1](#). In patients with renal impairment, the total daily dosage should be reduced. For IV administration, the drug should be diluted in either 0.9% sodium chloride injection or 5% dextrose and infused over 30 minutes or more. Tobramycin should not be mixed with penicillins in the same IV solution. Duration of treatment is usually 7 to 10 days.

87.2.2.2.2 Nebulization.

For patients with *cystic fibrosis*, tobramycin [TOBI] is available in solution (300 mg/5 mL) for use in a nebulizer. The dosage is 300 mg twice daily administered in a repeating cycle

consisting of 28 days of drug use followed by 28 days off. Cystic fibrosis is discussed in [Chapter 106](#).

87.2.3 Amikacin

87.2.3.1 Uses, Adverse Effects, and Interactions.

Amikacin [Amikin] has two outstanding features: (1) of all the aminoglycosides, amikacin is active against the broadest spectrum of gram-negative bacilli; and (2) of all the aminoglycosides, amikacin is the least vulnerable to inactivation by bacterial enzymes. Because most aminoglycoside-inactivating enzymes do not affect amikacin, the incidence of bacterial resistance to this agent is lower than with other major aminoglycosides (gentamicin and tobramycin). In hospitals where resistance to gentamicin and tobramycin is common, amikacin is the preferred agent for initial treatment of infections caused by aerobic gram-negative bacilli. However, in settings where resistance to the other aminoglycosides is infrequent, amikacin should be reserved for infections of proven aminoglycoside resistance. Why? Because this practice will delay emergence of organisms resistant to amikacin. Like all other aminoglycosides, amikacin is toxic to the kidney and inner ear. Caution should be exercised if amikacin is used in combination with other ototoxic or nephrotoxic drugs.

87.2.3.2 Preparations, Dosage, and Administration.

Amikacin sulfate [Amikin] is available in solution (50, 100, and 250 mg/mL) for IM and IV administration. For IV use, amikacin should be diluted in 0.9% sodium chloride injection or 5% dextrose; infusion time should be 30 to 60 minutes in adults and 1 to 2 hours in infants. The recommended dosage for adults and children is 15 mg/kg/day administered either (1) as a single daily dose or (2) in equally divided doses at 8- or 12-hour intervals. In patients with renal impairment, dosage should be reduced or the dosing interval increased. Dosage adjustments should be based on measurements of serum drug levels. As a rule, duration of treatment should not exceed 10 days.

87.2.4 Other Aminoglycosides

87.2.4.1 Neomycin

Neomycin is more ototoxic and nephrotoxic than any other aminoglycoside. As a result, neomycin is not used parenterally. Instead, the drug is employed for topical treatment of infections of the eye, ear, and skin. Neomycin is also administered orally to suppress bowel flora prior to surgery of the intestine. Because aminoglycosides are not absorbed from the GI

tract, oral administration constitutes a local (nonsystemic) use of the drug. Oral neomycin can cause suprainfection of the bowel as well as an intestinal malabsorption syndrome.

87.2.4.2 Kanamycin

Kanamycin [Kantrex] is an older aminoglycoside to which bacterial resistance is common. The drug is still active against some gram-negative bacilli, but *Serratia* and *Pseudomonas* 1022
aeruginosa are resistant. Because of resistance, systemic use of the drug has sharply declined; 1023
gentamicin, tobramycin, and amikacin are preferred. Like neomycin, kanamycin is employed to suppress bacterial flora of the bowel prior to elective colorectal surgery. Kanamycin is supplied in capsules for oral use and in solution for IM and IV use.

87.2.4.3 Streptomycin

Streptomycin, discovered in 1943, was the first aminoglycoside drug. Although once employed widely, streptomycin has been largely replaced by safer or more effective medications. As discussed in [Chapter 89](#), streptomycin can be used in combination with other drugs to treat tuberculosis, but newer and safer agents (rifampin, isoniazid, ethambutol) are generally preferred. Streptomycin is also indicated for several uncommon infections (plague, tularemia, glanders, brucellosis). When combined with ampicillin or penicillin G, streptomycin may be used for enterococcal endocarditis.

87.2.4.4 Paromomycin

Paromomycin [Humatin] is an aminoglycoside employed only for local effects within the intestine. The drug is approved for oral therapy of intestinal amebiasis, and has been used investigationally against other intestinal parasites. The dosage for amebiasis in adults and children is 8 to 12 mg/kg 3 times daily for 5 to 10 days. Principal adverse effects are nausea, cramps, and diarrhea. Paromomycin is supplied in 250-mg capsules.

87.2.4.4.1

KEY POINTS

- Aminoglycosides are narrow-spectrum antibiotics, used primarily against aerobic gram-negative bacilli.
- Aminoglycosides disrupt protein synthesis and cause rapid bacterial death.

- Aminoglycosides are highly polar polycations. As a result, they are not absorbed from the GI tract, do not cross the blood-brain barrier, and are excreted rapidly by the kidney.
- Aminoglycosides can cause irreversible injury to sensory cells of the inner ear, resulting in hearing loss and disturbed balance.
- The risk of ototoxicity is related primarily to persistently elevated *trough* drug levels, rather than to excessive peak levels.
- Aminoglycosides are nephrotoxic, but renal injury is usually reversible.
- The risk of nephrotoxicity is related to the total cumulative dose, not to elevated trough levels.
- Because the same aminoglycoside dose can produce very different plasma levels in different patients, monitoring serum levels is common. *Peak* levels must be high enough to cause bacterial kill; *trough* levels must be low enough to minimize toxicity.

87.2.4.4.2

Summary of Major Nursing Implications^{*}

87.2.4.4.2.1

AMINOGLYCOSIDES

Amikacin

Gentamicin

Kanamycin

Neomycin

Paromomycin

Tobramycin

Except where noted, the implications summarized below apply to all aminoglycosides.

87.2.4.4.2....

Preadministration Assessment

87.2.4.4.2....

Therapeutic Goal

87.2.4.4.2....

Parenteral Therapy.

Treatment of serious infections caused by gram-negative aerobic bacilli. One aminoglycoside—*gentamicin*—is also used (in combination with vancomycin or a beta-lactam antibiotic) to treat serious infections caused by certain gram-positive cocci, namely *Enterococcus* species, some streptococci, and *S. aureus*.

87.2.4.4.2....

Oral Therapy.

Suppression of bowel flora prior to elective colorectal surgery.

87.2.4.4.2....

Topical Therapy.

Treatment of local infections of the eyes, ears, and skin.

87.2.4.4.2....

Identifying High-Risk Patients

Aminoglycosides must be used with *caution* in patients with renal impairment, pre-existing hearing impairment, and myasthenia gravis, and in patients receiving ototoxic drugs (especially ethacrynic acid), nephrotoxic drugs (eg, amphotericin B, cephalosporins, vancomycin, cyclosporine, NSAIDs), and neuromuscular blocking agents.

87.2.4.4.2....

Implementation: Administration

87.2.4.4.2....

Routes

87.2.4.4.2....

Intramuscular and Intravenous.

Gentamicin, tobramycin, amikacin, kanamycin.

87.2.4.4.2....

Oral.

Neomycin, paromomycin.

87.2.4.4.2....	Topical. Neomycin, tobramycin.	
87.2.4.4.2....	Dosing Schedule Aminoglycosides may be given as one large dose each day, or in two or three divided doses administered at equally spaced intervals around-the-clock.	
87.2.4.4.2....	Administration Aminoglycosides must be given parenterally (IV, IM) to treat systemic infections. Intravenous infusions should be done slowly (over 30 minutes or more). Do not mix aminoglycosides and penicillins in the same IV solution. When possible, adjust the dosage on the basis of plasma drug levels. When using divided daily doses, draw blood samples for measuring peak levels 1 hour after IM injection and 30 minutes after completing an IV infusion. When using a single daily dose, measuring peak levels is unnecessary. Draw samples for trough levels just prior to the next dose (when using divided daily doses) or 1 hour before the next dose (when using a single daily dose). In patients with renal impairment, the dosage should be reduced or the dosing interval increased.	1023 1024
87.2.4.4.2....	Ongoing Evaluation and Interventions	
87.2.4.4.2....	Monitoring Summary Monitor aminoglycoside levels (peaks and troughs), inner ear function (hearing and balance), creatinine clearance, BUN, and urine output.	
87.2.4.4.2....	Minimizing Adverse Effects	
87.2.4.4.2....	Ototoxicity. Aminoglycosides can damage the inner ear, causing irreversible impairment of hearing and balance. Monitor for ototoxicity, using audiometry in high-risk patients. Instruct patients to report symptoms of ototoxicity (tinnitus, high-	

frequency hearing loss, persistent headache, nausea, unsteadiness, dizziness, vertigo). If ototoxicity is detected, aminoglycosides should be withdrawn.

87.2.4.4.2....

Nephrotoxicity.

Aminoglycosides can cause reversible acute tubular necrosis. To evaluate renal injury, monitor serum creatinine and BUN. If oliguria or anuria develops, withhold the aminoglycoside and notify the prescriber.

87.2.4.4.2....

Neuromuscular Blockade.

Aminoglycosides can inhibit neuromuscular transmission, causing potentially fatal respiratory depression. Carefully observe patients with myasthenia gravis and patients receiving skeletal muscle relaxants or general anesthetics.

Aminoglycoside-induced neuromuscular blockade can be reversed with IV calcium gluconate.

87.2.4.4.2....

Minimizing Adverse Interactions

87.2.4.4.2....

Penicillins.

Aminoglycosides can be inactivated by high concentrations of penicillins. Never mix penicillins and aminoglycosides in the same IV solution.

87.2.4.4.2....

Ototoxic and Nephrotoxic Drugs.

Exercise caution when using aminoglycosides in combination with other nephrotoxic or ototoxic drugs. Increased nephrotoxicity may occur with *amphotericin B*, *cephalosporins*, *polymyxins*, *vancomycin*, *cyclosporine*, and *NSAIDs*. Increased ototoxicity may occur with *ethacrynic acid*.

87.2.4.4.2....

Skeletal Muscle Relaxants.

Aminoglycosides can intensify neuromuscular blockade induced by pancuronium and other skeletal muscle relaxants. When aminoglycosides are used concurrently with these agents, exercise caution to avoid respiratory arrest.

* Patient education information is highlighted as **blue text**.

⁸⁸CHAPTER 87 Sulfonamides and Trimethoprim

The sulfonamides and trimethoprim are broad-spectrum antimicrobials that have closely related mechanisms: They all disrupt the synthesis of tetrahydrofolic acid. In approaching these drugs, we begin with the sulfonamides, followed by trimethoprim, and then conclude with trimethoprim/sulfamethoxazole, an important fixed-dose combination.

^{88.1}SULFONAMIDES

Sulfonamides were the first drugs available for systemic treatment of bacterial infections. Their introduction and subsequent widespread use produced a sharp decline in morbidity and mortality from susceptible infections. Until the penicillins became generally available, sulfonamides remained the mainstay of antibacterial chemotherapy. With the advent of newer antimicrobial drugs, use of sulfonamides has greatly declined. Today, only a few remain on the market. Nonetheless, the sulfonamides still have important uses, primarily against urinary tract infections. With the introduction of trimethoprim/sulfamethoxazole in the 1970s, indications for the sulfonamides have expanded.

^{88.1.1} Basic Pharmacology

Similarities among the sulfonamides are more striking than the differences. Accordingly, rather than focusing on a representative prototype, we discuss the sulfonamides as a group.

^{88.1.1.1} Chemistry

The general structural formula for the sulfonamides is shown in [Fig. 87-1](#). As you can see, sulfonamides are structural analogs of para-*aminobenzoic acid* (PABA). The antimicrobial actions of sulfonamides are based on this similarity.

Individual sulfonamides vary greatly with respect to solubility in water. Older sulfonamides had low solubility, and hence they often crystallized out in the urine, causing injury to the kidneys. The sulfonamides in current use are much more soluble, and hence the risk of renal damage is low.

^{88.1.1.2} Mechanism of Action

Sulfonamides suppress bacterial growth by inhibiting synthesis of *folic acid* (folate), a compound required by all cells to synthesize DNA, RNA, and proteins. The steps in folate synthesis are shown in [Fig. 87-2](#). As indicated, sulfonamides block the step in which PABA is combined with pteridine to form dihydropteroic acid. Because of their structural similarity to

PABA, sulfonamides act as competitive inhibitors of this reaction. Sulfonamides are usually bacteriostatic. Hence, host defenses are essential for a complete elimination of infection.

If all cells require folate, why don't sulfonamides harm us? The answer lies in how bacteria and mammalian cells acquire folic acid. Bacteria are unable to take up folate from their environment, and hence must synthesize folic acid from precursors. It is this process that sulfonamides disrupt. In contrast, mammalian cells do not manufacture their own folate. Rather, they simply take up folic acid obtained from the diet, using a specialized transport system for uptake. Because mammalian cells use preformed folic acid rather than synthesizing it, sulfonamides are harmless to us.

88.1.1.3 Microbial Resistance

Many bacterial species have developed resistance to sulfonamides, thereby decreasing the utility of these drugs. Resistance is especially high among gonococci, meningococci, streptococci, and shigellae. Resistance may be acquired by spontaneous mutation or by transfer of R factors. Principal resistance mechanisms are (1) synthesis of PABA in amounts sufficient to overcome sulfonamide-mediated inhibition of dihydropteroate synthetase, (2) alteration in the structure of dihydropteroate synthetase such that binding and inhibition by sulfonamides is reduced, and (3) reduced sulfonamide uptake.

88.1.1.4 Antimicrobial Spectrum

The sulfonamides are active against a broad spectrum of microbes. Susceptible organisms include gram-positive cocci (including methicillin-resistant *Staphylococcus aureus*), gram-negative bacilli, *Listeria monocytogenes*, actinomycetes (eg, *Nocardia*), chlamydiae (eg, *Chlamydia trachomatis*), some protozoa (eg, *Toxoplasma*, plasmodia, *Isospora belli*), and two fungi: *Pneumocystis jiroveci* (formerly thought to be *Pneumocystis carinii*) and *Paracoccidioides brasiliensis*.

88.1.1.5 Therapeutic Uses

Although the sulfonamides were once employed widely, their applications are now limited. Two factors explain why: (1) introduction of bactericidal antibiotics that are less toxic than the sulfonamides, and (2) development of sulfonamide resistance. Today, urinary tract infection is the principal indication for these drugs.

88.1.1.5.1 Urinary Tract Infections.

Sulfonamides are often preferred drugs for acute infections of the urinary tract. About 90% of these infections are due to *Escherichia coli*, a bacterium that is usually sulfonamide sensitive. Of the sulfonamides available, *sulfamethoxazole* (in combination with

1025

1026

Figure 87-1 Structural relationships among sulfonamides, PABA, and folic acid.

trimethoprim) is generally favored. Sulfamethoxazole has good solubility in urine and achieves effective concentrations within the urinary tract. Urinary tract infections and their treatment are the topic of [Chapter 88](#).

88.1.1.5.2 Other Uses.

Sulfonamides are useful drugs for nocardiosis (infection with *Nocardia asteroides*), listeria, paracoccidioidomycosis, and infection with *Pneumocystis jiroveci*. In addition, sulfonamides are alternatives to doxycycline and erythromycin for infections caused by *C. trachomatis* (trachoma, inclusion conjunctivitis, urethritis, lymphogranuloma venereum). Sulfonamides are used in conjunction with pyrimethamine to treat two protozoal infections: toxoplasmosis and malaria caused by chloroquine-resistant *Plasmodium falciparum*. Topical sulfonamides are used to treat superficial infections of the eye and to suppress bacterial colonization in burn patients.

One sulfonamide—sulfasalazine—is used to treat *ulcerative colitis*. However, benefits in this disorder do not result from inhibiting microbial growth. Ulcerative colitis is discussed in [Chapter 79](#).

88.1.1.6 Pharmacokinetics

88.1.1.6.1 Absorption.

Sulfonamides are well absorbed following oral administration. When applied topically to the skin or mucous membranes, these drugs may be absorbed in amounts sufficient to cause systemic effects.

88.1.1.6.2 Distribution.

Sulfonamides are well distributed to all tissues. Concentrations in pleural, peritoneal, ocular, and similar body fluids may be as much as 80% of the concentration in blood. Sulfonamides readily cross the placenta, and levels achieved in the fetus are sufficient to produce antimicrobial effects and toxicity.

88.1.1.6.3 Metabolism.

Sulfonamides are metabolized in the liver, principally by acetylation. Acetylated derivatives lack antimicrobial activity, but are just as toxic as the parent compounds. Acetylation may decrease sulfonamide solubility, thereby increasing the risk of renal damage from crystal formation.

88.1.1.6.4 Excretion.

Sulfonamides are excreted primarily by the kidneys. Hence, the rate of renal excretion is the principal determinant of their half-lives.

88.1.1.7 Adverse Effects

Sulfonamides can cause multiple adverse effects. Prominent among these are hypersensitivity reactions, blood dyscrasias, and kernicterus, which occurs in newborn infants. Renal damage from crystalluria was a problem with older sulfonamides but is of minimal concern with the drugs used today.

Figure 87-2 Sites of action of sulfonamides and trimethoprim.

Sulfonamides and trimethoprim inhibit sequential steps in the synthesis of tetrahydrofolic acid (FAH₄). In the absence of FAH₄, bacteria are unable to synthesize DNA, RNA, and proteins.

88.1.1.7.1 Hypersensitivity Reactions.

Sulfonamides can induce a variety of hypersensitivity reactions. Mild reactions—rash, drug fever, photosensitivity—are relatively common. To minimize photosensitivity reactions, patients should avoid prolonged exposure to sunlight, wear protective clothing, and apply a sunscreen to exposed skin.

Hypersensitivity reactions are especially frequent with topical sulfonamides. As a result, these preparations are no longer employed routinely. Rather, they are reserved for ophthalmic infections, burns, and bacterial vaginosis caused by *Gardnerella vaginalis* and a mixed population of anaerobic bacteria.

The most severe hypersensitivity response to sulfonamides is *Stevens-Johnson syndrome*, a rare reaction with a mortality rate of about 25%. Symptoms include widespread lesions of the skin and mucous membranes, combined with fever, malaise, and toxemia. The reaction is most likely with long-acting sulfonamides, which are now banned in the United States.

Short-acting sulfonamides may also induce the syndrome, but the incidence is low. To minimize the risk of severe reactions, sulfonamides should be discontinued immediately if skin rash of any sort is observed. In addition, sulfonamides should not be given to patients with a history of hypersensitivity to sulfonamide antibiotics or to chemically related drugs, including thiazide diuretics, loop diuretics, and sulfonylurea-type oral hypoglycemics (eg, tolbutamide).

1026

1027

88.1.1.7.2 Hematologic Effects.

Sulfonamides can cause *hemolytic anemia* in patients whose red blood cells have a genetically determined deficiency in glucose-6-phosphate dehydrogenase (G6PD). This inherited trait is most common among African Americans and people of Mediterranean origin. Rarely, hemolysis occurs in the absence of G6PD deficiency. Red cell lysis can produce fever, pallor, and jaundice; patients should be observed for these signs. In addition to hemolytic anemia, sulfonamides can cause agranulocytosis, leukopenia, thrombocytopenia, and, very rarely, aplastic anemia. When sulfonamides are used for a long time, periodic blood tests should be obtained.

88.1.1.7.3 Kernicterus.

Kernicterus is a disorder in newborns caused by deposition of bilirubin in the brain. Bilirubin is neurotoxic and can cause severe neurologic deficits and even death. Under normal conditions, infants are not vulnerable to kernicterus. Why? Because any bilirubin present in

their blood is tightly bound to plasma proteins, and therefore is not free to enter the central nervous system (CNS). Sulfonamides promote kernicterus by displacing bilirubin from plasma proteins. Since the blood-brain barrier of infants is poorly developed, the newly freed bilirubin has easy access to sites within the brain. *Because of the risk of kernicterus, sulfonamides should not be administered to infants under the age of 2 months. In addition, sulfonamides should not be given to pregnant women near term or to mothers who are breast-feeding.*

88.1.1.7.4 Renal Damage from Crystalluria.

Because of their low solubility, older sulfonamides tended to come out of solution in the urine, forming crystalline aggregates in the kidneys, ureters, and bladder. These aggregates caused irritation and obstruction, sometimes resulting in anuria and even death. Renal damage is uncommon with today's sulfonamides, owing to their increased water solubility. To minimize the risk of renal damage, adults should maintain a daily urine output of 1200 mL. This can be accomplished by consuming 8 to 10 glasses of water each day. Because the solubility of sulfonamides is highest at elevated pH, alkalinization of the urine (eg, with sodium bicarbonate) can further decrease the chances of crystalluria.

88.1.1.8 Drug Interactions

88.1.1.8.1 Metabolism-Related Interactions.

Sulfonamides can intensify the effects of warfarin, phenytoin, and sulfonylurea-type oral hypoglycemics (eg, glipizide, glyburide). The principal mechanism is inhibition of hepatic metabolism. When combined with sulfonamides, these drugs may require a reduction in dosage to prevent toxicity.

88.1.1.8.2 Allergy-Inducing Drugs.

People who are hypersensitive to sulfonamide antibiotics are likely to be hypersensitive to all other drugs that contain a sulfonamide moiety (eg, thiazide diuretics, loop diuretics, sulfonylurea-type oral hypoglycemics). This cross-reactivity appears to reflect a general predisposition to drug allergy, rather than a specific cross-reactivity with sulfonamides. Hence sulfonamide-allergic patients may also display hypersensitivity to penicillins and possibly other drugs.

88.1.2 Sulfonamide Preparations

The sulfonamides fall into two major categories: (1) systemic sulfonamides and (2) topical sulfonamides. The systemic agents are used more often.

88.1.2.1 Systemic Sulfonamides

In the past, we had three groups of systemic sulfonamides: short acting, intermediate acting, and long acting. Today, the long-acting agents are no longer available, owing to a high risk of Stevens-Johnson syndrome. The remaining two groups—short acting and intermediate acting—differ primarily with regard to dosing interval, which is much shorter for the shortacting drugs. Except where noted, the adverse effects and drug interactions of individual sulfonamides are the same as those discussed above.

88.1.2.1.1 Sulfamethoxazole.

Sulfamethoxazole is the only intermediate-acting sulfonamide available. Because its effects are moderately prolonged, dosing can be done less often than with the short-acting agents. The risk of renal damage from crystalluria can be reduced by maintaining adequate hydration. Sulfamethoxazole is not available for use by itself—but *is* available in combination with trimethoprim (see below).

88.1.2.1.2 Sulfisoxazole.

Sulfisoxazole is a short-acting sulfonamide. Prior to the introduction of trimethoprim/sulfamethoxazole, sulfisoxazole was the preferred sulfonamide for urinary tract infections. The drug is just as effective as other sulfonamides and less expensive. Moreover, owing to its high water solubility, sulfisoxazole poses a minimal risk of crystalluria. Because high plasma concentrations of sulfisoxazole can be achieved, the drug is useful against a variety of systemic infections (eg, nocardiosis, chancroid, trachoma). Administration is oral. The usual dosage for adults is 1 gm every 4 to 6 hours.

88.1.2.1.3 Sulfadiazine.

Sulfadiazine is a short-acting sulfonamide with lower solubility than sulfisoxazole. Accordingly, if renal damage is to be avoided, high urine flow must be maintained. Sulfadiazine crosses the blood-brain barrier with ease, and hence is the best sulfonamide for prophylaxis of meningitis (although other drugs—ciprofloxacin, ceftriaxone, rifampin—are preferred). When combined with pyrimethamine, sulfadiazine is useful against

toxoplasmosis. The drug is supplied in tablets for oral administration. The usual adult dosage is 1 gm every 4 to 6 hours.

88.1.2.2 Topical Sulfonamides

Topical sulfonamides have been associated with a high incidence of hypersensitivity and are not used routinely. The preparations discussed below have proven utility and a relatively low incidence of hypersensitivity.

88.1.2.2.1 Sulfacetamide.

Sulfacetamide is widely used for superficial infections of the eye (eg, conjunctivitis, corneal ulcer). The drug may cause blurred vision, sensitivity to bright light, headache, brow ache, and local irritation. Hypersensitivity is rare, but severe reactions have occurred. Accordingly, sulfacetamide should not be used by patients with a history of hypersensitivity to sulfonamides, sulfonyleureas, or thiazide or loop diuretics. Sulfacetamide is available in solution and ointment formulations for local application to the eye. Trade names include Isopto Cetamide and Sodium Sulamyd.

88.1.2.2.2 Silver Sulfadiazine and Mafenide.

Both of these sulfonamides are employed to suppress bacterial colonization in patients with second- and third-degree burns. Mafenide acts by the same mechanism as other sulfonamides. In contrast, antibacterial effects of silver sulfadiazine are due primarily to release of free silver—and not to the sulfonamide portion of the molecule. Local application of mafenide is frequently painful. In contrast, application of silver sulfadiazine is usually pain free. Following topical application, both agents can be absorbed in amounts sufficient to produce systemic effects. Mafenide, but not silver sulfadiazine, is metabolized to a compound that can suppress renal excretion of acid, thereby causing acidosis. Accordingly, patients receiving mafenide should be monitored for acid-base status. If acidosis becomes severe, mafenide should be discontinued for 1 to 2 days. Mafenide is marketed under the trade name Sulfamylon. Trade names for silver sulfadiazine are Silvadene, Thermazene, and SSD Cream.

1027

88.2 TRIMETHOPRIM

1028

Like the sulfonamides, trimethoprim [Proloprim, Trimplex] suppresses synthesis of tetrahydrofolic acid. Trimethoprim is active against a broad spectrum of microbes.

88.2.1 Mechanism of Action

As indicated in [Figure 87-2](#), trimethoprim *inhibits dihydrofolate reductase*, the enzyme that converts dihydrofolic acid to its active form: tetrahydrofolic acid. Hence, like the sulfonamides, trimethoprim suppresses bacterial synthesis of DNA, RNA, and proteins. Depending on conditions at the site of infection, trimethoprim may be bactericidal or bacteriostatic.

Although mammalian cells also contain dihydrofolate reductase, trimethoprim is selectively toxic to bacteria. Why? Because bacterial dihydrofolate reductase differs in structure from mammalian dihydrofolate reductase. As a result, trimethoprim inhibits the bacterial enzyme at concentrations about 40,000 times lower than those required to inhibit the mammalian enzyme. This allows suppression of bacterial growth with doses that have essentially no effect on the host.

88.2.2 Microbial Resistance

Bacteria acquire resistance to trimethoprim in three ways: (1) synthesizing increased amounts of dihydrofolate reductase, (2) producing an altered dihydrofolate reductase that has a low affinity for trimethoprim, and (3) reduced cellular permeability to trimethoprim. Resistance has resulted from spontaneous mutation and from transfer of R factors. In the United States, bacterial resistance is uncommon.

88.2.3 Antimicrobial Spectrum

Trimethoprim is active against most enteric gram-negative bacilli of clinical importance, including *E. coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Serratia marcescens*, *Salmonella*, and *Shigella*. The drug is also active against some gram-positive bacilli (eg, *Corynebacterium diphtheriae*, *Listeria monocytogenes*), as well as some pathogenic protozoa (eg, *Toxoplasma gondii*), and one fungus (*P. jiroveci*).

88.2.4 Therapeutic Uses

Trimethoprim is approved only for initial therapy of acute, uncomplicated urinary tract infections due to susceptible organisms (eg, *E. coli*, *Proteus mirabilis*, *K. pneumoniae*, *Enterobacter* species, and coagulase-negative *Staphylococcus* species, including *S. saprophyticus*). When combined with sulfamethoxazole, trimethoprim has considerably more applications, as discussed later in the chapter.

88.2.5 Pharmacokinetics

Trimethoprim is absorbed rapidly and completely from the GI tract. The drug is lipid soluble, and therefore undergoes wide distribution to body fluids and tissues. Trimethoprim readily crosses the placenta. Most of an administered dose is excreted unchanged in the urine. Hence, in the presence of renal impairment, the half-life of trimethoprim is prolonged. The concentration of trimethoprim achieved in urine is considerably higher than the concentration in blood.

88.2.6 Adverse Effects

Trimethoprim is generally well tolerated. The most frequent adverse effects are itching and rash. Gastrointestinal reactions (eg, epigastric distress, nausea, vomiting, glossitis, stomatitis) occur occasionally.

88.2.6.1 Hematologic Effects.

Because mammalian dihydrofolate reductase is relatively insensitive to trimethoprim, toxicities related to impaired tetrahydrofolate production are rare. These rare effects—*megaloblastic anemia*, *thrombocytopenia*, and *neutropenia*—occur only in individuals with preexisting folic acid deficiency. Accordingly, caution is needed when administering trimethoprim to patients in whom folate deficiency might be likely (eg, alcoholics, pregnant women, debilitated patients). If early signs of bone marrow suppression occur (eg, sore throat, fever, pallor), complete blood counts should be performed. If a significant reduction in blood cell counts is observed, trimethoprim should be discontinued. Administering folinic acid (leucovorin) will restore normal hematopoiesis.

88.2.6.2 Use in Pregnancy and Lactation.

Large doses of trimethoprim have caused fetal malformations in animals. To date, no developmental abnormalities have been observed in humans. Nonetheless, since trimethoprim readily crosses the placenta, prudence dictates avoiding routine use during pregnancy. The risk of exacerbating pregnancy-related folate deficiency is an additional reason to avoid the drug at this time.

Trimethoprim is excreted in breast milk and may interfere with folic acid utilization by the nursing infant. The drug should be administered with caution to women who are breast-feeding.

88.2.7 Preparations, Dosage, and Administration

Trimethoprim [Proloprim, Trimplex] is supplied in tablets (100 mg) and an oral solution (10 mg/mL). For urinary tract infections, the usual dosage is 100 mg PO every 12 hours or 200 mg PO every 24 hours. Duration of treatment is 10 days. Dosage should be reduced in patients with renal impairment.

88.3 TRIMETHOPRIM/SULFAMETHOXAZOLE

Trimethoprim (TMP) and sulfamethoxazole (SMZ) are marketed together in a fixed-dose combination product. This combination (TMP/SMZ) is a powerful antimicrobial preparation whose components act in concert to inhibit sequential steps in tetrahydrofolic acid synthesis. Trade names for TMP/SMZ are Bactrim, Cotrim, and Septra. In many countries, the combination is known generically as *co-trimoxazole*.

88.3.1 Mechanism of Action

The antimicrobial effects of TMP/SMZ result from inhibiting consecutive steps in the synthesis of tetrahydrofolic acid: SMZ acts first to inhibit incorporation of PABA into folic acid; TMP then inhibits dihydrofolate reductase, the enzyme that converts dihydrofolic acid into tetrahydrofolate (see [Fig. 87-2](#)). As a result, the ability of the target organism to make nucleic acids and proteins is greatly suppressed. By inhibiting two reactions required for synthesis of tetrahydrofolate, TMP and SMZ potentiate each other's effects. That is, the antimicrobial effect of the combination is more powerful than the sum of the effects of TMP alone plus SMZ alone. TMP/SMZ is selectively toxic to microbes because (1) mammalian cells use preformed folic acid, and therefore are not affected by SMZ; and (2) dihydrofolate reductases of mammalian cells are relatively insensitive to inhibition by TMP.

88.3.2 Microbial Resistance

Resistance to TMP/SMZ is less than to either drug alone. This is logical in that the chances of an organism acquiring resistance to both drugs are less than its chances of developing resistance to just one or the other. Specific mechanisms of resistance to sulfonamides and TMP are presented earlier in the chapter.

1028

88.3.3 Antimicrobial Spectrum

TMP/SMZ is active against a wide range of gram-positive and gram-negative bacteria. This should be no surprise in that TMP and SMZ by themselves are broad-spectrum antimicrobial drugs. About 80% of urinary tract pathogens are susceptible. Specific bacteria against which

1029

TMP/SMZ is consistently effective include *E. coli*, *Proteus mirabilis*, *Listeria monocytogenes*, *S. aureus* (including methicillin-resistant isolates), *Chlamydia trachomatis*, *Salmonella typhi*, *Shigella* species, *Vibrio cholerae*, *Haemophilus influenzae*, and *Yersinia pestis*. TMP/SMZ is also active against *Nocardia*, certain protozoa (eg, *T. gondii*), and two fungi (*P. jiroveci* and *Paracoccidioides brasiliensis*).

88.3.4 Therapeutic Uses

TMP/SMZ is a preferred or alternative medication for a variety of infectious diseases. The combination is especially valuable for urinary tract infections, otitis media, bronchitis, shigellosis, and pneumonia caused by *P. jiroveci*.

88.3.4.1 Urinary Tract Infection.

TMP/SMZ is indicated for chemotherapy of uncomplicated urinary tract infection caused by susceptible strains of *E. coli*, *Klebsiella*, *Enterobacter*, *Proteus mirabilis*, *Proteus vulgaris*, and *Morganella morganii*. The combination is particularly useful for chronic and recurrent infections.

88.3.4.2 Pneumocystis Pneumonia (PCP).

TMP/SMZ is the treatment of choice for PCP, an infection caused by *Pneumocystis jiroveci*, formerly thought to be *Pneumocystis carinii*. *Pneumocystis jiroveci* is an opportunistic fungus that thrives in immunocompromised hosts (eg, cancer patients, organ transplant recipients, individuals with AIDS). When given to AIDS patients, TMP/SMZ produces a high incidence of adverse effects.

88.3.4.3 Gastrointestinal Infections.

TMP/SMZ is a drug of choice for infections caused by several gram-negative bacilli, including *Yersinia enterocolitica* and *Aeromonas*. In addition, the combination is a preferred treatment for shigellosis caused by susceptible strains of *Shigella flexneri* and *S. sonnei*.

88.3.4.4 Other Infections.

TMP/SMZ can be used for otitis media and acute exacerbations of chronic bronchitis when these infections are due to susceptible strains of *H. influenzae* or *Streptococcus pneumoniae*. The preparation is also useful against urethritis and pharyngeal infection caused by penicillinase-producing *Neisseria gonorrhoeae*. Other infections that can be treated with TMP/SMZ include whooping cough, nocardiosis, brucellosis, melioidosis, listeria, and chancroid.

88.3.5 Pharmacokinetics

88.3.5.1 Absorption and Distribution.

TMP/SMZ may be administered orally or by IV infusion. Both components of TMP/SMZ are well distributed throughout the body. Therapeutic concentrations are achieved in tissues and body fluids (eg, vaginal secretions, cerebrospinal fluid, pleural effusions, bile, aqueous humor). Both TMP and SMZ readily cross the placenta, and both enter breast milk.

88.3.5.2 Plasma Drug Levels.

Optimal antibacterial effects are produced when the ratio of TMP to SMZ is 1:20. To achieve this ratio in plasma, TMP and SMZ must be administered in a ratio of 1:5. Hence, standard tablets contain 80 mg of TMP and 400 mg of SMZ. Because the plasma half-lives of TMP and SMZ are similar (10 hours for TMP and 11 hours for SMZ), levels of both drugs decline in parallel, and the 1:20 ratio is maintained as the drugs are eliminated.

88.3.5.3 Elimination.

Both TMP and SMZ are excreted primarily by the kidneys. About 70% of urinary SMZ is present as inactive metabolites. In contrast, TMP undergoes little metabolism prior to excretion. Both agents are concentrated in the urine. Hence, levels of active drug are higher in the urine than in plasma, despite some conversion to inactive products.

88.3.6 Adverse Effects

TMP/SMZ is generally well tolerated; toxicity from routine use is rare. The most common adverse effects are nausea, vomiting, and rash. However, although infrequent, all of the serious toxicities associated with sulfonamides can occur with TMP/SMZ. That is, the combination can cause hypersensitivity reactions (including Stevens-Johnson syndrome), blood dyscrasias (hemolytic anemia, agranulocytosis, leukopenia, thrombocytopenia, aplastic anemia), kernicterus, and renal damage. Primarily because of its TMP component, TMP/SMZ can induce megaloblastic anemia, but only in patients who are folate deficient. TMP/SMZ may also cause adverse CNS effects (headache, depression, hallucinations). Hyperkalemia is a potential complication of TMP/SMZ therapy, especially when the dosage is high. Patients suffering from AIDS are unusually susceptible to TMP/SMZ toxicity. In this group, the incidence of adverse effects (rash, recurrent fever, leukopenia) is about 55%.

Several measures can reduce the incidence and severity of adverse effects. Crystalluria can be avoided by maintaining adequate hydration. Periodic blood tests permit early detection of

hematologic disorders. To avoid kernicterus, TMP/SMZ should be withheld from pregnant women near term, nursing mothers, and infants under the age of 2 months. The risk of megaloblastic anemia can be reduced by withholding sulfonamides from individuals likely to be folate deficient (eg, debilitated patients, pregnant women, alcoholics). Hypersensitivity reactions can be minimized by avoiding TMP/SMZ in patients with a history of hypersensitivity to sulfonamides or to chemically related drugs, including thiazide diuretics, loop diuretics, and sulfonylurea-type oral hypoglycemics.

88.3.7 Drug Interactions

Interactions of TMP/SMZ with other drugs are due primarily to the presence of SMZ. Hence, like sulfonamides used alone, SMZ in the combination can intensify the effects of warfarin, phenytoin, and sulfonylurea-type oral hypoglycemics (eg, tolbutamide). Accordingly, when these drugs are combined with TMP/SMZ, a reduction in their dosage may be needed. TMP/SMZ may also intensify bone marrow suppression in patients receiving methotrexate.

88.3.8 Preparations, Dosage, and Administration

88.3.8.1 Preparations.

Trimethoprim/sulfamethoxazole [Bactrim, Cotrim, Septra] is supplied in tablets and a suspension for oral use, and in solution for IV infusion. The ratio of TMP to SMZ in all preparations is 1:5. Two tablet strengths are available: *standard tablets* contain 80 mg TMP and 400 mg SMZ; *double-strength tablets* contain 160 mg TMP and 800 mg SMZ. Each milliliter of the *oral suspension* contains 8 mg TMP and 40 mg SMZ. Each milliliter of the stock *solution for IV infusion* contains 16 mg TMP and 80 mg SMZ; this stock solution must be greatly diluted before use.

88.3.8.2 Oral Dosing.

For management of most infections, the usual *adult* dosage is 160 mg TMP plus 800 mg SMZ administered every 12 hours for 10 to 14 days. To treat shigellosis or traveler's diarrhea, the same dose is administered every 12 hours for 5 days. In the presence of renal impairment (creatinine clearance 15 to 30 mL/min), the dosage should be reduced by 50%. If creatinine clearance is below 15 mL/min, TMP/SMZ should not be used.

To treat urinary tract infections and acute otitis media in *children*, the usual dosage is 4 mg/kg TMP plus 20 mg/kg SMZ administered every 12 hours for 10 days. The same dose, administered every 12 hours for 5 days, is used to treat shigellosis. As in adults, the dosage should be reduced in patients with renal dysfunction.

For *prophylaxis of PCP* in patients with AIDS, the usual dosage is 160 mg TMP plus 800 mg SMZ once daily.

88.3.8.3 Intravenous Dosing.

Intravenous TMP/SMZ is reserved for severe infections. The following dosages are for adults and children, and are based on the TMP component of TMP/SMZ. For urinary tract infection or shigellosis, the total daily dose is 8 to 10 mg/kg. This total dose is administered in two to four divided doses given at equally spaced intervals. Duration of treatment is 14 days for urinary tract infection and 5 days for shigellosis. For treatment of PCP, the total daily dose is 15 to 20 mg/kg, administered in three or four divided doses given at equally spaced intervals. Duration of treatment is 3 weeks or more. Dosage for all indications should be reduced in patients with renal impairment. Intravenous TMP/SMZ represents a large fluid load, and hence must be used with care in patients needing fluid restriction.

1029

88.3.8.3.1

KEY POINTS

- The sulfonamides and trimethoprim act by inhibiting bacterial synthesis of folic acid.
- Sulfonamides are used primarily for urinary tract infections.
- The principal adverse effects of sulfonamides are (1) hypersensitivity reactions, ranging from rash and photosensitivity to Stevens-Johnson syndrome; (2) hemolytic anemia; (3) kernicterus; and (4) renal damage.
- The combination product TMP/SMZ inhibits sequential steps in bacterial folic acid synthesis, and therefore is much more powerful than TMP or SMZ alone.
- TMP/SMZ is a preferred drug for urinary tract infections and is the drug of choice for PCP in patients with AIDS and other immunodeficiency states.
- The principal adverse effects of TMP/SMZ are like those caused by sulfonamides (ie, hypersensitivity reactions, hemolytic anemia, kernicterus, and renal injury).

1030

88.3.8.3.2

Summary of Major Nursing Implications*

88.3.8.3.2.1

SULFONAMIDES (SYSTEMIC)

Sulfadiazine

Sulfamethoxazole[†]

Sulfisoxazole

The nursing implications summarized here apply only to systemic sulfonamides. Implications specific to topical sulfonamides are not summarized.

88.3.8.3.2....

Preadministration Assessment

88.3.8.3.2....

Therapeutic Goal

Sulfonamides are used primarily for urinary tract infections caused by *E. coli* and other susceptible organisms.

88.3.8.3.2....

Identifying High-Risk Patients

Sulfonamides are *contraindicated* for nursing mothers, pregnant women near term, infants under 2 months old, and patients with a history of severe hypersensitivity to sulfonamides and chemically related drugs, including thiazide diuretics, loop diuretics, and sulfonylurea-type oral hypoglycemics.

Exercise *caution* in patients with renal impairment.

88.3.8.3.2....

Implementation: Administration

88.3.8.3.2....

Routes

All systemic sulfonamides can be administered orally. *Sulfisoxazole* can also be administered parenterally (IV, IM, subQ).

88.3.8.3.2....

Administration

Instruct patients to complete the prescribed course of treatment, even though symptoms may abate before the full course is over.

Advise patients to take oral sulfonamides on an empty stomach and with a full glass of water.

Administer IV *sulfisoxazole* by slow injection or IV drip.

88.3.8.3.2.... Ongoing Evaluation and Interventions

88.3.8.3.2.... Minimizing Adverse Effects

88.3.8.3.2.... Hypersensitivity Reactions.

Sulfonamides can induce severe hypersensitivity reactions (eg, Stevens-Johnson syndrome). Do not give sulfonamides to patients with a history of severe hypersensitivity to sulfonamides or to chemically related drugs, including sulfonylureas, thiazide diuretics, and loop diuretics. **Instruct patients to discontinue drug use at the first sign of hypersensitivity (eg, rash).**

88.3.8.3.2.... Photosensitivity.

Photosensitivity reactions may occur. **Advise patients to avoid prolonged exposure to sunlight, wear protective clothing, and apply a sunscreen to exposed skin.**

88.3.8.3.2.... Hematologic Effects.

Sulfonamides can cause hemolytic anemia and other blood dyscrasias (agranulocytosis, leukopenia, thrombocytopenia, aplastic anemia). Observe patients for signs of hemolysis (fever, pallor, jaundice). When sulfonamide therapy is prolonged, periodic blood cell counts should be made.

88.3.8.3.2.... Kernicterus.

Sulfonamides can cause kernicterus in newborns. Do not give these drugs to pregnant women near term, nursing mothers, or infants under 2 months old.

88.3.8.3.2.... Renal Damage.

Deposition of sulfonamide crystals can injure the kidney. To minimize crystalluria, maintain hydration sufficient to produce a daily urine flow of 1200 mL in adults. Alkalinization of urine (eg, with sodium bicarbonate) can also help. **Advise outpatients to consume 8 to 10 glasses of water per day.**

88.3.8.3.2....	Minimizing Adverse Interactions	
88.3.8.3.2....	Metabolism-Related Interactions. Sulfonamides can intensify the effects of <i>warfarin</i>, <i>phenytoin</i>, and <i>sulfonylurea-type oral hypoglycemics</i> (eg, tolbutamide). When combined with sulfonamides, these drugs may require a reduction in dosage.	1030
88.3.8.3.2....	Allergy-Inducing Drugs. People who are hypersensitive to sulfonamide antibiotics may also be hypersensitive to chemically related drugs—<i>thiazide diuretics</i>, <i>loop diuretics</i>, and <i>sulfonylurea-type oral hypoglycemics</i>—as well as to <i>penicillins</i> and other drugs that induce allergic reactions.	1031
88.3.8.3.2.2	TRIMETHOPRIM	
88.3.8.3.2....	Preadministration Assessment	
88.3.8.3.2....	Therapeutic Goal Initial treatment of uncomplicated urinary tract infections caused by <i>E. coli</i> and other susceptible organisms.	
88.3.8.3.2....	Identifying High-Risk Patients Trimethoprim is <i>contraindicated</i> in patients with folate deficiency (manifested as megaloblastic anemia). When possible, the drug should be avoided during pregnancy and lactation.	
88.3.8.3.2....	Implementation: Administration	
88.3.8.3.2....	Route Oral.	
88.3.8.3.2....	Dosage and Administration Instruct patients to complete the prescribed course of treatment, even though symptoms may abate before the full course is over. Reduce the dosage in patients with renal dysfunction.	

88.3.8.3.2.... Ongoing Evaluation and Interventions

88.3.8.3.2.... Minimizing Adverse Effects

88.3.8.3.2.... Hematologic Effects.

Trimethoprim can cause blood dyscrasias (megaloblastic anemia, thrombocytopenia, neutropenia) by exacerbating pre-existing folic acid deficiency. Avoid trimethoprim when folate deficiency is likely (eg, in alcoholics, pregnant women, debilitated patients). **Inform patients about early signs of blood disorders (eg, sore throat, fever, pallor), and instruct them to notify the prescriber if these occur.** Complete blood counts should be performed. If a significant reduction in counts is observed, discontinue trimethoprim. Normal hematopoiesis can be restored with folinic acid (leucovorin).

88.3.8.3.2.... Use in Pregnancy and Lactation.

Trimethoprim should be avoided during pregnancy and lactation. The drug can exacerbate folate deficiency in pregnant women and cause folate deficiency in the nursing infant.

88.3.8.3.2.3 TRIMETHOPRIM/SULFAMETHOXAZOLE

88.3.8.3.2.... Preadministration Assessment

88.3.8.3.2.... Therapeutic Goal

Indications include urinary tract infections caused by *E. coli* and other susceptible organisms, shigellosis, and *Pneumocystis* pneumonia (PCP).

88.3.8.3.2.... Identifying High-Risk Patients

TMP/SMZ is *contraindicated* for nursing mothers, pregnant women near term, infants under 2 months old, patients with folate deficiency (manifested as megaloblastic anemia), and patients with a history of hypersensitivity to sulfonamides and chemically related drugs, including thiazide diuretics, loop diuretics, and sulfonylurea-type oral hypoglycemics.

88.3.8.3.2.... Implementation: Administration

88.3.8.3.2.... Routes

Oral; IV (for severe infections).

88.3.8.3.2.... Dosage Adjustment

In patients with renal impairment (creatinine clearance of 15 to 30 mL/min), decrease dosage by 50%. If creatinine clearance falls below 15 mL/min, discontinue drug use.

88.3.8.3.2.... Administration

Instruct patients to complete the prescribed course of treatment, even though symptoms may abate before the full course is over.

88.3.8.3.2.... Ongoing Evaluation and Interventions

88.3.8.3.2.... Minimizing Adverse Effects

Although serious adverse reactions are rare, TMP/SMZ can nonetheless cause all of the toxicities associated with sulfonamides and trimethoprim used alone. Hence, the nursing implications summarized above regarding adverse effects of the sulfonamides alone and trimethoprim alone also apply to the combination of TMP/SMZ.

88.3.8.3.2.... Minimizing Adverse Interactions

TMP/SMZ has the same drug interactions as sulfonamides used alone. That is, TMP/SMZ can increase the effects of *warfarin*, *phenytoin*, and *sulfonylurea-type oral hypoglycemics*. When combined with TMP/SMZ, these drugs may require a reduction in dosage.

* Patient education information is highlighted as blue text.

† Sulfamethoxazole is available only in combination with trimethoprim.

⁸⁹CHAPTER 88 Drug Therapy of Urinary Tract Infections

Urinary tract infections (UTIs) are the most common infections encountered today. In the United States, UTIs account for over 7 million visits to healthcare providers each year. Among sexually active young women, 25% to 35% develop at least one UTI a year. Among elderly women in nursing homes, between 30% and 50% have bacteriuria at any given time. UTIs occur much less frequently in males, but are more likely to be associated with complications (eg, septicemia, pyelonephritis).

Infections may be limited to bacterial colonization of the urine, or bacteria may invade tissues of the urinary tract. When bacteria invade tissues, characteristic inflammatory syndromes result: *urethritis* (inflammation of the urethra), *cystitis* (inflammation of the urinary bladder), *pyelonephritis* (inflammation of the kidney and its pelvis), and *prostatitis* (inflammation of the prostate).

UTIs may be classified according to their location, in either the lower urinary tract (bladder and urethra) or upper urinary tract (kidney). Within this classification scheme, *cystitis* and *urethritis* are considered *lower tract infections*, whereas *pyelonephritis* is considered an *upper tract infection*.

UTIs are referred to as being *complicated* or *uncomplicated*. *Complicated* UTIs occur in both males and females and, by definition, are associated with some predisposing factor, such as calculi (stones), prostatic hypertrophy, an indwelling catheter, or an impediment to the flow of urine (eg, physical obstruction). *Uncomplicated* UTIs occur primarily in women of child-bearing age and are not associated with any particular predisposing factor.

Several classes of antibiotics are used to treat UTIs. Among these are sulfonamides, trimethoprim, penicillins, aminoglycosides, cephalosporins, fluoroquinolones, and the urinary tract antiseptics: nitrofurantoin, methenamine, nalidixic acid, and cinoxacin. With the exception of the urinary tract antiseptics, these drugs are discussed at length in other chapters. The basic pharmacology of the urinary tract antiseptics is introduced here.

^{89.1} ORGANISMS THAT CAUSE URINARY TRACT INFECTIONS

The bacteria that cause UTIs differ between community-acquired infections and hospital-acquired (nosocomial) infections. The majority (more than 80%) of uncomplicated, community-acquired UTIs are caused by *Escherichia coli*. Rarely, other gram-negative bacilli—*Klebsiella pneumoniae*, *Enterobacter*, *Proteus*, *Providencia*, and *Pseudomonas*—are the cause. Gram-positive cocci, especially *Staphylococcus saprophyticus*, account for 10% to 15% of community-acquired infections. Hospital-acquired UTIs are frequently caused by *Klebsiella*, *Proteus*, *Enterobacter*, *Pseudomonas*, staphylococci, and enterococci; *E. coli* is responsible for less than 50% of these

infections. Although most UTIs involve only one organism, infection with multiple organisms may occur, especially in patients with an indwelling catheter, renal stones, or chronic renal abscesses.

89.2 SPECIFIC URINARY TRACT INFECTIONS AND THEIR TREATMENT

In this section, we consider the characteristics and treatment of the major UTIs: acute cystitis, acute urethral syndrome, acute pyelonephritis, acute bacterial prostatitis, and recurrent UTIs. Most of these can be treated with oral therapy at home. The principal exception is severe pyelonephritis, which requires IV therapy in a hospital. Drugs and dosages for outpatient therapy in nonpregnant women are summarized in [Table 88-1](#).

89.2.1 Acute Cystitis

Acute cystitis is a lower urinary tract infection that occurs most often in women of child-bearing age. Clinical manifestations are dysuria, urinary urgency, urinary frequency, suprapubic discomfort, pyuria, and bacteriuria (more than 100,000 bacteria per milliliter of urine). It is important to note that many women (30% or more) with symptoms of acute cystitis also have asymptomatic upper urinary tract infection (subclinical pyelonephritis). In uncomplicated, community-acquired cystitis, the principal causative organisms are *E. coli* (80%), *S. saprophyticus* (11%), and *Enterococcus faecalis*.

1032

1033

TABLE 88-1 Regimens for Oral Therapy of Urinary Tract Infections in Nonpregnant Women

Drug	Dose	Duration
Acute Cystitis		
First-Line Drugs		
Trimethoprim/sulfamethoxazole	160/800 mg 2 times/day	3 days
Trimethoprim	100 mg 2 times/day	3 days
Ciprofloxacin	250 mg 2 times/day	3 days
Norfloxacin	400 mg 2 times/day	3 days
Levofloxacin	250 mg once daily	3 days
Second-Line Drugs		
Nitrofurantoin (macrocrystals)	50–100 mg 4 times/day	7 days
Nitrofurantoin (monohydrate/macrocrystals)	100 mg 2 times/day	7 days
Fosfomycin	3 gm once	1 day
Acute Uncomplicated Pyelonephritis		
First-Line Drugs		
Trimethoprim/sulfamethoxazole	160/800 mg 2 times/day	14 days
Trimethoprim	100 mg 2 times/day	14 days
Ciprofloxacin	250–500 mg 2 times/day	14 days
Levofloxacin	500 mg once daily	10–14 days
Second-Line Drugs		
Amoxicillin (with clavulanic acid)	500 mg 3 times/day	14 days
Cephalexin	500 mg 4 times/day	14 days
Cefotaxime	1 gm 3 times/day	14 days
Ceftriaxone	1–2 gm once daily	14 days
Complicated Urinary Tract Infections		
Trimethoprim/sulfamethoxazole	160/800 mg 2 times/day	7–14 days
Norfloxacin	400 mg 2 times/day	7–14 days
Ciprofloxacin	250–500 mg 2 times/day	7–14 days
Levofloxacin	500 mg once daily	7–14 days
Amoxicillin (with clavulanic acid)	500 mg 3 times/day	7–14 days

Cephalexin	500 mg 3 times/day	7–14 days
Prophylaxis of Recurrent Infection		
Trimethoprim/sulfamethoxazole	40/200 mg* at bedtime 3 times/wk	6 months
Trimethoprim	100 mg at bedtime	6 months
Nitrofurantoin	50–100 mg at bedtime	6 months
Norfloxacin	200 mg at bedtime	6 months

* One-half of a single-strength tablet.

For community-acquired infections, three types of oral therapy can be employed: (1) single-dose therapy, (2) short-course therapy (3 days), and (3) conventional therapy (7 days). *Single-dose* therapy and *short-course* therapy are recommended only for uncomplicated, community-acquired infections in women who are not pregnant and whose symptoms began less than 7 days before starting treatment. As a rule, short-course therapy is more effective than single-dose therapy and hence is generally preferred. Advantages of short-course therapy over conventional therapy are lower cost, greater adherence, fewer side effects, and less potential for promoting emergence of bacterial resistance. *Conventional* therapy is indicated for all patients who do not meet the criteria for short-course therapy. Among these are males, children, pregnant women, and women with suspected upper tract involvement.

As indicated in [Table 88-1](#), a variety of drugs can be used for treatment. Trimethoprim/sulfamethoxazole and trimethoprim alone are traditional agents of choice. In communities where resistance to these drugs exceeds 20%, the fluoroquinolones (eg, ciprofloxacin, norfloxacin) are good alternatives. When adherence is a concern, fosfomycin, which requires just one dose, is an attractive choice. As a rule, beta-lactam antibiotics (eg, amoxicillin; cephalexin and other cephalosporins) should be avoided. Why? Because they are less effective than the alternatives, and less well tolerated.

89.2.2 Acute Uncomplicated Pyelonephritis

Acute uncomplicated pyelonephritis is an infection of the kidneys. The disorder is common in young children, the elderly, and women of child-bearing age. Clinical manifestations include fever, chills, severe flank pain, dysuria, urinary frequency, urinary urgency, pyuria, and, usually, bacteriuria (more than 100,000 bacteria per milliliter of urine). *Escherichia coli* is the causative organism in 90% of initial community-acquired infections.

1033

Mild to moderate infection can be treated at home with oral antibiotics. Preferred options are trimethoprim/sulfamethoxazole, trimethoprim alone, ciprofloxacin, and levofloxacin. Treatment should last 14 days. Some regimens for oral therapy are shown in [Table 88-1](#).

Severe pyelonephritis requires hospitalization and IV antibiotics. Options include ciprofloxacin, ceftriaxone, ceftazidime, ampicillin plus gentamicin, and ampicillin/sulbactam. Once the infection has been controlled with IV antibiotics, a switch to oral antibiotics should be made (usually within 24 to 48 hours).

89.2.3 Complicated Urinary Tract Infections

Complicated UTIs occur in males and females who have a structural or functional abnormality of the urinary tract that predisposes them to developing infection. Such predisposing factors include prostatic hypertrophy, renal calculi (stones), nephrocalcinosis, renal or bladder tumors, ureteric stricture, or an indwelling urethral catheter. Symptoms of complicated UTIs can range from mild to severe. Some patients even develop systemic illness, manifesting as fever, bacteremia, and septic shock.

The microbiology of complicated UTIs is less predictable than that of uncomplicated UTIs. Although *E. coli* is a common pathogen, it is by no means the only one. Other possibilities include *Klebsiella*, *Proteus*, *Pseudomonas*, *Staphylococcus aureus*, *Enterobacter* species, *Serratia* species, and even *Candida* species. Accordingly, if treatment is to succeed, we must determine the identity and drug sensitivity of the causative organism. To do so, urine for microbiologic testing should be obtained *before* giving any antibiotics. If symptoms are relatively mild, treatment should wait until test results are available. However, if symptoms are severe, immediate treatment with a broad-spectrum antibiotic can be instituted. Some options are presented in [Table 88-1](#). Once test results are known, a drug specific to the pathogen can be substituted. Duration of treatment ranges from 7 days (for cystitis) to 14 days (for pyelonephritis or when there is systemic involvement).

89.2.4 Recurrent Urinary Tract Infection

Recurrent UTIs result from *relapse* or from *reinfection*. *Relapse* is caused by recolonization with the same organism responsible for the initial infection. In contrast, *reinfection* is caused by colonization with a new organism.

89.2.4.1 Reinfection.

More than 80% of recurrent UTIs in females are due to reinfection. These usually involve the lower urinary tract and may be related to sexual intercourse or use of a contraceptive diaphragm. If reinfections are *infrequent* (only one or two a year), each episode should be treated as a separate infection. Single-dose or short-course therapy can be used.

When reinfections are *frequent* (three or more a year), long-term prophylaxis may be indicated. Prophylaxis can be achieved with low daily doses of several agents, including trimethoprim (100 mg), nitrofurantoin (50 or 100 mg), or trimethoprim/sulfamethoxazole (160 mg/800 mg). Prophylaxis should continue for at least 6 months. During this time, periodic urine cultures should be obtained. If a symptomatic episode occurs, standard therapy for acute cystitis should be given. If reinfection is associated with sexual intercourse, the risk can be decreased by voiding after intercourse and by single-dose prophylaxis (eg, trimethoprim/sulfamethoxazole [160 mg/800 mg] taken after intercourse).

89.2.4.2 Relapse.

Recolonization with the original infecting organism accounts for 20% of recurrent UTIs. Symptoms that reappear shortly after completion of a course of therapy suggest either a structural abnormality of the urinary tract, involvement of the kidneys, or chronic bacterial prostatitis (the most common cause of recurrent UTI in males). If obstruction of the urinary tract is present, it should be corrected surgically. If renal calculi are the cause, they should be removed.

Drug therapy is progressive. When relapse occurs in women after short-course therapy, a 2-week course of therapy should be tried. If this fails, an additional 4 to 6 weeks of therapy should be tried. If this too is unsuccessful, long-term therapy (6 months) may be indicated. Drugs employed for long-term therapy of relapse include trimethoprim/sulfamethoxazole, norfloxacin, and cephalexin.

89.2.5 Acute Bacterial Prostatitis

Acute bacterial prostatitis is defined as inflammation of the prostate caused by local bacterial infection. Clinical manifestations include high fever, chills, malaise, myalgia, localized pain, and various urinary tract symptoms (dysuria, nocturia, urinary urgency, urinary frequency, urinary retention). In most cases (80%), *E. coli* is the causative organism. Infection is frequently

associated with an indwelling urethral catheter, urethral instrumentation, or transurethral prostatic resection. However, in many patients, the infection has no obvious cause.

Bacterial prostatitis responds well to antimicrobial therapy. Because of local inflammation, antibiotics can readily penetrate to the site of infection. (In the absence of inflammation, penetration of the prostate is difficult.) Drug selection and route depend on the causative organism and infection severity. For severe infection with *E. coli*, treatment starts with an IV agent (either aztreonam or a fluoroquinolone [eg, ciprofloxacin]), followed by 4 weeks with an oral agent (either doxycycline or a fluoroquinolone). For severe infection with vancomycinsensitive *Enterococcus faecalis*, treatment starts with IV ampicillin/sulbactam, followed by 4 weeks with PO amoxicillin, levofloxacin, or doxycycline.

89.3 URINARY TRACT ANTISEPTICS

Four urinary tract antiseptics are available: nitrofurantoin, methenamine, nalidixic acid, and cinoxacin. These drugs are used only for UTIs. All four become concentrated in the urine, and are active against the common urinary tract pathogens. These drugs do not achieve effective antibacterial concentrations in blood or tissues, and hence are not indicated for infections outside the urinary tract. As a rule, the urinary tract antiseptics are second-choice drugs for treatment or prophylaxis of UTIs.

89.3.1 Nitrofurantoin

89.3.1.1 Mechanism of Action

Nitrofurantoin [Furadantin, Macrochantin, Macrobid] is a broad-spectrum antimicrobial drug. The agent is bacteriostatic in low concentrations and bactericidal in high concentrations. Therapeutic levels are achieved only in urine. Hence the drug is useful only against infections of the urinary tract. Nitrofurantoin can cause serious adverse effects.

Nitrofurantoin injures bacteria by damaging DNA. However, in order to damage DNA, the drug must first be converted to a reactive form. Nitrofurantoin is selectively toxic to bacteria because, unlike mammalian cells, bacteria possess relatively high levels of the enzyme that activates the drug.

89.3.1.2 Antimicrobial Spectrum

Nitrofurantoin is active against a large number of gram-positive and gram-negative bacteria. Susceptible organisms include staphylococci, streptococci, *Neisseria*, *Bacteroides*, and most

1034

1035

strains of *E. coli*. These sensitive bacteria rarely acquire resistance. Organisms that are frequently insensitive include *Proteus*, *Pseudomonas*, *Enterobacter*, and *Klebsiella*.

89.3.1.3 Therapeutic Use

Nitrofurantoin is indicated for acute infections of the lower urinary tract caused by susceptible organisms. In addition, the drug can be used for prophylaxis of recurrent lower UTI.

Nitrofurantoin is not recommended for infections of the upper urinary tract.

89.3.1.4 Pharmacokinetics

89.3.1.4.1 Absorption and Distribution.

Nitrofurantoin is available in three crystalline forms: *microcrystals*, *macrocrystals*, and *monohydrate/macrocrystals*. The two macrocrystalline forms are absorbed relatively slowly and produce less GI distress than the microcrystalline form. All formulations produce equivalent therapeutic effects. Nitrofurantoin is distributed to tissues, but only in small amounts. Therapeutic concentrations are achieved only in urine.

89.3.1.4.2 Metabolism and Excretion.

About two-thirds of each dose undergoes metabolic degradation, primarily in the liver; the remaining one-third is excreted intact in the urine. Nitrofurantoin achieves a urinary concentration of about 200 mcg/mL (compared with less than 2 mcg/mL in plasma). The drug imparts a harmless brown color to the urine; patients should be informed of this effect.

For two reasons, nitrofurantoin should not be administered to individuals with renal impairment, defined here as creatinine clearance less than 40 mL/min. First, in the absence of good renal function, levels of nitrofurantoin in the urine are too low to be effective. Second, renal impairment reduces nitrofurantoin excretion, causing plasma levels of the drug to rise, thereby posing a risk of systemic toxicity.

89.3.1.5 Adverse Effects

89.3.1.5.1 Gastrointestinal Effects.

The most frequent adverse reactions are GI disturbances (eg, anorexia, nausea, vomiting, diarrhea). These can be minimized by administering nitrofurantoin with milk or with meals, by reducing the dosage, and by using the macrocrystalline formulation.

89.3.1.5.2 Pulmonary Reactions.

Nitrofurantoin can induce two kinds of pulmonary reactions: acute and subacute. Acute reactions, which are most common, manifest with dyspnea, chest pain, chills, fever, cough, and alveolar infiltrates. These symptoms resolve 2 to 4 days after discontinuing the drug. Acute pulmonary responses are thought to be hypersensitivity reactions. Patients with a history of these responses should not receive nitrofurantoin again. Subacute reactions are rare and occur during prolonged treatment. Symptoms (eg, dyspnea, cough, malaise) usually regress over weeks to months following nitrofurantoin withdrawal. However, in some patients, permanent lung damage may occur.

89.3.1.5.3 Hematologic Effects.

Nitrofurantoin can cause a variety of hematologic reactions, including agranulocytosis, leukopenia, thrombocytopenia, and megaloblastic anemia. In addition, hemolytic anemia may occur in infants and in patients whose red blood cells have an inherited deficiency in glucose-6-phosphate dehydrogenase. Because of the potential for hemolytic anemia in newborns, nitrofurantoin is contraindicated for pregnant women near term and for infants under the age of 1 month.

89.3.1.5.4 Peripheral Neuropathy.

Damage to sensory and motor nerves is a serious concern. Demyelination and nerve degeneration can occur and may be irreversible. Early symptoms include muscle weakness, tingling sensations, and numbness. Patients should be informed about these symptoms and instructed to report them immediately. Neuropathy is most likely in patients with renal impairment and in those taking nitrofurantoin chronically.

89.3.1.5.5 Other Adverse Effects.

Nitrofurantoin can cause multiple neurologic effects (eg, headache, vertigo, drowsiness, nystagmus); all are readily reversible. Hepatotoxicity (cholestatic jaundice, chronic hepatitis, hepatocellular damage) occurs rarely.

89.3.1.6 Preparations, Dosage, and Administration

89.3.1.6.1 Preparations.

Nitrofurantoin is available in three crystalline forms: microcrystals, macrocrystals, and monohydrate/macrocrystals. *Nitrofurantoin microcrystals* [Furadantin] are supplied as an oral suspension (5 g/mL). *Nitrofurantoin macrocrystals* [Macrochantin] are supplied in capsules (25, 50, and 100 mg). *Nitrofurantoin monohydrate/macrocrystals* [Macrobid] are supplied in 100-mg capsules.

89.3.1.6.2 Administration.

Dosing is oral. To reduce GI distress, nitrofurantoin can be administered with meals or with milk.

89.3.1.6.3 Dosage.

For *acute cystitis*, dosage depends on which formulation is used. With the macrocrystals, the adult dosage is 50 to 100 mg 4 times a day for 7 days. With the monohydrate/macrocrystals, the adult dosage is 100 mg twice a day for 7 days.

For *prophylaxis of recurrent cystitis*, low doses are employed (eg, 50 to 100 mg at bedtime for adults and 1 mg/kg/day in one or two doses for children).

89.3.2 Methenamine

89.3.2.1 Mechanism of Action

Methenamine [Mandelamine, Hiprex, Urex] is a prodrug that, under acidic conditions, breaks down into ammonia and formaldehyde. The formaldehyde denatures bacterial proteins, causing cell death. For formaldehyde to be released, the urine must be acidic (pH 5.5 or less). Since formaldehyde is not formed at physiologic systemic pH, methenamine is devoid of systemic toxicity.

89.3.2.2 Antimicrobial Spectrum

Virtually all bacteria are susceptible to formaldehyde; there is no resistance. Certain bacteria (eg, *Proteus* species) can elevate urinary pH (by splitting urea to form ammonia). Since

formaldehyde is not released under alkaline conditions, infections with urea-splitting organisms are often unresponsive.

89.3.2.3 Therapeutic Uses

Methenamine is used for *chronic infection of the lower urinary tract*. However, trimethoprim/sulfamethoxazole is preferred. Methenamine is not active against infection of the upper tract. Why? Because, there is insufficient time for formaldehyde to form as the drug passes through. Methenamine does not prevent UTIs associated with catheters.

89.3.2.4 Pharmacokinetics

89.3.2.4.1 Absorption and Distribution.

Methenamine is rapidly absorbed after oral administration. However, approximately 30% of each dose may be converted to ammonia and formaldehyde in the acidic environment of the stomach. This can be minimized by using an enteric-coated formulation. The drug is distributed throughout total body water.

89.3.2.4.2 Excretion.

Methenamine is eliminated by the kidneys. Within the urinary tract, about 20% of the drug decomposes to form formaldehyde. Levels of formaldehyde are highest in the bladder. Since formaldehyde generation takes place slowly, and since transit time through the kidney is brief, formaldehyde levels in the kidney remain subtherapeutic. Ingestion of large volumes of fluid reduces antibacterial effects by diluting methenamine and raising urinary pH. Poorly metabolized acids (eg, hippuric acid, mandelic acid, ascorbic acid) have been administered with methenamine in attempts to acidify the urine, and thereby increase formaldehyde formation. However, there is no evidence that these acids enhance therapeutic effects.

89.3.2.5 Adverse Effects and Precautions

Methenamine is relatively safe and generally well tolerated. Gastric distress occurs occasionally, probably from formaldehyde in the stomach. Use of enteric-coated preparations may reduce this effect. Chronic high-dose therapy can cause bladder irritation, manifested as dysuria, frequent voiding, urinary urgency, proteinuria, and hematuria. Since decomposition of methenamine generates ammonia (in addition to formaldehyde), the drug is contraindicated for patients with liver dysfunction. Methenamine salts (methenamine mandelate, methenamine

hippurate) should not be used by patients with renal impairment, since crystalluria may be caused by precipitating the mandelate or hippurate moiety.

89.3.2.6 Drug Interactions

89.3.2.6.1 Urinary Alkalinizers.

Drugs that elevate urinary pH (eg, acetazolamide, sodium bicarbonate) inhibit formaldehyde production, and can thereby reduce the antibacterial effects. Patients taking methenamine should not receive alkalinizing agents.

89.3.2.6.2 Sulfonamides.

Methenamine should not be combined with sulfonamides. Why? Because formaldehyde forms an insoluble complex with sulfonamides, thereby posing a risk of urinary tract injury from crystalluria.

89.3.2.7 Preparations, Dosage, and Administration

Methenamine is available as two salts: methenamine mandelate and methenamine hippurate. *Methenamine mandelate* [Mandelamine] is supplied in enteric-coated tablets (0.5 and 1 gm) and an oral suspension (0.1 gm/mL). The usual adult dosage is 1 gm 4 times a day. The dosage for children ages 6 to 12 years is 0.5 gm 4 times a day. For children under 6 years, the dosage is 18 mg/kg 4 times a day.

Methenamine hippurate [Hiprex, Urex] is supplied in 1-gm tablets. The dosage for adults and for children over 12 years is 1 gm twice a day. For children ages 6 to 12 years, the dosage is 500 mg to 1 gm twice a day.

1035

89.3.3 Nalidixic Acid

1036

89.3.3.1 Mechanism of Action

Nalidixic acid [NegGram], a relative of the fluoroquinolones, inhibits replication of bacterial DNA, thereby causing DNA degradation and cell death. The precise target of nalidixic acid is *DNA gyrase*, the bacterial enzyme that converts closed circular DNA into a supercoiled configuration. If supercoiling does not occur, DNA replication cannot take place.

89.3.3.2 Microbial Resistance

Resistant bacteria often emerge during treatment. Two mechanisms have been described: (1) production of an altered DNA gyrase that has reduced sensitivity to nalidixic acid and (2) reduced bacterial uptake of nalidixic acid. Crossresistance with cinoxacin is common. A frequent factor in resistance is suboptimal dosing. (Low levels of nalidixic acid favor overgrowth with drug-resistant organisms.) Fortunately, resistance to nalidixic acid is not carried on R factors, and therefore is not transferable.

89.3.3.3 Antimicrobial Spectrum

Nalidixic acid is active against most gram-negative urinary tract pathogens, including *E. coli*, *Klebsiella*, *Enterobacter*, and *Proteus* species. *Pseudomonas aeruginosa* is resistant, as are most gram-positive aerobic cocci.

89.3.3.4 Therapeutic Uses

Nalidixic acid is approved only for UTIs. The drug has been used to control acute infection and to prevent recurrent UTI. However, for both applications, other drugs are preferred. Nalidixic acid is not useful against infections outside the urinary tract.

89.3.3.5 Pharmacokinetics

Nalidixic acid is well absorbed from the GI tract, and then undergoes rapid hepatic metabolism. Only one metabolite—hydroxynalidixic acid—has antibacterial actions. Nalidixic acid and its metabolites are excreted in the urine. The concentration of active drug in urine is about 10 times greater than in plasma. Therapeutic levels are achieved in urine even in patients with moderate to severe renal impairment. Drug concentrations outside the urinary tract are too low for antibacterial effects.

89.3.3.6 Adverse Effects

Although nalidixic acid can cause multiple adverse effects, the incidence of severe effects is low. The most common effects are GI disturbances (nausea, vomiting, abdominal discomfort), visual disturbances (blurred vision, diplopia, poor accommodation, photophobia, altered color perception), and rash. Patients who experience a reduction in visual acuity should exercise appropriate caution (eg, when driving). Photosensitivity reactions can occur. Accordingly, patients should be advised to avoid excessive exposure to sunlight, wear protective clothing, and apply a sunscreen to exposed skin. Convulsions have occurred on occasion. Accordingly,

nalidixic acid should be avoided by individuals with a history of convulsive disorders. Nalidixic acid may produce intracranial hypertension in pediatric patients, and hence should not be given to children under the age of 3 months. Blood dyscrasias (thrombocytopenia, leukopenia, hemolytic anemia) and jaundice are rare. Nonetheless, when nalidixic acid is used for more than 2 weeks, blood cell counts and liver function tests should be performed. Like the fluoroquinolone antibiotics, nalidixic acid may pose a risk of tendon rupture (eg, in the shoulder, hand, or lower leg). Accordingly, the drug should be discontinued if the patient experiences pain, inflammation, or tendon rupture.

89.3.3.7 Drug Interactions

Nalidixic acid can intensify the effects of warfarin (by displacing the anticoagulant from binding sites on plasma proteins). Accordingly, when warfarin is combined with nalidixic acid, a reduction in warfarin dosage may be needed.

89.3.3.8 Preparations, Dosage, and Administration

Nalidixic acid [NegGram] is supplied in 500-mg tablets. The adult dosage is 1 gm PO 4 times a day for 1 or 2 weeks. For children under the age of 12 years, the dosage is 55 mg/kg/day in four divided doses. Nalidixic acid should not be given to children under 3 months old.

89.3.4 Cinoxacin

Cinoxacin [Cinobac] is a close relative of nalidixic acid. Both drugs have the same mechanism of action, antimicrobial spectrum, and indications. Furthermore, organisms that are resistant to nalidixic acid are often resistant to cinoxacin. As with other urinary tract antiseptics, therapeutic levels are achieved only in the urine. Adverse effects are like those of nalidixic acid, but their incidence is relatively low. Cinoxacin is excreted by the kidneys, primarily unchanged. The drug is supplied in 250- and 500-mg capsules for oral use. The usual adult dosage is 1 gm/day administered in two or four divided doses. Dosage should be reduced in patients with renal impairment; if not, cinoxacin might accumulate to toxic levels.

89.3.4.1

KEY POINTS

- *Escherichia coli* is the most common cause of uncomplicated, community-acquired UTIs.
- Except for pyelonephritis, most UTIs can be treated with oral therapy at home.

- Trimethoprim/sulfamethoxazole is frequently the treatment of choice for oral therapy of UTIs.
- Many drugs, including penicillins, cephalosporins, and fluoroquinolones, may be used for parenteral therapy of UTIs.
- Prophylaxis of recurrent UTI can be achieved with daily low doses of oral antibiotics (eg, trimethoprim/sulfamethoxazole).
- The urinary tract antiseptics—nitrofurantoin, methenamine, nalidixic acid, and cinoxacin—are second-choice drugs for UTIs.

⁹⁰CHAPTER 89 Antimycobacterial Agents: Drugs for Tuberculosis, Leprosy, and *Mycobacterium avium* Complex Infection

Our topic for this chapter is infections caused by three species of mycobacteria: *Mycobacterium tuberculosis*, *Mycobacterium leprae*, and *Mycobacterium avium*. The mycobacteria are slow-growing microbes, and the infections they cause require prolonged treatment. Because therapy is prolonged, drug toxicity and poor patient adherence are significant obstacles to success. In addition, prolonged treatment promotes the emergence of drug-resistant mycobacteria. Because mycobacteria resist decolorizing by the dilute acid used in some staining protocols, these microorganisms are often referred to as *acid-fast bacteria*.

^{90.1} DRUGS FOR TUBERCULOSIS

Tuberculosis (TB) is a global epidemic. Worldwide, approximately 2 billion people are infected—nearly one-third of the Earth's population. Each year, TB kills about 2 million people—more than any other infectious disease. Although new cases in the United States continue to decline (down from 20,673 in 1992 to 12,898 in 2008), in the rest of the world, new cases are on the rise. The current estimate is 9 million new cases a year. Of these, the vast majority (95%) occur in developing countries. There are two reasons for this resurgence: HIV/AIDS and the emergence of multidrug-resistant mycobacteria.

^{90.2} CLINICAL CONSIDERATIONS

^{90.2.1} Pathogenesis

Tuberculosis is caused by *Mycobacterium tuberculosis*, an organism also known as the tubercle bacillus. Infections may be limited to the lungs or may become disseminated. In most cases, the bacteria are quiescent, and the infected individual has no symptoms. However, when the disease is active, morbidity can be significant. In the United States, approximately 10 million people harbor tubercle bacilli. However, only a small fraction have symptomatic disease.

^{90.2.1.1} Primary Infection

Infection with *M. tuberculosis* is transmitted from person to person by inhaling infected sputum that has been aerosolized, usually by coughing or sneezing. As a result, initial infection is in the lung. Once in the lung, tubercle bacilli are taken up by phagocytic cells (macrophages and neutrophils). At first, the bacilli are resistant to the destructive activity of phagocytes and

multiply freely within them. Infection can spread from the lungs to other organs via the lymphatic and circulatory systems.

In most cases, immunity to *M. tuberculosis* develops within a few weeks, and the infection is brought under complete control. The immune system facilitates control by increasing the ability of phagocytes to suppress multiplication of tubercle bacilli. Because of this rapid response by the immune system, most individuals (90%) with primary infection never develop clinical or radiologic evidence of disease. However, even though symptoms are absent and the progression of infection is halted, the infected individual is likely to harbor tubercle bacilli lifelong (unless drugs are given to eliminate quiescent bacilli). Hence, in the absence of treatment, there is always some risk that latent infection may become active.

1037

If the immune system fails to control the primary infection, clinical disease (tuberculosis) develops. The result is necrosis and cavitation of lung tissue. Lung tissue may also become caseous (cheese-like in appearance). In the absence of treatment, tissue destruction progresses, and death may result.

1038

90.2.1.2 Reactivation

The term *reactivation* refers to renewed multiplication of tubercle bacilli that had been dormant following control of a primary infection. Until recently, it was assumed that most new cases of symptomatic TB resulted from reactivation of an old (latent) infection. However, we now know that, among some groups, reactivation may be responsible for only 60% of new infections—the remaining 40% result from recent person-to-person transmission.

90.2.2 Diagnosis and Treatment of Active Tuberculosis

The availability of modern chemotherapeutic agents has dramatically altered the treatment of TB. In the past, most patients required lengthy hospitalization. Today, hospitalization is generally unnecessary. Prolonged bed rest is neither required nor recommended. To reduce emergence of resistance, treatment is *always* done with two or more drugs. In addition, direct observation of drug administration is now considered standard care.

The goal of treatment is to eliminate symptoms and prevent relapse. To accomplish this, treatment must kill tubercle bacilli that are actively dividing as well as those that are “resting.” Success is indicated by an absence of observable mycobacteria in sputum and by the failure of sputum cultures to yield colonies of *M. tuberculosis*.

90.2.2.1 Diagnosis

Diagnostic testing is indicated for (1) individuals with clinical manifestations that suggest TB and (2) individuals with a positive skin test or blood test (see below under *Diagnosis and Treatment of Latent Tuberculosis*), who are at high risk of developing active disease. A definitive diagnosis is made with a chest radiograph and microbiologic evaluation of sputum. A chest radiograph should be ordered for all persons suspected of active infection.

To determine if *M. tuberculosis* is present, sputum is evaluated in two ways: by (1) microscopic examination of sputum smears and (2) culturing of sputum samples followed by laboratory evaluation. Microscopic examination cannot provide a definitive diagnosis. Why? Because direct observation cannot distinguish between *M. tuberculosis* and other mycobacteria. Furthermore, microscopic examination is much less sensitive than evaluation of cultured samples. Accordingly, sputum cultures are required for definitive diagnosis. Depending on the technology employed, identification can take several days to several weeks. Evaluation of drug susceptibility can take 10 days to 1 month.

90.2.2.2 Drug Resistance

Drug resistance is a major impediment to successful therapy. Some infecting bacilli are inherently resistant; others develop resistance over the course of treatment. Some bacilli are resistant to just one drug; others are resistant to multiple drugs. Infection with a resistant organism may be acquired in two ways: (1) through contact with someone who harbors resistant bacteria, and (2) through repeated ineffectual courses of therapy (see below).

The emergence of *multidrug-resistant TB* (MDR-TB) and *extensively drug-resistant TB* (XDR-TB) are recent and ominous developments. MDR-TB is defined as TB that is resistant to both isoniazid and rifampin, our two most effective antituberculosis (anti-TB) drugs. XDR-TB, a severe form of MDR-TB, is defined as TB that is resistant not only to isoniazid and rifampin, but also to all fluoroquinolones (eg, moxifloxacin), and at least one of the injectable second-line anti-TB drugs (amikacin, kanamycin, or capreomycin). Infection with multidrug-resistant organisms greatly increases the risk of death, especially among patients with AIDS. In addition, multidrug resistance is expensive: The cost of treating one case of resistant TB is about \$180,000, compared with \$12,000 per case of nonresistant TB. Fortunately, multidrug resistance is rare in the United States: In 2006, there were 166 reported cases of MDR-TB and only 4 reported cases of XDR-TB.

The principal cause underlying the emergence of resistance is inadequate drug therapy. Treatment may be too short; dosage may be too low; patient adherence may be erratic; and, perhaps most importantly, the regimen may contain too few drugs.

90.2.2.3 The Prime Directive: Always Treat Tuberculosis with Two or More Drugs

Antituberculosis regimens must always contain two or more drugs to which the infecting organism is sensitive. To understand why this is so, we need to begin with five facts:

- Resistance in *M. tuberculosis* occurs because of spontaneous mutations.
- Each mutational event confers resistance to only one drug.
- Mutations conferring resistance to a single drug occur in about 1 of every 100 million (10^8) bacteria.
- The bacterial burden in active TB is well above 10^8 organisms but far below 10^{16} .
- *M. tuberculosis* grows slowly, hence treatment is prolonged.

Now, let's assume we initiate therapy with a single drug, and that all bacteria present are sensitive when we start. What will happen? Over time, at least one of the more than 10^8 bacteria in our patient will mutate to a resistant form. Hence, as we proceed with treatment, we will kill all sensitive bacteria, but the descendants of the newly resistant bacterium will continue to flourish, thereby causing treatment failure. In contrast, if we initiate therapy with *two* drugs, treatment will succeed. Why? Because failure would require that at least one bacterium undergo *two* resistance-conferring mutations, one for each drug. Since two such mutations occur in only 1 of every 10^{16} bacteria (10^{16} is the product of the probabilities for each mutation), and since the total bacterial load is much less than 10^{16} , the chances of the two events occurring in one of the bacteria in our patient are nil.

Not only do drug combinations decrease the risk of resistance, they can reduce the incidence of relapse. Because some drugs (eg, isoniazid, rifampin) are especially effective against actively dividing bacilli, whereas other drugs (eg, pyrazinamide) are most active against intracellular (quiescent) bacilli, by using certain combinations of anti-TB agents, we can increase the

1038

chances of killing all tubercle bacilli present, whether they are actively multiplying or dormant. Hence, the risk of relapse is lowered.

In [Chapter 82](#) (Basic Principles of Antimicrobial Therapy), we noted that treatment with multiple antibiotics broadens the spectrum of antimicrobial coverage, thereby increasing the risk of suprainfection. This is not the case with multidrug therapy of TB. The major drugs used against *M. tuberculosis* are *selective* for this organism. As a result, these drugs, even when used in combination, do not kill off other microorganisms, and therefore do not create the conditions that lead to suprainfection.

In summary, because treatment is prolonged, there is a high risk that drug-resistant bacilli will emerge if only one anti-TB agent is employed. Because the chances of a bacterium developing resistance to two drugs are very low, treatment with two or more drugs minimizes the risk of drug resistance. Therefore, when treating TB, we must always use two or more drugs to which the organism is sensitive.

90.2.2.4 Determining Drug Sensitivity

Because resistance to one or more anti-TB drugs is common, and because many patterns of resistance are possible, it is essential that we determine drug sensitivity in isolates from each patient at treatment onset. Unfortunately, the process of culturing samples and testing them for susceptibility is slow, usually taking 6 to 16 weeks to complete. Until test results are available, drug selection must be empiric, based on (1) patterns of drug resistance in the community and (2) the immunocompetence of the patient. However, once test results are available, the regimen should be adjusted accordingly. In the event of treatment failure, sensitivity tests should be repeated.

90.2.2.5 Treatment Regimens

Several regimens may be employed for active TB. Drug selection is based largely on the susceptibility of the infecting organism and the immunocompetence of the host. Therapy is usually initiated with a *four-drug* regimen; isoniazid and rifampin are almost always included. In the event of suspected or proved resistance, more drugs are added; the total may be as high as seven. Representative regimens are shown in [Table 89-1](#) and discussed below.

Treatment can be divided into two phases. The goal of the initial phase (induction phase) is to eliminate actively dividing extracellular tubercle bacilli, and thereby render the sputum

noninfectious. The goal of the second phase (continuation phase) is to eliminate intracellular “persisters.”

90.2.2.5.1 Drug-Sensitive Tuberculosis.

If the infecting organisms are not resistant to isoniazid or rifampin, treatment is relatively simple. As indicated in [Table 89-1](#), the induction phase, which lasts 2 months, consists of four drugs: *isoniazid*, *rifampin*, *pyrazinamide*, and *ethambutol*. Dosing may be done daily, twice weekly, or thrice weekly. The continuation phase, which lasts 4 months, consists of two drugs—*isoniazid* and *rifampin*—administered daily, twice weekly, or thrice weekly. Note that the entire course of treatment is prolonged, making adherence a significant problem.

90.2.2.5.2 Isoniazid- or Rifampin-Resistant Tuberculosis.

Infection that is resistant to a single drug—isoniazid or rifampin—usually responds well. Isoniazid-resistant TB can be treated for 6 months with three drugs: rifampin, ethambutol, and pyrazinamide. Rifampin-resistant TB can also be treated with three drugs—isoniazid, ethambutol, and pyrazinamide—but the duration is longer: 18 to 24 months, rather than 6 months.

90.2.2.5.3 Multidrug-Resistant TB and Extensively Drug-Resistant TB.

MDR-TB and XDR-TB are much harder to manage than drug-sensitive TB. Treatment is prolonged (at least 24 months) and must use second- and third-line drugs, which are less effective than the first-line drugs (eg, isoniazid and rifampin) and are generally more toxic. Initial therapy may consist of five, six, or even seven drugs. Hence, an initial regimen might include (1) isoniazid; (2) rifampin; (3) pyrazinamide; (4) ethambutol; (5) kanamycin, amikacin, or capreomycin; (6) ciprofloxacin or ofloxacin; and (7) cycloserine, ethionamide, or *para*-aminosalicylic acid. As a last resort, infected tissue may be removed by surgery. Even with all of these measures, the prognosis is often poor: Among patients with XDR-TB, between 40% and 60% die. Factors that determine outcome include the extent of drug resistance, infection severity, and the immunocompetence of the host.

1039

1040

TABLE 89-1 Representative Antituberculosis Regimens

Drug Resistance	HIV-Negative Patients [*]	HIV-Positive Patients [*]	Interaction with Drugs for HIV Infection [†]
None	<i>Induction Phase:</i> IRPE for 2 months <i>Continuation Phase:</i> IR for 4 months	<i>Induction Phase:</i> IRPE for 2 months <i>Continuation Phase:</i> IR for 4–7 months OR <i>Induction Phase:</i> IPE + rifabutin for 2 months <i>Continuation Phase:</i> I + rifabutin for 4–7 months	<i>PIs:</i> Rifampin can be used with ritonavir, but not with other PIs. <i>NNRTIs:</i> Rifampin can be used with high-dose nevirapine or efavirenz, but not with delavirdine. <i>PIs:</i> Rifabutin can be used with all PIs. <i>NNRTIs:</i> Rifabutin can be used with normal-dose nevirapine or efavirenz, but not with delavirdine.
Isoniazid resistance	RPE for 6 months	RPE for 6–9 months OR PE + rifabutin for 6–9 months	<i>PIs and NNRTIs:</i> Same as for rifampin above. <i>PIs and NNRTIs:</i> Same as for rifabutin above.
Rifampin resistance	IPE for 18–24 months	IPE for 18–24 months OR <i>Induction Phase:</i> IPSE for 2 months <i>Continuation Phase:</i> IPS for 7–10 months	All drugs for HIV infection can be used. All drugs for HIV infection can be used.
[*] Drugs used in these regimens: E = ethambutol, I = isoniazid, P = pyrazinamide, R = rifampin, S = streptomycin.			
[†] PI = HIV-protease inhibitor; NNRTI = non-nucleoside reverse transcriptase inhibitor.			

90.2.2.5.4 Patients with TB and HIV Infection.

Between 2% and 20% of patients with HIV infection develop active TB. Because of their reduced ability to fight infection, these patients require therapy that is more aggressive than in immunocompetent patients, and should last several months longer.

Drug interactions are a big problem, especially for patients taking *rifampin*. Why? Because rifampin, a cornerstone of TB therapy, can accelerate the metabolism of antiretroviral drugs (ie, drugs used to fight HIV), and can thereby decrease their effects. Specifically, rifampin can decrease the effects of most protease inhibitors and most non-nucleoside reverse transcriptase inhibitors (NNRTIs). Accordingly, it is best to avoid combining rifampin with these agents. Unfortunately, this means that patients will be denied optimal treatment for one of their infections. That is, if they take rifampin to treat TB, they will be unable to take most protease inhibitors or NNRTIs for HIV. Conversely, if they take protease inhibitors and NNRTIs to treat HIV, they will be unable to take rifampin for TB. This dilemma does not have an easy solution.

Like rifampin, *rifabutin* can accelerate metabolism of antiretroviral drugs. However, the degree of acceleration is much less. As a result, many of the antiretroviral drugs that must be avoided in patients taking rifampin can still be used in patients taking rifabutin.

90.2.2.6 Duration of Treatment

The ideal duration of treatment has not been established. For patients with drug-sensitive TB, the minimum duration is 6 months. For patients with multidrug-resistant infection, and for patients with HIV/AIDS, treatment may last as long as 24 months after sputum cultures have become negative.

90.2.2.7 Promoting Adherence: Directly Observed Therapy Combined with Intermittent Dosing

Patient nonadherence is the most common cause of treatment failure, relapse, and increased drug resistance. Recall that patients with TB must take multiple drugs for 6 months or more, making adherence a very real problem. Directly observed therapy (DOT), combined with intermittent dosing, helps ensure adherence and thereby increases the chances of success.

In DOT, administration of each dose is done in the presence of an observer, usually a representative of the health department. DOT is now considered the standard of care for TB. In addition to promoting bacterial kill, DOT permits ongoing evaluation of the clinical response to treatment and adverse drug effects.

Intermittent dosing is defined as dosing 2 or 3 times a week, rather than every day. Of course, each dose is larger than with daily dosing. Clinical studies have shown that intermittent dosing

is just as effective as daily dosing, and no more toxic. The great advantage of intermittent dosing is that it makes DOT more convenient, and hence enhances adherence.

90.2.2.8 Evaluating Treatment

Three modes are employed to evaluate therapy: bacteriologic evaluation of sputum, clinical evaluation, and chest radiographs.

In patients with positive pretreatment sputum tests, sputum should be evaluated every 2 to 4 weeks initially, and then monthly after sputum cultures become negative. With proper drug selection and good adherence, sputum cultures become negative in over 90% of patients after 3 months of treatment.

Treatment failures should be evaluated for drug resistance and patient adherence. In the absence of demonstrated drug resistance, treatment with the same regimen should continue, using direct observation of drug administration to ensure that medication is being taken as prescribed. In patients with drug-resistant TB, *two* effective drugs should be added to the regimen.

In patients with negative pretreatment sputum tests, treatment is monitored by chest radiographs and clinical evaluation. In most patients, clinical manifestations (eg, fever, malaise, anorexia, cough) should decrease markedly within 2 weeks. The radiograph should show improvement within 3 months.

After completing therapy, patients should be examined every 3 to 6 months for signs and symptoms of relapse.

90.2.3 Diagnosis and Treatment of Latent Tuberculosis

In the United States, an estimated 9 to 14 million people have latent TB. In the absence of treatment, 5% to 10% of these people will develop active TB. Because latent TB can become active, the condition poses a threat to the infected individual and to the community as well. Accordingly, testing and treatment are clearly desirable—but not for everyone: Because treatment of latent TB is prolonged and carries a risk of drug toxicity, testing and treatment should be limited to people who really need it. In 2000, the American Thoracic Society and the Centers for Disease Control and Prevention (CDC) issued revised clinical guidelines—*Targeted Tuberculin Testing and Treatment of Latent Tuberculosis Infection*—that specify who should be

tested, who should be treated, and what drugs should be used. Recommendations specific to drug therapy were revised again in 2003. The discussion below reflects the updated recommendations.

90.2.3.1 Who Should Be Tested for Latent Tuberculosis?

Testing should be limited to people who are at high risk of either (1) having acquired the infection recently or (2) progressing from latent TB to active TB. Included in this group are people with HIV infection, people receiving immunosuppressive drugs, recent contacts of TB patients, and people with high-risk medical conditions, such as diabetes, silicosis, or chronic renal failure. A complete list of candidates for testing is given in [Table 89-2](#). Routine testing of low-risk individuals is not recommended.

90.2.3.2 How Do We Test for Latent Tuberculosis?

There are two tests for latent TB: (1) the tuberculin skin test (TST), which has been in use for over 100 years; and (2) the QuantiFERON-TB Gold (QFT-G) blood test, which was approved for American use in 2005.

1040

90.2.3.2.1 Tuberculin Skin Test.

1041

The TST is performed by giving an intradermal injection of a preparation known as *purified protein derivative* (PPD), an antigen derived from *M. tuberculosis*. If the individual has an intact immune system and has been exposed to *M. tuberculosis* in the past, the PPD will elicit a local immune response. The test is read 48 to 72 hours after the injection. A positive reaction is indicated by a region of induration (hardness) around the injection site.

TABLE 89-2 Candidates for Targeted Tuberculosis Testing

Individuals at High Risk of Recent Tuberculosis Infection
Contacts of TB patients
Residents and staff of high-risk congregate settings:
• Prisons and jails • Nursing homes • Hospitals and other healthcare facilities • Homeless shelters • Residential facilities for patients with AIDS
Persons who, in the last 5 years, immigrated from a country where TB is prevalent
Staff of mycobacteriology laboratories
Children and adolescents exposed to high-risk adults
Children under the age of 4 years
Individuals at High Risk of Progression from Latent to Active Tuberculosis
HIV-infected persons
Intravenous drug abusers
Patients taking immunosuppressive drugs for 1 month or more
Patients with a chest radiograph indicating fibrotic changes consistent with prior TB
Patients with other high-risk medical conditions, including
• Diabetes mellitus • Chronic renal failure • Silicosis • Leukemia or lymphoma • Clinical conditions associated with substantial weight loss, including postgastrectomy state, intestinal bypass surgery, chronic peptic ulcer disease, chronic malabsorption

syndromes, and carcinomas of the oropharynx and upper GI tract that inhibit adequate nutritional intake

The decision to treat latent TB is based on two factors: (1) the risk category of the individual and (2) the size of the region of induration produced by the TST ([Table 89-3](#)). For individuals at high risk, treatment is recommended if the region of induration is relatively small (5 mm). For individuals at moderate risk, treatment is indicated when the region of induration is larger (10 mm). And for individuals at low risk (who should not be routinely tested), the region must be larger still (15 mm) to justify treatment.

90.2.3.2.2 QuantiFERON-TB Gold Blood Test.

The QFT-G test is a simple, one-step *blood* test that can be used in all situations in which the traditional TST has been used. Comparative studies indicate that the QFT-G test and the TST are equally sensitive, and that the QFT-G test is more specific. Results for the QFT-G test are available faster than with the TST (24 hours vs. 48 to 72 hours), and only one office visit is required, compared with two visits for the TST. Current CDC guidelines permit using the QFT-G test in all situations in which the TBT is used.

90.2.3.3 How Do We Treat Latent Tuberculosis?

Isoniazid has been the treatment of choice for latent TB for over 30 years, and remains so today. The drug is effective, relatively safe, and inexpensive. However, isoniazid does have two drawbacks. First, to be effective, isoniazid must be taken for a long time—at least 6 months and preferably 9 months. Second, isoniazid poses a risk of liver damage. Because of these problems, alternative regimens have been developed ([Table 89-4](#)). Unfortunately, although the alternative regimens are of shorter duration, they still pose a risk of liver damage.

Before starting treatment for latent TB, active TB must be ruled out. Why? Because latent TB is treated with just one (or two) drugs, and hence, if active TB were present, treatment would promote emergence of resistant bacilli. To exclude active disease, the patient should receive a physical examination and chest radiograph; if indicated, bacteriologic studies may also be ordered.

1041

1042

TABLE 89-3 Tuberculin Skin Test Results That Are Considered Positive—and Hence Justify Treatment—in Patients at Low, Moderate, and High Risk of Latent Tuberculosis

Risk Category	Who Is In the Risk Category?	Test Result Considered Positive
High	HIV-positive people Recent contacts of patients with TB People with fibrotic changes on their chest radiograph consistent with prior TB People taking immunosuppressive drugs for more than 1 month	5 mm of induration
Moderate	Recent immigrants from countries with a high prevalence of TB Intravenous drug abusers Residents and staff of high-risk congregate settings (eg, prisons, nursing homes, hospitals, homeless shelters) Mycobacteriology laboratory personnel Persons with high-risk medical conditions (eg, diabetes mellitus, chronic renal failure, silicosis, leukemia, lymphoma) Children and adolescents exposed to high-risk adults Children under 4 years old	10 mm of induration
Low	Persons with no risk factors for TB	15 mm of induration

TABLE 89-4 Options for Treating Latent Tuberculosis Infection

				Recommendation*	
Drugs	Duration (months)	Dosing Schedule	Dosage	HIV neg	HIV pos
Preferred Regimen					
Isoniazid	9	Daily	Adults: 5 mg/kg (max 300 mg) Children: 10–20 mg/kg (max 300 mg)	A	A
Alternative Regimens					
Isoniazid	9	Twice weekly†	Adults: 15 mg/kg (max 900 mg) Children: 20–40 mg/kg (max 900 mg)	B	B
Isoniazid	6	Daily	Adults: 5 mg/kg (max 300 mg) Children: Not recommended	B	C
Isoniazid	6	Twice weekly†	Adults: 15 mg/kg (max 900 mg) Children: Not recommended	B	C
Rifampin	4	Daily	Adults: 10 mg/kg (max 600 mg) Children: 10–20 mg/kg (max 600 mg)	B	B
Data from Centers for Disease Control and Prevention: Update: Adverse event data and revised American Thoracic Society/CDC recommendations against the use of rifampin and pyrazinamide for treatment of latent tuberculosis infection—United States, 2003. MMWR Morb Mortal Wkly Rep 52:735–739, 2003.					

* A = preferred treatment, B = acceptable alternative to A, C = offer when A and B cannot be given.

† Twice-weekly dosing should be administered by directly observed therapy.

90.2.3.3.1 Isoniazid.

Isoniazid is the preferred drug for treating latent TB in all patients, including those who are HIV positive. Ideally, treatment should continue for 9 months. Treatment for 6 months is an option, but is not as reliable. Two dosing schedules can be used: daily or twice weekly.

When twice-weekly dosing is selected, each dose should be administered under direct observation of a healthcare provider (to ensure adherence).

Isoniazid is hepatotoxic. To reduce the risk of liver injury, liver function should be evaluated at the beginning of therapy and every 4 weeks thereafter. If hepatotoxicity develops, isoniazid should be withdrawn.

90.2.3.3.2 Short-Course Therapy: Rifampin Alone.

Four months of daily therapy with rifampin alone is an alternative for patients who cannot take isoniazid. Dosing is done daily. Twice-weekly dosing is not an option.

90.2.3.3.3 Short-Course Therapy: Rifampin Plus Pyrazinamide.

Owing to high rates of hospitalization and death from liver injury (rifampin and pyrazinamide are hepatotoxic), use of this combination for latent TB is no longer recommended. However, both drugs are still recommended for use in multidrug regimens to treat *active* TB. If rifampin and pyrazinamide must be used, close monitoring is needed. Serum aminotransferases and bilirubin should be measured at baseline and at 2, 4, 6, and 8 weeks of treatment. Treatment should stop immediately if (1) aminotransferase levels exceed 5 times the upper limit of normal (in an asymptomatic patient); (2) aminotransferase levels exceed the upper limit of normal (in a patient with symptoms of hepatitis); or (3) bilirubin levels exceed normal, regardless of hepatitis symptoms. Rifampin plus pyrazinamide should never be used in patients with active liver disease or a history of isoniazid-induced liver injury, and should be used with caution in patients who are taking hepatotoxic drugs or who drink alcohol in excess (even if drinking is discontinued during treatment).

90.2.4 Vaccination Against Tuberculosis

Protection against TB can be conferred by inoculation with BCG vaccine, a freeze-dried preparation of attenuated *Mycobacterium bovis* (bacillus of Calmette and Guérin). In countries where TB is endemic, the World Health Organization recommends BCG vaccination in infancy, to protect children against severe, life-threatening infection (ie, miliary TB and tuberculous meningitis). In the United States, routine vaccination is not done. Why? Because there is a low risk of infection with *M. tuberculosis* and protection against pulmonary TB in adulthood is variable. Furthermore, vaccination with BCG can produce a false-positive result in the tuberculin skin test, which can't distinguish between antigens in *M. bovis* and antigens in *M. tuberculosis*. (Since the QFT-G is highly specific for antigens in *M. tuberculosis*, vaccination with BCG does

not affect the results of this test.) As discussed in [Chapter 102](#), BCG vaccine is also used to treat carcinoma of the bladder.

90.3 PHARMACOLOGY OF INDIVIDUAL ANTITUBERCULOSIS DRUGS

Based on their clinical utility, the anti-TB drugs can be divided into two groups: first-line drugs and second-line drugs. The first-line drugs are *isoniazid*, *rifampin*, *rifapentine*, *rifabutin*, *pyrazinamide*, and *ethambutol*. Of these, isoniazid and rifampin are the most important. The second-line drugs—*levofloxacin*, *moxifloxacin*, *kanamycin*, *amikacin*, *capreomycin*, *para-aminosalicylic acid*, *ethionamide*, and *cycloserine*—are generally less effective, more toxic, and more expensive than the primary drugs. Second-line agents are used in combination with the primary drugs to treat disseminated TB and TB caused by organisms resistant to first-line drugs. Adverse effects and routes of administration of the anti-TB drugs are summarized in [Table 89-5](#).

90.3.1 Isoniazid

Isoniazid is the primary agent for treatment and prophylaxis of TB. This drug is superior to alternative drugs with regard to efficacy, toxicity, ease of use, patient acceptance, and affordability. With the exception of patients who cannot tolerate the drug, isoniazid should be taken by all individuals infected with isoniazid-sensitive strains of *M. tuberculosis*.

90.3.1.1 Antimicrobial Spectrum and Mechanism of Action

Isoniazid is highly selective for *M. tuberculosis*. The drug can kill tubercle bacilli at concentrations 10,000 times lower than those needed to affect gram-positive and gram-negative bacteria. Isoniazid is bactericidal to mycobacteria that are actively dividing, but is only bacteriostatic to “resting” organisms.

1042

1043

TABLE 89-5 Antituberculosis Drugs: Routes and Major Adverse Effects

Drug	Route	Major Adverse Effects
First-Line Drugs		
Isoniazid	PO, IM	Hepatotoxicity, peripheral neuritis
Rifampin	PO, IV	Hepatotoxicity
Rifapentine	PO	Hepatotoxicity
Rifabutin	PO	Hepatotoxicity
Pyrazinamide	PO	Hepatotoxicity
Ethambutol	PO	Optic neuritis
Second-Line Drugs		
Fluoroquinolones		
Levofloxacin	PO, IV	GI intolerance
Moxifloxacin	PO, IV	GI intolerance
Injectable Drugs		
Capreomycin	IM	Eighth nerve damage, nephrotoxicity
Kanamycin	IM, IV	Eighth nerve damage, nephrotoxicity
Amikacin	IM, IV	Eighth nerve damage, nephrotoxicity
Others		
<i>p</i> -Aminosalicylic acid	PO	GI intolerance
Ethionamide	PO	GI intolerance, hepatotoxicity
Cycloserine	PO	Psychoses, seizure, rash

Although the mechanism by which isoniazid acts is not known with certainty, available data suggest the drug suppresses bacterial growth by inhibiting synthesis of mycolic acid, a component of the mycobacterial cell wall. Since mycolic acid is not produced by other bacteria or by cells of the host, this mechanism would explain why isoniazid is so selective for tubercle bacilli.

90.3.1.2 Resistance

Tubercle bacilli can develop resistance to isoniazid during treatment. Acquired resistance results from spontaneous mutation—not from transfer of R factors. The precise mechanism underlying resistance has not been established. Emergence of resistance can be decreased through multidrug therapy. Organisms resistant to isoniazid are cross-resistant to ethionamide, but not to other drugs used for TB.

90.3.1.3 Pharmacokinetics

90.3.1.3.1 Absorption and Distribution.

Isoniazid is administered orally and IM. Absorption is good with both routes. Once in the blood, isoniazid is widely distributed to tissues and body fluids. Concentrations in cerebrospinal fluid (CSF) are about 20% of those in plasma.

90.3.1.3.2 Metabolism.

Isoniazid is inactivated in the liver, primarily by *acetylation*. The ability to acetylate isoniazid is genetically determined: about 50% of people in the United States are *rapid* acetylators and the other 50% are *slow* acetylators. The drug's half-life is about 1 hour in rapid acetylators and 3 hours in slow acetylators. It is important to note that differences in rates of acetylation generally have little impact on the *efficacy* of isoniazid, provided patients are taking the drug daily. However, *nonhepatic toxicities* may be more likely in slow acetylators, because drug accumulation is greater in these patients.

90.3.1.3.3 Excretion.

Isoniazid is excreted in the urine, primarily as inactive metabolites. In patients who are slow acetylators and who also have renal insufficiency, the drug may accumulate to toxic levels.

90.3.1.4 Therapeutic Use

Isoniazid is indicated only for treating active and latent TB. When used for latent TB, the drug is administered alone. When used for active TB, it must be taken in combination with at least one other agent (eg, rifampin).

90.3.1.5 Adverse Effects

90.3.1.5.1 Peripheral Neuropathy.

Dose-related peripheral neuropathy is the most common adverse effect. Principal symptoms are symmetric paresthesias (tingling, numbness, burning, pain) of the hands and feet. Clumsiness, unsteadiness, and muscle ache may also develop. Peripheral neuropathy results from isoniazid-induced deficiency in pyridoxine (vitamin B₆). If peripheral neuropathy develops, it can be reversed by administering pyridoxine (50 to 200 mg daily). In patients predisposed to neuropathy (eg, alcohol abusers and diabetics), small doses of pyridoxine (6 to 50 mg/day) can be administered with isoniazid as prophylaxis against peripheral neuritis. This practice reduces the risk of neuropathy from 20% down to less than 1%.

90.3.1.5.2 Hepatotoxicity.

Isoniazid can cause hepatocellular injury and multilobular necrosis. Deaths have occurred. Liver injury is thought to result from production of a toxic isoniazid metabolite. The greatest risk factor for liver damage is advancing age: The incidence is extremely low in patients under 20 years; 1.2% in those ages 35 to 49, 2.3% in those ages 50 to 64, and 8% in those over 65. Patients should be informed about signs of hepatitis (anorexia, malaise, fatigue, nausea, yellowing of the skin or eyes) and instructed to notify the prescriber if these develop. Patients should also undergo monthly evaluation for these signs. Some clinicians perform monthly determinations of serum aspartate aminotransferase (AST) activity, because elevation of AST activity is indicative of liver injury. However, because AST levels may rise and then return to normal, despite continued isoniazid use, increases in AST may not be predictive of clinical hepatitis. It is recommended that isoniazid be withdrawn if signs of hepatitis develop or if AST activity exceeds 3 to 5 times the pretreatment baseline. Caution should be exercised when giving isoniazid to alcoholics and individuals with pre-existing disorders of the liver.

1043

1044

90.3.1.5.3 Other Adverse Effects.

A variety of *central nervous system (CNS) effects* can occur, including optic neuritis, seizures, dizziness, ataxia, and psychologic disturbances (depression, agitation, impairment of memory, hallucinations, toxic psychosis). *Anemia* may result from isoniazid-induced deficiency in pyridoxine. *GI distress, dry mouth, and urinary retention* occur on occasion.

Allergy to isoniazid can produce fever, rashes, and a syndrome resembling lupus erythematosus.

90.3.1.6 Drug Interactions

90.3.1.6.1 Phenytoin.

Isoniazid can interfere with the metabolism of phenytoin, thereby causing phenytoin to accumulate to toxic levels. Signs of phenytoin excess include ataxia and incoordination. Plasma levels of phenytoin should be monitored, and phenytoin dosage should be reduced as appropriate. Dosage of isoniazid should not be changed.

90.3.1.6.2 Alcohol, Rifampin, and Pyrazinamide.

Daily ingestion of alcohol or concurrent therapy with rifampin or pyrazinamide increases the risk of hepatotoxicity. Patients should be encouraged to reduce or eliminate alcohol intake.

90.3.1.7 Preparations, Dosage, and Administration

90.3.1.7.1 Preparations.

Isoniazid is supplied in tablets (100 and 300 mg) and a syrup (10 mg/mL) for oral use, and in solution (100 mg/mL in 10-mL vials), sold as *Nydrazid*, for IM injection. Isoniazid is also available in two fixed-dose combinations: (1) capsules, sold as *Rifamate*, contain 150 mg of isoniazid and 300 mg of rifampin, and (2) tablets, sold as *Rifater*, contain 50 mg of isoniazid, 120 mg of rifampin, and 300 mg of pyrazinamide.

90.3.1.7.2 Oral Dosage.

For treatment of *active TB*, the adult dosage is 5 mg/kg/day or 15 mg/kg 2 or 3 times a week; the pediatric dosage is 10 to 20 mg/kg/day or 20 to 40 mg/kg 2 or 3 times a week. For treatment of *latent TB*, the preferred adult dosage is 5 mg/kg/day and the preferred pediatric dosage is 10 mg/kg/day.

90.3.1.7.3 Intramuscular Dosage.

Parenteral therapy is administered in critical situations when oral treatment is not possible. The dosage is 300 mg/day.

90.3.2 Rifampin

Rifampin [Rifadin, Rimactane] equals isoniazid regarding importance as an anti-TB drug. Prior to the appearance of resistant tubercle bacilli, the combination of rifampin plus isoniazid was the most frequently prescribed regimen for uncomplicated pulmonary TB. Rifampin is a powerful inducer of cytochrome P450 enzymes, and hence can decrease the levels of many other drugs.

90.3.2.1 Antimicrobial Spectrum

Rifampin is a broad-spectrum antibiotic. The drug is active against most gram-positive bacteria as well as many gram-negative bacteria. The drug is bactericidal to *M. tuberculosis* and *M. leprae*. Other bacteria that are highly sensitive include *Neisseria meningitidis*, *Haemophilus influenzae*, *Staphylococcus aureus*, and *Legionella* species.

90.3.2.2 Mechanism of Action and Bacterial Resistance

Rifampin inhibits bacterial DNA-dependent RNA polymerase, and thereby suppresses RNA synthesis and, consequently, protein synthesis. The results are bactericidal. Because mammalian RNA polymerases are not affected, rifampin is selectively toxic to microbes. Bacterial resistance to rifampin results from production of an altered form of RNA polymerase.

90.3.2.3 Pharmacokinetics

90.3.2.3.1 Absorption and Distribution.

Rifampin is well absorbed if taken on an empty stomach. However, if dosing is done with or shortly after a meal, both the rate and extent of absorption can be significantly lowered. Rifampin is distributed widely to tissues and body fluids, including the CSF. The drug is lipid soluble, and hence has ready access to intracellular bacteria.

90.3.2.3.2 Elimination.

Rifampin is eliminated primarily by hepatic metabolism. Only about 20% of the drug leaves in the urine. Rifampin induces hepatic drug-metabolizing enzymes, including those responsible for its own inactivation. As a result, the rate at which rifampin is metabolized increases over the first weeks of therapy, causing the half-life of the drug to decrease—from an initial value of about 4 hours down to 2 hours at the end of 2 weeks.

90.3.2.4 Therapeutic Use

90.3.2.4.1 Tuberculosis.

Rifampin is one of our most effective anti-TB drugs. This agent is bactericidal to tubercle bacilli at extracellular and intracellular sites. Rifampin is a drug of choice for treating pulmonary TB and disseminated disease. Because resistance can develop rapidly when rifampin is employed alone, the drug is always employed in combination with at least one other anti-TB agent. Despite the capacity of rifampin to produce a variety of adverse effects, toxicity rarely requires discontinuing treatment.

90.3.2.4.2 Leprosy.

Rifampin is bactericidal to *M. leprae* and has become an important agent for treating leprosy (see below under *Drugs for Leprosy [Hansen's Disease]*).

90.3.2.4.3 Meningococcus Carriers.

Rifampin is highly active against *Neisseria meningitidis* and is indicated for short-term therapy to eliminate this bacterium from the nasopharynx of asymptomatic carriers. Because resistant organisms emerge rapidly, rifampin should not be used for active meningococcal disease.

90.3.2.5 Adverse Effects

Rifampin is generally well tolerated. When employed at recommended dosages, the drug rarely causes significant toxicity. The most common adverse effect of concern is hepatitis.

90.3.2.5.1 Hepatotoxicity.

Rifampin is toxic to the liver, posing a risk of jaundice and even hepatitis. Asymptomatic elevation of liver enzymes occurs in about 14% of patients. However, the incidence of overt hepatitis is less than 1%. Hepatotoxicity is most likely in alcohol abusers and patients with pre-existing liver disease. These individuals should be monitored closely for signs of liver dysfunction. Tests of liver function (serum aminotransferase levels) should be made prior to treatment and every 2 to 4 weeks thereafter. Patients should be informed about signs of hepatitis (jaundice, anorexia, malaise, fatigue, nausea) and instructed to notify the prescriber if they develop.

90.3.2.5.2 Discoloration of Body Fluids.

Rifampin frequently imparts a red-orange color to urine, sweat, saliva, and tears. Patients should be informed of this harmless effect. Permanent staining of soft contact lenses has occurred on occasion; the patient should consult an ophthalmologist regarding the advisability of contact lens use.

90.3.2.5.3 Other Adverse Effects.

Gastrointestinal disturbances (anorexia, nausea, abdominal discomfort) and *cutaneous reactions* (flushing, itching, rash) occur occasionally. Rarely, intermittent high-dose therapy has produced a *flu-like syndrome*, characterized by fever, chills, muscle aches, headache, and dizziness. This reaction appears to have an immunologic basis. In some patients, high-dose therapy has been associated with *shortness of breath*, *hemolytic anemia*, *shock*, and *acute renal failure*.

1044

1045

90.3.2.6 Drug Interactions

90.3.2.6.1 Accelerated Metabolism of Other Drugs.

Because rifampin induces cytochrome P450 enzymes, it can hasten the metabolism of many drugs, thereby reducing their effects. This interaction is of special concern with *oral contraceptives*, *warfarin* (an anticoagulant), and certain *protease inhibitors* and *NNRTIs* used for HIV infection. Women taking oral contraceptives should consider a nonhormonal form of birth control. The dosage of warfarin may need to be increased.

90.3.2.6.2 Isoniazid and Pyrazinamide.

Rifampin, isoniazid, and pyrazinamide are all hepatotoxic. Hence, when these drugs are used in combination, as they often are, the risk of liver injury is greater than when they are used alone.

90.3.2.7 Preparations, Dosage, and Administration

90.3.2.7.1 Preparations.

Rifampin [Rifadin, Rimactane], by itself, is available in 150- and 300-mg capsules. In addition, rifampin is available in two fixed-dose combinations: (1) capsules, sold as

Rifamate, contain 300 mg of rifampin and 150 mg of isoniazid, and (2) tablets, sold as *Rifater*, contain 120 mg of rifampin, 50 mg of isoniazid, and 300 mg of pyrazinamide.

90.3.2.7.2 Intravenous.

Rifampin [Rifadin] is available in powdered form (600 mg) to be reconstituted for IV infusion.

90.3.2.7.3 Oral Dosage and Administration.

For treatment of TB, the usual adult dosage is 600 mg, taken once a day, twice a week, or 3 times a week. The pediatric dosage is 10 to 20 mg/kg taken once a day, twice a week, or 3 times a week. Rifampin is administered 1 hour before meals or 2 hours after. Because rifampin is eliminated by hepatic metabolism, patients with liver impairment require a reduction in dosage. No change in dosage is needed in patients with kidney disease.

90.3.2.7.4 Intravenous Administration.

Dissolve 600 mg of powdered rifampin in 10 mL of sterile water for injection to make a concentrated solution (60 mg/mL). Dilute an appropriate dose of the concentrate in 500 mL of 5% dextrose and infuse over 3 hours.

90.3.3 Rifapentine

Rifapentine [Priftin] is a long-acting analog of rifampin. Both drugs have the same mechanism of action, adverse effects, and drug interactions. When rifapentine was approved in 1998, it was the first new drug for TB in over 25 years.

90.3.3.1 Actions and Uses.

Rifapentine is indicated only for pulmonary TB. At therapeutic doses, the drug is lethal to *M. tuberculosis*. The mechanism underlying cell kill is inhibition of DNA-dependent RNA polymerase. To minimize emergence of resistance, rifapentine must always be combined with at least one other anti-TB drug.

90.3.3.2 Pharmacokinetics.

Rifapentine is well absorbed from the GI tract, especially in the presence of food. Plasma levels peak 5 to 6 hours after dosing. In the liver, rifapentine undergoes conversion to 25-

desacetyl rifapentine, an active metabolite. Excretion is primarily (70%) fecal. Rifapentine and its metabolite have the same half-life—about 13 hours.

90.3.3.3 Adverse Effects.

Rifapentine is well tolerated at recommended doses. Like rifampin, the drug imparts a red-orange color to urine, sweat, saliva, and tears. Permanent staining of contact lenses can occur.

Hepatotoxicity is the principal concern. In clinical trials, serum transaminase levels increased in 5% of patients. However, overt hepatitis occurred in only one patient. Because of the risk of hepatotoxicity, liver function tests (bilirubin, serum transaminases) should be performed at baseline and monthly thereafter. Patients should be informed about signs of hepatitis (jaundice, anorexia, malaise, fatigue, nausea) and instructed to notify the prescriber if these develop.

90.3.3.4 Drug Interactions.

Like rifampin, rifapentine is a powerful inducer of cytochrome P450 drug-metabolizing enzymes. As a result, it can decrease the levels of other drugs. Important among these are *protease inhibitors* and *NNRTIs* (used for HIV infection), *oral contraceptives*, and *warfarin*.

90.3.3.5 Preparation, Dosage, and Administration.

Rifapentine [Priftin] is available in 150-mg tablets. For the first 2 months, the dosage is 600 mg twice a week (with at least 3 days between doses). For the next 4 months, the dosage is 600 mg once a week. Like all other drugs for TB, rifapentine must always be combined with at least one other anti-TB agent.

90.3.4 Rifabutin

90.3.4.1 Actions and Uses.

Rifabutin [Mycobutin] is a close chemical relative of rifampin. Like rifampin, rifabutin inhibits mycobacterial DNA-dependent RNA polymerase, and thereby suppresses protein synthesis. The drug is approved for prevention of disseminated *M. avium* complex (MAC) disease in patients with advanced HIV infection (CD4 lymphocyte counts below 200 cells/mm³). In addition to this approved application, rifabutin is used off-label to treat active MAC disease and TB in patients with HIV infection.

90.3.4.2 Pharmacokinetics.

Rifabutin is administered orally. Absorption is unaffected by food. Plasma levels peak in 2 to 3 hours. The drug is widely distributed and achieves high concentrations in the lungs. Rifabutin is metabolized in the liver and excreted in the urine, bile, and feces. Its half-life is 45 hours.

90.3.4.3 Adverse Effects.

Rifabutin is generally well tolerated. The most common side effects are rash (4%), GI disturbances (3%), and neutropenia (2%). Like rifampin, rifabutin can impart a harmless red-orange color to urine, sweat, saliva, and tears; soft contact lenses may be permanently stained. Rifabutin poses a risk of uveitis, and hence should be discontinued if ocular pain or blurred vision develops. Other adverse effects include myositis, hepatitis, arthralgia, chest pain with dyspnea, and a flu-like syndrome.

90.3.4.4 Drug Interactions.

Like rifampin, rifabutin *induces cytochrome P450 enzymes*, although less strongly than rifampin does. By increasing enzyme activity, rifabutin can decrease blood levels of other drugs, especially *oral contraceptives* and *delavirdine*, an NNRTI. Women using oral contraceptives should be advised to use a nonhormonal method of birth control.

90.3.4.5 Preparations, Dosage, and Administration.

Rifabutin [Mycobutin] is supplied in 150-mg capsules. For treatment of TB, the adult dosage is 300 mg taken once a day, twice a week, or 3 times a week. The pediatric dosage is 10 to 20 mg/kg taken once a day or twice a week.

90.3.5 Pyrazinamide

90.3.5.1 Antimicrobial Activity and Therapeutic Use

Pyrazinamide is bactericidal to *M. tuberculosis*. How it kills bacteria is unknown. Currently, the combination of pyrazinamide with rifampin, isoniazid, and ethambutol is a preferred regimen for initial therapy of active disease caused by nonresistant *M. tuberculosis*. In addition, pyrazinamide, in combination with rifampin, may be used for short-course therapy of latent TB, although other regimens are preferred.

90.3.5.2 Pharmacokinetics

Pyrazinamide is well absorbed following oral administration and undergoes wide distribution to tissues and body fluids. In the liver, the drug is converted to pyrazinoic acid, an active metabolite, and then to 5-hydroxypyrazinoic acid, which is inactive. Excretion is renal, primarily as inactive metabolites.

90.3.5.3 Adverse Effects and Interactions

90.3.5.3.1 Hepatotoxicity.

Liver injury is the principal adverse effect. High-dose therapy has caused hepatitis, and, rarely, fatal hepatic necrosis. The earliest manifestations of liver damage are elevations in serum levels of transaminases (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]). Levels of these enzymes should be measured prior to treatment and every 2 weeks thereafter. Patients should be informed about signs of hepatitis (eg, malaise, anorexia, nausea, vomiting, yellowish discoloration of the skin and eyes) and instructed to notify the prescriber if they develop. Pyrazinamide should be discontinued if significant injury to the liver occurs. The drug should not be used by patients with preexisting liver disease.

The risk of liver injury is increased by concurrent therapy with isoniazid or rifampin, both of which are hepatotoxic. Pyrazinamide plus rifampin is contraindicated for patients with active liver disease or a history of isoniazid-induced liver injury, and should be used with caution in patients who are taking hepatotoxic drugs or who drink alcohol in excess.

1045

90.3.5.3.2 Other Adverse Effects.

1046

Pyrazinamide and its metabolites can inhibit renal excretion of uric acid, thereby causing *hyperuricemia*. Although usually asymptomatic, pyrazinamide-induced hyperuricemia has (rarely) resulted in *gouty arthritis*. Additional adverse effects include *arthralgia*, *GI disturbances* (nausea, vomiting, diarrhea), *rashes*, and *photosensitivity*.

90.3.5.4 Preparations, Dosage, and Administration

Pyrazinamide is supplied in 500-mg tablets. The dosage for adults is 15 to 30 mg/kg taken once a day or 50 to 70 mg/kg taken 2 or 3 times a week. The dosage for children is 15 to 20 mg/kg

taken once a day or 50 to 70 mg/kg taken 2 or 3 times a week. For all patients, the maximum daily dosage is 2 gm. Pyrazinamide is also available in a fixed-dose combination with isoniazid and rifampin, sold as *Rifater*.

90.3.6 Ethambutol

90.3.6.1 Antimicrobial Action

Ethambutol [Myambutol] is active only against mycobacteria; nearly all strains of *M. tuberculosis* are sensitive. The drug is bacteriostatic, not bactericidal. In most cases, ethambutol is active against tubercle bacilli that are resistant to isoniazid and rifampin. Although we know that ethambutol can suppress incorporation of mycolic acid in the cell wall, the precise mechanism by which it suppresses bacterial growth has not been established.

90.3.6.2 Therapeutic Use

Ethambutol is an important anti-TB drug. This agent is employed for initial treatment of TB and for treating patients who have received therapy previously. Like other drugs for TB, ethambutol is always employed as part of a multidrug regimen.

90.3.6.3 Pharmacokinetics

Ethambutol is readily absorbed following oral administration. The drug is widely distributed to most tissues and body fluids; levels in CSF, however, remain low. Ethambutol undergoes little hepatic metabolism and is excreted primarily in the urine. The half-life is 3 to 4 hours in patients with healthy kidneys, and increases to 8 hours in those with significant renal impairment.

90.3.6.4 Adverse Effects

Ethambutol is generally well tolerated. The only significant adverse effect is optic neuritis.

90.3.6.4.1 Optic Neuritis.

Ethambutol can produce dose-related optic neuritis, resulting in blurred vision, constriction of the visual field, and disturbance of color discrimination. The mechanism underlying these effects is unknown. Symptoms usually resolve upon discontinuation of treatment. However, for some patients, visual disturbance may persist. Color discrimination and visual acuity should be assessed prior to treatment and monthly thereafter. Patients should be advised to

report any alteration in vision. If ocular toxicity develops, ethambutol should be withdrawn immediately. Because visual changes can be difficult to monitor in pediatric patients, ethambutol is not recommended for children younger than 8 years.

90.3.6.4.2 Other Adverse Effects.

Ethambutol can produce *allergic reactions* (dermatitis, pruritus), *GI upset*, and *confusion*. The drug inhibits renal excretion of uric acid, causing *asymptomatic hyperuricemia* in about 50% of patients; occasionally, elevation of uric acid levels results in *acute gouty arthritis*. Rare adverse effects include *peripheral neuropathy*, *renal damage*, and *thrombocytopenia*.

90.3.6.5 Preparations, Dosage, and Administration

Ethambutol [Myambutol] is supplied in 100- and 400-mg tablets. For initial therapy of TB, the dosage for adults and children is 15 to 25 mg/kg once a day, 50 mg/kg twice a week, or 25 to 30 mg/kg 3 times a week. For re-treatment therapy, the usual dosage is 25 mg/kg/day for the first 60 days and 15 mg/kg/day thereafter. Ethambutol may be taken with food if GI upset occurs.

90.3.7 Second-Line Antituberculosis Drugs

The group of second-line anti-TB drugs consists of two fluoroquinolones (levofloxacin and moxifloxacin), three injectable drugs (kanamycin, capreomycin, amikacin), and three other drugs (*para*-aminosalicylic acid [PAS], ethionamide, and cycloserine). In general, these drugs are less effective, more toxic, and more expensive than the first-line drugs. As a result, their principal indication is TB caused by organisms that have proved resistant to first-line agents. In addition, second-line drugs are used to treat severe pulmonary TB as well as disseminated (extrapulmonary) infection. The second-line drugs are always employed in conjunction with a major anti-TB drug. Principal toxicities are summarized in [Table 89-5](#).

90.3.7.1 Fluoroquinolones

Levofloxacin [Levaquin] and moxifloxacin [Avelox] are fluoroquinolone antibiotics indicated for a wide variety of bacterial infections (see [Chapter 90](#)). Both drugs have good activity against *M. tuberculosis*. As therapy for TB, these drugs are reserved for infection caused by multidrug-resistant organisms. Both drugs are generally well tolerated, although GI disturbances are relatively common. Tendon rupture occurs rarely. Oral dosages for adults are

as follows: levofloxacin, 500 to 750 mg/day and moxifloxacin, 400 mg/day. These drugs are not recommended for children.

90.3.7.2 Injectable Drugs

90.3.7.2.1 Capreomycin

Capreomycin [Capastat Sulfate] is an antibiotic derived from a species of *Streptomyces*. Antibacterial effects probably result from inhibiting protein synthesis. The drug is bacteriostatic to *M. tuberculosis*. Capreomycin is used only for TB resistant to primary agents. The principal toxicity is renal damage, and hence the drug should not be taken by patients with kidney disease. Capreomycin may also cause eighth cranial nerve damage, resulting in hearing loss, tinnitus, and disturbed balance. Administration is by deep IM injection (the drug is not absorbed from the GI tract, and therefore cannot be administered PO). The usual adult dosage is 1 gm/day for 60 to 120 days, followed by 1-gm doses 2 to 3 times a week. The pediatric dosage is 15 mg/kg/day (up to a maximum of 1 gm).

90.3.7.2.2 Kanamycin and Amikacin.

Kanamycin [Kantrex] and amikacin [Amikin] are aminoglycoside antibiotics that have good activity against *M. tuberculosis*. Like other aminoglycosides, kanamycin and amikacin are nephrotoxic and may also damage the eighth cranial nerve. Neither drug is absorbed from the GI tract, and hence administration is parenteral (IM or IV). The adult dosage for both routes is 15 mg/kg/day; the pediatric dosage is 15 to 30 mg/kg/day. The pharmacology of kanamycin, amikacin, and the other aminoglycosides is discussed in [Chapter 86](#).

90.3.7.3 Other Second-Line Drugs

90.3.7.3.1 Para-Aminosalicylic Acid.

Actions and Uses. PAS [Paser Granules] is similar in structure and actions to the sulfonamides. Like the sulfonamides, PAS exerts its antibacterial effects by inhibiting synthesis of folic acid. However, in contrast to the sulfonamides, which are broad-spectrum antibiotics, PAS is active only against mycobacteria. In the United States, PAS has been employed primarily as a substitute for ethambutol in pediatric patients. The drug is always used in combination with other anti-TB agents.

90.3.7.3.2 Pharmacokinetics.

PAS is administered orally, and absorption is good. The drug is distributed widely to most tissues and body fluids, although levels in CSF remain low. PAS undergoes extensive hepatic metabolism. Metabolites and parent drug are excreted in the urine.

90.3.7.3.3 Adverse Effects.

PAS is poorly tolerated by adults; children accept the drug somewhat better. The most frequent adverse effects are GI disturbances (nausea, vomiting, diarrhea). Because PAS is administered in large doses as a sodium salt, substantial sodium loading may occur. Additional adverse effects are allergic reactions, hepatotoxicity, and goiter.

90.3.7.3.4 Preparations, Dosage, and Administration.

Para-aminosalicylate [Paser Granules] is supplied in 4-gm packets containing delayed-release granules. Administration is oral. If stomach upset occurs, PAS may be administered with food. The daily dosage for adults is 4 gm 3 times a day. The daily dosage for children is 275 to 420 mg/kg in three to four divided doses. The drug loses its effectiveness if exposed to heat, and hence should be stored cool (below 59°F).

90.3.7.3.5 Ethionamide.

Actions and Uses. Ethionamide [Trecator], a relative of isoniazid, is active against mycobacteria, but less so than isoniazid itself. Ethionamide is administered with other anti-TB drugs to treat TB that is resistant to first-line agents. Gastrointestinal disturbances limit patient acceptance. Ethionamide is the least well tolerated of all anti-TB agents, and hence should be used only when there is no alternative.

90.3.7.3.6 Pharmacokinetics.

Ethionamide is readily absorbed following oral administration. The drug is widely distributed to tissues and body fluids, including the CSF. Ethionamide undergoes extensive metabolism and is excreted in the urine, primarily as metabolites.

1046

1047

90.3.7.3.7 Adverse Effects.

Gastrointestinal effects (anorexia, nausea, vomiting, diarrhea, metallic taste) occur often; intolerance of these effects frequently leads to discontinuation. Ethionamide is toxic to the liver. Hepatotoxicity is assessed by measuring serum transaminases (AST, ALT) prior to treatment and periodically thereafter. Additional adverse effects include peripheral neuropathy, CNS effects (convulsions, mental disturbance), and allergic reactions.

90.3.7.3.8 Preparations, Dosage, and Administration.

Ethionamide [Trecator] is supplied in 250-mg tablets. The usual adult dosage is 15 to 20 mg/kg taken once daily or in two or three divided doses (to reduce GI upset). The recommended pediatric dosage is 15 to 20 mg/kg/day taken in two or three divided doses.

90.3.7.3.9 Cycloserine. Actions and Uses.

Cycloserine [Seromycin Pulvules] is an antibiotic produced by a species of *Streptomyces*. The drug is bacteriostatic and acts by inhibiting cell wall synthesis. Cycloserine is used against TB resistant to first-line drugs.

90.3.7.3.10 Pharmacokinetics.

Cycloserine is rapidly absorbed following oral administration. The drug is widely distributed to tissues and body fluids, including the CSF. Elimination is by hepatic metabolism and renal excretion; about 50% of the drug leaves the body unchanged in the urine. Cycloserine may accumulate to toxic levels in patients with renal impairment.

90.3.7.3.11 Adverse Effects.

CNS effects occur frequently and can be severe. Possible reactions include anxiety, depression, confusion, hallucinations, paranoia, hyperreflexia, and seizures. Psychotic episodes occur in approximately 10% of patients; symptoms usually subside within 2 weeks following drug withdrawal. Pyridoxine may prevent neurotoxic effects. Other adverse effects include peripheral neuropathy, hepatotoxicity, and folate deficiency. To minimize the risk of adverse effects, serum concentrations of cycloserine should be measured periodically; peak concentrations, measured 2 hours after dosing, should be 25 to 35 mcg/mL.

90.3.7.3.12 Preparations, Dosage, and Administration.

Cycloserine [Seromycin Pulvules] is supplied in 250-mg capsules. The initial dosage for adults is 250 mg twice daily for 2 weeks; the maintenance dosage is 500 mg to 1 gm daily in divided doses. The dosage for children is 10 to 20 mg/kg/day.

90.3.8 R207910, a Promising Investigational Drug

R207910 is the working name for the first representative of a new class of antimicrobial drugs, the *diarylquinolines*. This drug works faster and better than all other anti-TB drugs, and may also prove safer. In addition, R207910 does not accelerate the metabolism of other drugs, and hence can be used safely in patients taking drugs for HIV. Because of these attributes, R207910 is considered the most promising agent for TB to emerge in decades.

R207910 is highly effective. In a mouse model of TB, a three-drug regimen consisting of R207910 plus rifampin and pyrazinamide was compared with a conventional three-drug regimen consisting of isoniazid plus rifampin and pyrazinamide. The result? After *one* month with the R207910 regimen, bacterial load was as low as seen after *two* months with the conventional regimen, indicating accelerated bacterial kill. And after *two* months with the R207910 regimen, mycobacteria were cleared entirely from the lungs, an unprecedented outcome. In laboratory tests, R207910 was bactericidal to all isolates of *M. tuberculosis* resistant to conventional therapy, including strains that were multidrug resistant.

R207910 has a unique mechanism of action: Bacterial kill results from inhibiting ATP synthase, an enzyme required by *M. tuberculosis* to make ATP. No other drug shares this mechanism, which explains why there's no cross-resistance between R207910 and conventional drugs. Since humans (and most other bacteria too) make ATP by a different pathway, R207910 should be highly specific for mycobacteria, and should also prove very safe.

R207910 has desirable kinetics. The drug undergoes rapid absorption after oral administration, and distributes to all tissues. Of particular importance, it concentrates in cells of the lungs, reaching levels 10 times those in blood. Furthermore, R207910 remains in the body for days, permitting continued bactericidal effects with just once-a-week dosing.

Although resistance to R207910 is uncommon, it does occur: About 1 in 200 million tubercle bacilli make a form of ATP synthase that is not inhibited by the drug. Accordingly, to prevent

overgrowth with these resistant microbes, the regimen should always contain other anti-TB drugs.

Is R207910 safe and effective in humans? We don't know yet. When the drug was given to 50 healthy volunteers for 2 weeks, no significant side effects were observed. Whether prolonged use in many more patients will yield the same result remains to be seen. Tests of efficacy in patients with active TB are in progress.

^{90.4} DRUGS FOR LEPROSY (HANSEN'S DISEASE)

Leprosy is a chronic infectious disease caused by *M. leprae*, an acid-fast bacillus. The infection is also known as Hansen's disease, in recognition of Gerhard Armauer Hansen, who demonstrated the involvement of *M. leprae* in 1873. Left untreated, leprosy can cause grotesque disfigurement. Fortunately, with the drugs available today, most patients can be cured. As a result, the worldwide incidence of leprosy has declined dramatically—from an estimated 12 million cases in the mid-1980s to 259,017 new cases in 2006. In the United States, only 66 new cases were reported in 2006, and these occurred primarily among immigrants from endemic areas (eg, India, Brazil, Indonesia).

Infection with *M. leprae* affects the skin, peripheral nerves, and mucous membranes of the upper respiratory tract. Characteristic features are (1) skin lesions with local loss of sensation, (2) thickening of peripheral nerves, and (3) acid-fast bacilli in smears from skin lesions.

Leprosy is divided into two main classes: (1) paucibacillary (PB) leprosy and (2) multibacillary (MB) leprosy. Classification is based on clinical manifestations and the presence of *M. leprae* in skin smears. If skin smears are negative, the diagnosis is PB leprosy. Conversely, if any smear is positive, the diagnosis is MB leprosy. In many places, microbiologic analysis of skin smears is either unavailable or unreliable. Hence, in these places, classification must be based on clinical findings alone. In this case, if the patient has one to five skin lesions, the diagnosis is PB leprosy; if the patient has six or more skin lesions, the diagnosis is MB leprosy. The distinction between PB leprosy and MB leprosy is important because treatment differs for the two forms.

^{90.4.1} Overview of Treatment

As with TB, the cornerstone of treatment is multidrug therapy. If just one drug is used, resistance will occur. Most regimens include *rifampin*, the most effective drug for killing *M. leprae*. For patients with *MB leprosy*, the World Health Organization (WHO) recommends 12 months of treatment with three drugs: rifampin, dapsone, and clofazimine. For patients with *PB leprosy*, the

WHO recommends 6 months of treatment with two drugs: rifampin and dapsone. For patients with *single-lesion PB leprosy* (ie, PB leprosy with just one skin lesion), the WHO recommends a single dose of the “ROM” regimen: rifampin, ofloxacin, and minocycline. With all three regimens, the relapse rate is very low (about 0.1%). Accordingly, all three are considered curative. Specific dosages for these regimens are summarized in [Table 89-6](#).

90.4.2 Pharmacology of Individual Antileprosy Drugs

90.4.2.1 Rifampin

The basic pharmacology of rifampin [Rifadin, Rimactane] is discussed above under *Pharmacology of Individual Antituberculosis Drugs*. Discussion here is limited to its use in leprosy.

Rifampin is by far our most effective agent for treating leprosy. In fact, the drug is more effective than any *combination* of other agents. A single dose kills more than 99.9% of viable *M. leprae*. After three monthly doses, less than 0.001% of the initial *M. leprae* population remains. Because of its powerful bactericidal actions, rifampin is a key component of standard antileprosy regimens.

The dosage currently recommended by the WHO is 600 mg *once a month*. In the past, rifampin was administered daily. However, we now know that monthly administration is just as effective. Moreover, monthly administration is much less expensive and minimizes adverse effects, including hepatotoxicity. Resistance can occur if rifampin is used alone. Accordingly, the drug is always combined with other antileprosy agents (eg, dapsone plus clofazimine).

90.4.2.2 Dapsone

90.4.2.2.1 Actions and Uses.

Dapsone, taken orally, is weakly bactericidal to *M. leprae*. The drug is safe, inexpensive, and moderately effective. Dapsone is chemically related to the sulfonamides and shares their mechanism of action: inhibition of folic acid synthesis. Although once employed alone to treat leprosy, dapsone is now employed in combination with other antileprosy drugs, usually rifampin and clofazimine. In 2008, a topical formulation, sold as Aczone, was approved for treating acne (see [chapter 104](#)).

90.4.2.2.2 Pharmacokinetics.

Dapsone is absorbed rapidly and nearly completely from the GI tract. Once in the blood, the drug is widely distributed to tissues and body fluids. Dapsone undergoes hepatic metabolism followed by excretion in the urine. The average half-life is 28 hours.

1047

TABLE 89-6 Adult Regimens for Leprosy, as Recommended by the World Health Organization

Multibacillary Leprosy (Treat 12 Months with all 3 Drugs)	
Rifampin	600 mg once a month, supervised
Dapsone	100 mg daily, self-administered
Clofazimine	300 mg once a month, supervised
	<i>or</i>
	50 mg daily, self-administered
Paucibacillary Leprosy (Treat 6 Months with Both Drugs)	
Rifampin	600 mg once a month, supervised
Dapsone	100 mg daily, self-administered
Single-Lesion Paucibacillary Leprosy (Take all 3 Drugs Once)	
Rifampin	600 mg
Ofloxacin	400 mg
Minocycline	100 mg
Rifampin-Resistant Leprosy (Treat 12 Months)	
First 6 Months (Take All 3 Drugs Daily)	
Clofazimine	50 mg
Ofloxacin	400 mg
Minocycline	100 mg
Next 6 Months (Take Either Pair of Drugs Daily)	
Clofazimine	50 mg
Ofloxacin	400 mg
	<i>or</i>
Clofazimine	50 mg
Minocycline	100 mg

90.4.2.2.3 Adverse Effects.

Dapsone is generally well tolerated. The drug has been taken for years without significant untoward effects. The most common adverse effects are GI disturbances, headache, rash, and

a syndrome that resembles mononucleosis. Hemolytic anemia occurs occasionally; severe reactions are usually limited to patients with profound glucose-6-phosphate dehydrogenase deficiency. Rare reactions include agranulocytosis, exfoliative dermatitis, and hepatitis.

90.4.2.2.4 Preparations, Dosage, and Administration.

Dapsone is formulated in 25- and 100-mg tablets. The usual dosage for adults is 100 mg/day. The dosage for children is 1 mg/kg/day. To prevent emergence of resistance, dapsone is always combined with another antileprosy drug (eg, rifampin, clofazimine).

90.4.2.3 Clofazimine

90.4.2.3.1 Actions and Uses.

Clofazimine [Lamprene] is slowly bactericidal to *M. leprae*. Its mechanism of action is unknown. To prevent emergence of resistance, clofazimine is always combined with another antileprosy drug (eg, rifampin, dapsone). In addition to its antibacterial action, clofazimine has anti-inflammatory actions.

90.4.2.3.2 Pharmacokinetics

Clofazimine is administered orally and undergoes partial absorption. Absorbed drug is retained in fatty tissue and the skin. Because of tissue retention, the half-life of clofazimine is extremely long—about 70 days.

90.4.2.3.3 Adverse Effects.

Clofazimine is very safe. Dangerous reactions are rare. GI symptoms (nausea, vomiting, cramping, diarrhea) are common but mild. The drug frequently imparts a harmless red color to feces, urine, sweat, tears, and saliva. Deposition of clofazimine in the small intestine produces the most serious effects: intestinal obstruction, pain, and bleeding.

Clofazimine causes reversible reddish-black discoloration of the skin in most patients. Pigmentation begins 4 to 8 weeks after the onset of treatment, and generally clears within 12 months of drug cessation. Because it can darken the skin, patients with light-colored skin often find clofazimine unacceptable.

90.4.2.3.4 Preparations, Dosage, and Administration.

Clofazimine [Lamprene] is formulated in 50- and 100-mg capsules. The usual adult dosage is 50 mg daily. Clofazimine is not available in the United States.

90.4.2.4 The ROM Regimen

The ROM regimen (rifampin, ofloxacin, minocycline) is indicated for patients with single-lesion PB leprosy. Treatment consists of one-time dosing with rifampin (600 mg), ofloxacin (400 mg), and minocycline (100 mg). Ofloxacin [Floxin], a fluoroquinolone antibiotic, is discussed in [Chapter 90](#). Minocycline [Minocin], a member of the tetracycline family, is discussed in [Chapter 85](#).

90.5 DRUGS FOR **MYCOBACTERIUM AVIUM** COMPLEX INFECTION

Mycobacterium avium complex (MAC) consists of two nearly indistinguishable organisms: *M. avium* and *M. intracellulare*. Colonization with MAC begins in the lungs or GI tract, but then may spread to the blood, bone marrow, liver, spleen, lymph nodes, brain, kidneys, and skin. Disseminated infection is common in patients with HIV infection; the incidence at autopsy is 50%. Among immunocompetent patients, symptomatic MAC infection is usually limited to the lungs. Signs and symptoms of disseminated MAC infection include fever, night sweats, weight loss, lethargy, anemia, and abnormal liver function tests.

Drug therapy may be done for prophylaxis or to treat active infection. The preferred agents for *prophylaxis* of disseminated infection are *azithromycin* and *clarithromycin*. Regimens for treating *active infection* in immunocompetent hosts should include (1) *azithromycin* or *clarithromycin* plus (2) *ethambutol* plus (3) *rifampin* or *rifabutin*. Additional drugs may be added as needed; options include streptomycin, ciprofloxacin, clofazimine, and amikacin. Treatment of active infection in immunocompetent patients should continue for 12 months after cultures become negative.

Representative regimens for immunocompetent patients are presented in [Table 89-7](#). Regimens for patients with HIV infection are presented in [Chapter 93](#).

1048

TABLE 89-7 Regimens for MAC Infection in Immunocompetent Adults

Pulmonary MAC Daily Regimen Clarithromycin (500 mg twice daily) <i>or</i> azithromycin (250 mg) <i>plus</i> Ethambutol (25 mg/kg for 2 months, then 15 mg/kg thereafter) <i>plus</i> Rifampin (600 mg) <i>or</i> rifabutin (300 mg) <i>may also add</i> Streptomycin (15 mg/kg 3 times a week for 2–6 months) Duration Treat until cultures remain negative for 12 months Disseminated MAC Daily Regimen Clarithromycin (500 mg twice daily) <i>or</i> azithromycin (250–500 mg) <i>plus</i> Ethambutol (15 mg/kg) <i>plus</i> Rifampin (600 mg) <i>or</i> rifabutin (300 mg) <i>may also add</i> Streptomycin (15 mg/kg 3 times a week for 2–6 months) Duration Treat until cultures remain negative for 12 months MAC = <i>Mycobacterium avium</i> complex.

90.5.1

KEY POINTS

- Most people infected with *M. tuberculosis* remain asymptomatic, although they will harbor dormant bacteria for life (in the absence of drug therapy).
- Symptomatic TB can result from reactivation of an old infection or from recent person-to-person transmission of a new infection.

- Drug resistance, and especially multidrug resistance, is a serious impediment to successful therapy of TB.
- The principal cause of drug resistance in TB is inadequate drug therapy, which kills sensitive bacteria while allowing resistant mutants to flourish.
- To prevent emergence of resistance, initial therapy of TB should consist of at least two drugs to which the infection is sensitive, and preferably four. Accordingly, isolates from all patients must undergo testing of drug sensitivity, a process that may take 6 to 16 weeks.
- Therapy of TB is prolonged, lasting from a minimum of 6 months to 2 years and even longer. As a result, patient adherence is a serious issue.
- Adherence can be greatly increased by using directly observed therapy (DOT) combined with intermittent dosing (rather than daily dosing).
- Three methods are employed to evaluate TB therapy: bacteriologic evaluation of sputum, clinical evaluation, and chest radiographs.
- The principal first-line drugs for TB are isoniazid, rifampin, pyrazinamide, and ethambutol.
- For initial therapy of active TB, patients may be given four drugs: isoniazid, rifampin, pyrazinamide, and ethambutol.
- Initial therapy of MDR-TB and XDR-TB may require up to seven drugs.
- Tuberculosis in HIV-positive patients often can be treated with the same regimens used for HIV-negative patients, although the duration of treatment may be longer.
- Isoniazid can cause peripheral neuropathy by depleting pyridoxine (vitamin B₆). Peripheral neuropathy can be reversed or prevented with pyridoxine supplements.
- Isoniazid can injure the liver. The greatest risk factor is advancing age.
- Rifampin induces drug-metabolizing enzymes, and can thereby increase the metabolism of other drugs; important among these are oral contraceptives, warfarin, and certain protease inhibitors and NNRTIs used for HIV infection.

- Like isoniazid, rifampin and pyrazinamide are hepatotoxic. Accordingly, when these three drugs are combined, as they often are, the risk of liver injury can be significant.
- Ethambutol can cause optic neuritis.
- The *tuberculin skin test* (TST)—used to identify people with latent TB—is performed by giving an intradermal injection of PPD (purified protein derivative) and then measuring the zone of induration (hardness) at the site 48 to 72 hours later.
- A new *blood test* for latent TB—QuantiFERON-TB Gold (QFT-G)—is as sensitive as the TST and more specific. Moreover, results with the QFT-G are available faster (within 24 hours) and don't require a return visit to the office.
- Isoniazid, taken daily for 9 months, is the preferred treatment for latent TB.

90.5.2 Summary of Major Nursing Implications*

The nursing implications summarized below are limited to the drug therapy of TB.

90.5.... IMPLICATIONS THAT APPLY TO ALL ANTITUBERCULOSIS DRUGS

90.5.... Promoting Adherence

Treatment of active TB is prolonged and demands concurrent use of two or more drugs; as a result, adherence can be a significant problem. **To promote adherence, educate the patient about the rationale for multidrug therapy and the need for long-term treatment. Encourage patients to take their medication exactly as prescribed, and to continue treatment until the infection has resolved.** Adherence can be greatly increased by using directly observed therapy (DOT) combined with intermittent dosing (rather than daily dosing).

90.5.... Evaluating Treatment

Success is indicated by (1) reductions in fever, malaise, anorexia, cough, and other clinical manifestations of TB (usually within weeks); (2) radiographic evidence of improvement (usually in 3 months); and (3) an absence of *M. tuberculosis* in sputum cultures (usually after 3 to 6 months).

90.5....	ISONIAZID In addition to the implications summarized below, see above for implications on <i>Promoting Adherence</i> and <i>Evaluating Treatment</i> that apply to all anti-TB drugs.	
90.5....	Preadministration Assessment	
90.5....	Therapeutic Goal Treatment of active or latent infection with <i>M. tuberculosis</i>.	
90.5....	Baseline Data Obtain a chest radiograph, microbiologic tests of sputum, and baseline tests of liver function.	
90.5....	Identifying High-Risk Patients Isoniazid is <i>contraindicated</i> for patients with acute liver disease or a history of isoniazid-induced hepatotoxicity. Use with <i>caution</i> in alcohol abusers, diabetic patients, patients with vitamin B₆ deficiency, patients over the age of 50, and patients who are taking phenytoin, rifampin, or pyrazinamide.	1049 1050
90.5....	Implementation: Administration	
90.5....	Routes Oral, IM.	
90.5....	Administration Advise patients to take isoniazid on an empty stomach, either 1 hour before meals or 2 hours after. Advise patients to take the drug with meals if GI upset occurs.	

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Peripheral Neuropathy.

Inform patients about symptoms of peripheral neuropathy (tingling, numbness, burning, or pain in the hands or feet), and instruct them to notify the prescriber if these occur. Peripheral neuritis can be reversed with small daily doses of pyridoxine (vitamin B₆). In patients at high risk of neuropathy (eg, alcohol abusers, diabetic patients), give pyridoxine prophylactically.

Hepatotoxicity.

Isoniazid can cause hepatocellular damage and multilobular hepatic necrosis. **Inform patients about signs of hepatitis (jaundice, anorexia, malaise, fatigue, nausea), and instruct them to notify the prescriber if these develop.** Evaluate patients monthly for signs of hepatitis. Monthly determinations of AST activity may be ordered. If clinical signs of hepatitis appear, or if AST activity exceeds 3 to 5 times the pretreatment baseline, isoniazid should be withdrawn. Daily ingestion of alcohol increases the risk of liver injury; **urge the patient to minimize or eliminate alcohol consumption.**

Minimizing Adverse Interactions

Phenytoin.

Isoniazid can suppress the metabolism of phenytoin, thereby causing phenytoin levels to rise. Plasma phenytoin should be monitored. If necessary, phenytoin dosage should be reduced.

RIFAMPIN

In addition to the implications summarized below, see above for implications on *Promoting Adherence* and *Evaluating Treatment* that apply to all anti-TB drugs.

90.5.... Preadministration Assessment

90.5.... Therapeutic Goal

Treatment of active TB or leprosy.

90.5.... Baseline Data

Obtain a chest radiograph, microbiologic tests of sputum, and baseline tests of liver function.

90.5.... Identifying High-Risk Patients

Rifampin is *contraindicated* for patients taking delavirdine (an NNRTI) and most protease inhibitors.

Use with *caution* in alcohol abusers, patients with liver disease, and patients taking warfarin.

90.5.... Implementation: Administration

90.5.... Routes

Oral, IV.

90.5.... Dosage

Reduce the dosage in patients with liver disease.

90.5.... Administration

Instruct the patient to take oral rifampin once a day, either 1 hour before a meal or 2 hours after.

Administer IV rifampin by slow infusion (over 3 hours).

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Hepatotoxicity.

Rifampin may cause jaundice or hepatitis. **Inform patients about signs of liver dysfunction (anorexia, darkened urine, pale stools, yellow discoloration of eyes or skin), and instruct them to notify the prescriber if these develop.** Monitor patients for signs of liver dysfunction. Tests of liver function should be made prior to treatment and every 2 to 4 weeks thereafter.

Discoloration of Body Fluids.

Inform patients that rifampin may impart a harmless red-orange color to urine, sweat, saliva, and tears. Warn patients that soft contact lenses may undergo permanent staining; advise them to consult an ophthalmologist about continued use of these lenses.

Minimizing Adverse Interactions

Accelerated Metabolism of Other Drugs.

Rifampin can accelerate the metabolism of many drugs, thereby reducing their effects. This action is of particular concern with *oral contraceptives, warfarin, most protease inhibitors, and delavirdine* (an NNRTI). **Advise women taking oral contraceptives to use a nonhormonal form of birth control.** Monitor warfarin effects and increase dosage as needed. Do not combine protease inhibitors or NNRTIs with rifampin.

Pyrazinamide and Isoniazid.

These hepatotoxic anti-TB drugs can increase the risk of liver injury when used with rifampin.

PYRAZINAMIDE

In addition to the implications summarized below, see above for implications on *Promoting Adherence* and *Evaluating Treatment* that apply to all anti-TB drugs.

90.5....	Preadministration Assessment	
90.5....	Therapeutic Goal	
	Treatment of active and latent TB.	
90.5....	Baseline Data	
	Obtain a chest radiograph, microbiologic tests of sputum, and baseline tests of liver function.	1050
90.5....	Identifying High-Risk Patients	1051
	Pyrazinamide is <i>contraindicated</i> for patients with severe liver dysfunction or acute gout.	
	Use with <i>caution</i> in alcohol abusers.	
90.5....	Implementation: Administration	
90.5....	Route	
	Oral.	
90.5....	Administration	
	Usually administered once a day.	
90.5....	Ongoing Evaluation and Interventions	
90.5....	Minimizing Adverse Effects	
90.5....	Hepatotoxicity.	
	Inform patients about symptoms of hepatitis (malaise, anorexia, nausea, vomiting, yellowish discoloration of the skin and eyes), and instruct them to notify the prescriber if these develop. Levels of AST and ALT should be measured prior to treatment and every 2 weeks thereafter. If severe liver injury occurs, pyrazinamide should be withdrawn. The risk of liver injury is increased by concurrent therapy with isoniazid and rifampin, both of which are hepatotoxic.	

ETHAMBUTOL

In addition to the implications summarized below, see above for implications on *Promoting Adherence* and *Evaluating Treatment* that apply to all anti-TB drugs.

Preadministration Assessment

Therapeutic Goal

Treatment of active TB.

Baseline Data

Obtain a chest radiograph, microbiologic tests of sputum, and baseline vision tests.

Identifying High-Risk Patients

Ethambutol is *contraindicated* for patients with optic neuritis.

Implementation: Administration

Route

Oral.

Administration

Usually administered once a day. **Advise patients to take ethambutol with food if GI upset occurs.**

Ongoing Evaluation and Interventions

Minimizing Adverse Effects

Optic Neuritis.

Ethambutol can cause dose-related optic neuritis. Symptoms include blurred vision, altered color discrimination, and constriction of visual fields. Baseline vision tests are required. **Instruct patients to report any alteration in vision (eg, blurring of vision,**

reduced color discrimination). If ocular toxicity develops, ethambutol should be withdrawn at once.

* Patient education information is highlighted as blue text.

⁹¹CHAPTER 90 Miscellaneous Antibacterial Drugs Fluoroquinolones, Metronidazole, Daptomycin, Rifampin, Bacitracin, and Polymyxins

^{91.1}FLUOROQUINOLONES

The fluoroquinolones are fluorinated analogs of nalidixic acid, a narrow-spectrum quinolone antibiotic used only for urinary tract infections (UTIs). However, unlike nalidixic acid, the fluoroquinolones are broad-spectrum agents and have multiple applications. Benefits derive from disrupting DNA replication and cell division. Fluoroquinolones do not disrupt synthesis of proteins or the cell wall. All of the fluoroquinolones can be administered orally. As a result, these drugs are attractive alternatives for people who might otherwise require intravenous antibacterial therapy. Although side effects are generally mild, all fluoroquinolones can cause tendon rupture, usually of the Achilles tendon. Fortunately, the risk is low. Bacterial resistance develops slowly, but has become common in *Neisseria gonorrhoeae*, and hence these drugs are no longer recommended for this infection. Seven fluoroquinolones are currently available for systemic therapy. Five others—gatifloxacin, enoxacin, sparfloxacin, trovafloxacin, and alatrofloxacin—were recently discontinued.

^{91.1.1}Ciprofloxacin

Ciprofloxacin [Cipro] was among the first fluoroquinolones available and will serve as our prototype for the group. The drug, which can be administered PO and IV, is active against a broad spectrum of bacterial pathogens. Ciprofloxacin has been used as an alternative to parenteral antibiotics for treatment of several serious infections. Because it can be administered by mouth, patients receiving ciprofloxacin can be treated at home, rather than going to the hospital for IV antibacterial therapy.

^{91.1.1.1} Mechanism of Action

Ciprofloxacin inhibits two bacterial enzymes: *DNA gyrase* and *topoisomerase IV*. Both are needed for DNA replication and cell division. DNA gyrase converts closed circular DNA into a supercoiled configuration. In the absence of supercoiling, DNA replication cannot take place. Topoisomerase IV helps separate daughter DNA strands during cell division. Since the mammalian equivalents of DNA gyrase and topoisomerase IV are relatively insensitive to fluoroquinolones, cells of the host are spared. Ciprofloxacin is rapidly bactericidal.

91.1.1.2 Antimicrobial Spectrum

Ciprofloxacin is active against a broad spectrum of bacteria, including most aerobic gram-negative bacteria and some gram-positive bacteria. Most urinary tract pathogens, including *Escherichia coli* and *Klebsiella*, are sensitive. The drug is also highly active against most bacteria that cause enteritis (eg, *Salmonella*, *Shigella*, *Campylobacter jejuni*, *E. coli*). Other sensitive organisms include *Bacillus anthracis*, *Pseudomonas aeruginosa*, *Haemophilus influenzae*, meningococci, and many streptococci. Activity against anaerobes is fair to poor. *Clostridium difficile* is resistant.

91.1.1.3 Bacterial Resistance

Resistance to fluoroquinolones has developed during treatment of infections caused by *Staphylococcus aureus*, *Serratia marcescens*, *C. jejuni*, *P. aeruginosa*, and *N. gonorrhoeae*. Two mechanisms appear responsible: (1) alterations in DNA gyrase and topoisomerase IV and (2) increased export of these drugs. Bacteria do not directly inactivate these drugs, and there have been no reports of resistance transfer via R factors.

91.1.1.4 Pharmacokinetics

Ciprofloxacin may be administered orally or IV. Following oral administration, the drug is absorbed rapidly but incompletely. High concentrations are achieved in urine, stool, bile, saliva, bone, and prostate tissue. Drug levels in cerebrospinal fluid remain low. Ciprofloxacin has a plasma half-life of about 4 hours. Elimination is by hepatic metabolism and renal excretion.

91.1.1.5 Therapeutic Uses

Ciprofloxacin is approved for a wide variety of infections. Among these are infections of the respiratory tract, urinary tract, GI tract, bones, joints, skin, and soft tissues. Also, ciprofloxacin is a preferred drug for preventing anthrax in people who have inhaled anthrax spores. Because it is active against a variety of pathogens and can be given orally, ciprofloxacin represents an alternative to parenteral treatment for many serious infections. Owing to high rates of resistance, ciprofloxacin is a poor choice for staphylococcal infections. The drug is not useful against infections caused by anaerobes.

1052

Because of concerns about tendon injury (see below), *systemic* ciprofloxacin is generally avoided in children under 18 years old. Nonetheless, the drug does have two approved pediatric uses: (1) treatment of complicated urinary tract and kidney infections caused by *E. coli*, and (2) postexposure treatment of inhalational anthrax. Ciprofloxacin is the only systemic fluoroquinolone approved for pediatric use.

91.1.1.6 Adverse Effects

Ciprofloxacin can induce a variety of mild adverse effects, including GI reactions (nausea, vomiting, diarrhea, abdominal pain) and central nervous system (CNS) effects (dizziness, headache, restlessness, confusion). *Candida* infections of the pharynx and vagina may develop as a result of treatment. Very rarely, seizures have occurred. In the elderly, ciprofloxacin poses a significant risk of confusion, somnolence, psychosis, and visual disturbances.

Rarely, ciprofloxacin and other fluoroquinolones have caused *tendon rupture*, usually of the Achilles tendon. The incidence is 1 in 10,000 or less. The highest risk is in people age 60 and older, and in people taking glucocorticoids. Risk in children is also elevated. How do fluoroquinolones damage tendons? When given to immature animals, fluoroquinolones disrupt the extracellular matrix of cartilage. A similar mechanism may underlie tendon rupture in humans. Since tendon injury is reversible if diagnosed early, fluoroquinolones should be discontinued at the first sign of tendon pain, swelling, or inflammation. In addition, patients should refrain from exercise until tendinitis has been ruled out. Although there are no controlled studies on the use of ciprofloxacin during pregnancy or lactation, available data indicate that such use poses little or no risk of tendon damage to the fetus or nursing infant.

Ciprofloxacin and other fluoroquinolones pose a risk of *phototoxicity* (severe sunburn), characterized by burning, erythema, exudation, vesicles, blistering, and edema. These can occur following exposure to direct sunlight, indirect sunlight, and sunlamps—even if a sunscreen has been applied. Patients should be warned about phototoxicity and advised to avoid sunlight and sunlamps. People who must go outdoors should wear protective clothing and apply a sunscreen. Ciprofloxacin should be withdrawn at the first sign of a phototoxic reaction (eg, burning sensation, redness, rash).

91.1.1.7 Drug and Food Interactions

91.1.1.7.1 Cationic Compounds.

Absorption of ciprofloxacin can be reduced by compounds that contain cations. Among these are (1) aluminum- or magnesium-containing antacids, (2) iron salts, (3) zinc salts, (4) sucralfate, and (5) milk and other dairy products, all of which contain calcium ions. These cationic agents should be administered at least 6 hours before ciprofloxacin or 2 hours after.

91.1.1.7.2 Elevation of Drug Levels.

Ciprofloxacin can increase plasma levels of several drugs, including *theophylline* (used for asthma), *warfarin* (an anticoagulant), and *tinidazole* (an antifungal drug). Toxicity could result. For patients taking theophylline, drug levels should be monitored and the dosage adjusted accordingly. For patients taking warfarin, prothrombin time should be monitored and the dosage of warfarin reduced as appropriate.

91.1.1.8 Preparations, Dosage, and Administration

91.1.1.8.1 Preparations.

Ciprofloxacin is available for oral and IV administration. For oral therapy, ciprofloxacin is supplied in standard tablets (100, 250, 500, and 750 mg) sold as *Cipro*, extended-release tablets (500 and 1000 mg) sold as *Cipro XR* and *Proquin XR*, and a suspension (250 and 500 mg/5 mL) sold as *Cipro*. For IV therapy, ciprofloxacin is supplied in solution (2 and 10 mg/mL) sold as *Cipro I.V.*

91.1.1.8.2 Dosage and Administration. Oral.

The dosage for urinary tract infections is 250 or 500 mg 2 times a day, usually for 7 to 14 days. For other infections, dosages range from 500 to 750 mg 2 times a day. Dosage should be reduced for patients with renal impairment. Dosages for anthrax prevention are presented below.

91.1.1.8.3 Intravenous.

Intravenous dosages range from 200 to 400 mg every 12 hours. Infusions should be done slowly (over 60 minutes). Dosages for anthrax prevention are presented below.

91.1.1.8.4 Inhalational Anthrax.

Ciprofloxacin is used to reduce the incidence of anthrax or prevent anthrax progression in people who have inhaled *B. anthracis* spores. The dosage for adults is 500 mg PO (or 400 mg IV) every 12 hours for 60 days. The dosage for children is 15 mg/kg PO (or 10 mg/kg IV) every 12 hours for 60 days (with the proviso that individual oral doses not exceed 500 mg, and individual IV doses not exceed 400 mg).

91.1.2 Other Fluoroquinolones

91.1.2.1 Ofloxacin

91.1.2.1.1 Basic Pharmacology.

Ofloxacin [Floxin] is similar to ciprofloxacin in mechanism of action, antimicrobial spectrum, therapeutic applications, and adverse effects. Like ciprofloxacin, the drug may be administered PO or IV. In the absence of food, bioavailability is 90%; food greatly reduces availability. Ofloxacin is widely distributed to tissues and excreted in the urine. Like ciprofloxacin, ofloxacin can cause a variety of mild adverse effects, including nausea, vomiting, headache, and dizziness. In addition, ofloxacin may intensify sensitivity to sunlight, thereby increasing the risk of severe sunburn. Like other fluoroquinolones, ofloxacin poses a risk of tendon rupture. Ofloxacin elevates plasma levels of warfarin, but, in contrast to ciprofloxacin, has little effect on levels of theophylline. Absorption of oral ofloxacin is reduced by cationic substances: milk, milk products, sucralfate, iron and zinc salts, and magnesium- and aluminum-containing antacids.

91.1.2.1.2 Preparations, Dosage, and Administration.

Ofloxacin is available in tablets (200, 300, and 400 mg) for oral administration and in solution (4 and 40 mg/mL) for slow IV infusion; concentrated solutions must be diluted prior to administration. The usual oral dosage is 200 to 400 mg every 12 hours; treatment may last from 1 day to 6 weeks. Dosage should be reduced in patients with renal impairment. Ofloxacin may be taken with or without food.

91.1.2.2 Lomefloxacin

91.1.2.2.1 Actions, Uses, and Pharmacokinetics.

Lomefloxacin [Maxaquin] is similar to ciprofloxacin with regard to mechanism and antimicrobial spectrum. Approved indications are limited to UTIs, acute bronchitis caused by *H. influenzae* or *Moraxella catarrhalis*, and preoperative prophylaxis of infection. Administration is oral, and bioavailability is high (98%), even in the presence of food. The drug is widely distributed to tissues and eliminated by the kidneys. Lomefloxacin has a prolonged half-life that permits once-a-day dosing.

91.1.2.2.2 Adverse Effects.

Phototoxicity reactions (eg, sunburn, blistering) can be moderate to severe. These can occur following exposure to direct sunlight, indirect sunlight, and sunlamps—even if a sunscreen has been applied. Patients should be warned about phototoxicity and advised to avoid sunlight and sunlamps. Lomefloxacin should be withdrawn at the first sign of a phototoxic reaction (eg, burning sensation, redness, rash).

Like ciprofloxacin, lomefloxacin can cause various mild adverse effects, including nausea, vomiting, headache, and dizziness. Like other fluoroquinolones, lomefloxacin poses a risk of tendon rupture. Rarely, patients have developed peripheral neuropathy, manifesting as pain, burning, tingling, numbness, or weakness, as well as deficits in light touch, temperature and position sense, and strength.

91.1.2.2.3 Drug and Food Interactions.

Absorption of lomefloxacin is reduced by magnesium- and aluminum-containing antacids, iron and zinc salts, sucralfate, and milk products. In contrast to ciprofloxacin, lomefloxacin does not elevate plasma levels of theophylline.

91.1.2.2.4 Preparations, Dosage, and Administration.

Lomefloxacin is available in 400-mg tablets for oral dosing. The drug may be taken without regard to meals. The usual dosage is 400 mg once a day for 10 to 14 days. Dosage should be reduced in patients with renal impairment.

91.1.2.3 Sparfloxacin

91.1.2.3.1 Actions and Uses.

Sparfloxacin [Zagam] is an oral fluoroquinolone approved for once-daily treatment of community-acquired pneumonia (CAP) and acute bacterial exacerbations of chronic bronchitis. The drug is active against virtually all common respiratory tract pathogens, including drug resistant strains of *Streptococcus pneumoniae*, a major cause of CAP. Despite its efficacy, sparfloxacin has been withdrawn from the market.

1053

1054

91.1.2.3.2 Adverse Effects.

Sparfloxacin is generally well tolerated. However, it can prolong the QT interval, thereby posing a risk of *dysrhythmias*. Accordingly, the drug should be avoided by patients with pre-existing QT prolongation and by patients taking drugs that can prolong the QT interval (eg, quinidine, sotalol). Like other fluoroquinolones, sparfloxacin may pose a risk of tendon injury and phototoxicity. Additional side effects include tendinitis, GI disturbances (nausea, diarrhea, abdominal discomfort), headache, dizziness, and insomnia.

91.1.2.3.3 Drug Interactions.

As with other fluoroquinolones, absorption of sparfloxacin is reduced by cations (eg, magnesium- and aluminum-containing antacids, zinc and iron salts, milk products, sucralfate). In contrast to some other fluoroquinolones, sparfloxacin does not elevate levels of theophylline.

91.1.2.4 Trovafloxacin and Alatrofloxacin

Trovafloxacin [Trovan] and its prodrug form, alatrofloxacin [Trovan IV], are active against more bacterial pathogens than any other fluoroquinolone. Unfortunately, within a year of their introduction in 1998, reports of drug-induced liver dysfunction began to appear, including several cases of fatal liver failure. Symptomatic pancreatitis has also been reported. Because of these serious adverse effects, and because safe and effective alternatives are available, these drugs have been withdrawn.

91.1.2.5 Moxifloxacin

91.1.2.5.1 Basic Pharmacology.

Moxifloxacin [Avelox] is a broad-spectrum fluoroquinolone indicated for respiratory tract infections (CAP, acute sinusitis, acute exacerbations of chronic bronchitis), intra-abdominal infections, and infections of the skin and skin structures. Administration is oral or IV. The drug is well absorbed from the GI tract, undergoes wide distribution, and is eliminated by hepatic metabolism and renal excretion. Side effects are generally mild, the most common being nausea, vomiting, diarrhea, stomach pain, dizziness, and altered sense of taste. Like other fluoroquinolones, moxifloxacin can cause tendon rupture, and may pose a risk of phototoxicity. The drug does not increase levels of warfarin or digoxin, but does prolong the QT interval, and hence may pose a risk of dysrhythmias. Accordingly, moxifloxacin should not be given to patients taking prodysrhythmic drugs or to those with hypokalemia or pre-existing QT prolongation.

91.1.2.5.2 Preparations, Dosage, and Administration.

For systemic therapy, moxifloxacin [Avelox, Avelox I.V.] is available in 400-mg tablets and in solution for IV infusion. Oral and IV dosages are the same. The dosage for sinusitis and pneumonia is 400 mg once a day for 10 days; the dosage for bronchitis is 400 mg once a day for 5 days. Oral dosing may be done without regard to meals. However, because absorption can be reduced by cationic substances (eg, milk, sucralfate, iron and zinc salts, magnesium- or aluminum-containing antacids), moxifloxacin should be administered at least 4 hours before these agents or 8 hours after.

91.1.2.6 Norfloxacin

Norfloxacin [Noroxin] is a fluoroquinolone antibiotic with an antimicrobial spectrum like that of ciprofloxacin. The drug is used for oral therapy of UTIs and prostatitis.

91.1.2.6.1 Pharmacokinetics.

Norfloxacin undergoes rapid but incomplete absorption from the GI tract. The drug is widely distributed to body tissues and fluids. Excretion is primarily renal, resulting in high concentrations in the urine. About 30% of the drug is eliminated in the bile and feces. In

patients with normal kidney function, the half-life is approximately 4 hours; this value doubles in patients with renal impairment.

91.1.2.6.2 Therapeutic Uses.

Norfloxacin is approved for prostatitis caused by *E. coli* and for UTIs caused by *P. aeruginosa* and other gram-negative bacteria that can display multiple drug resistance. The drug is also approved for uncomplicated urethral and cervical gonorrhea, but is no longer recommended for this use.

91.1.2.6.3 Adverse Effects.

Norfloxacin is generally well tolerated. Gastrointestinal effects (nausea, vomiting, anorexia) have been most frequent. The drug has produced a variety of CNS reactions, including headache, dizziness, drowsiness, lightheadedness, depression, and disturbance of vision. Skin rash develops occasionally. Like other fluoroquinolones, norfloxacin poses a risk of tendon rupture and phototoxicity.

91.1.2.6.4 Drug and Food Interactions.

Norfloxacin shares the same interactions as ciprofloxacin. Absorption is suppressed by cationic agents, including milk products, aluminum- and magnesium-containing antacids, iron and zinc salts, and sucralfate. The drug can elevate levels of theophylline and intensify effects of warfarin.

91.1.2.6.5 Preparations, Dosage, and Administration.

Norfloxacin [Noroxin] is supplied in 400-mg tablets. The drug should be taken on an empty stomach with a full glass of water. For uncomplicated UTIs, the usual dosage is 400 mg twice daily for 3 days. Prolonged treatment (10 days to 3 weeks) is employed for patients with complicated infections of the urinary tract. Dosage should be reduced in patients with renal impairment.

91.1.2.7 Levofloxacin

Levofloxacin [Levaquin] is active against *Strep. pneumoniae* (also known as pneumococcus), *H. influenzae*, *Staph. aureus*, *Enterococcus faecalis*, *Streptococcus pyogenes*, and *Proteus mirabilis*. Approved indications include urinary tract infections, chronic bacterial prostatitis,

inhalational anthrax, complicated skin and skin structure infections, and certain respiratory tract infections: acute maxillary sinusitis, acute bacterial exacerbations of chronic bronchitis, and CAP, including CAP caused by penicillin-resistant pneumococci. Possible adverse effects include peripheral neuropathy, rhabdomyolysis, tendon rupture, and phototoxicity. To treat systemic infections, levofloxacin may be administered PO or IV. Absorption from the GI tract is reduced by cationic substances (eg, magnesium- and aluminum-containing antacids, zinc and iron salts, sucralfate, milk and milk products) but not by most foods. Levofloxacin is available in tablets (250, 500, and 750 mg), an oral solution (25 mg/mL), and solution for injection (5 and 25 mg/mL). The usual dosage is 500 mg once a day for 7 to 14 days. In patients with renal impairment, the dosage is 500 mg every 48 hours.

91.1.2.8 Gemifloxacin

91.1.2.8.1 Therapeutic Use.

Gemifloxacin [Factive] is an oral fluoroquinolone approved for two *respiratory tract infections* in adults: (1) mild to moderate CAP and (2) acute bacterial exacerbations of chronic bronchitis (ABECB). The drug is active against *H. influenzae*, *Moraxella catarrhalis*, *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, *Legionella pneumophila*, and *Strep. pneumoniae*, including strains that are multidrug resistant. Gemifloxacin causes a high incidence of rash and, compared with older fluoroquinolones used for respiratory infections, has no significant advantages and costs more. Accordingly, the older agents—levofloxacin and moxifloxacin—are preferred.

91.1.2.8.2 Adverse Effects.

Gemifloxacin is generally well tolerated. The most common reactions are diarrhea, rash, nausea, headache, abdominal pain, vomiting, dizziness, and altered sense of taste. In addition, the drug may cause tendon injury, phototoxicity, hypersensitivity reactions, and liver damage. Like some other fluoroquinolones, gemifloxacin can prolong the QT interval, thereby posing a risk of dysrhythmias. Accordingly, the drug should not be used by patients taking prodysrhythmic drugs or those with hypokalemia or pre-existing QT prolongation.

The incidence of *rash* with gemifloxacin is much higher than with other fluoroquinolones. Women under 40 years of age are at greatest risk. Symptoms are severe in about 10% of patients who develop a rash; in the rest, symptoms are mild to moderate. As a rule, gemifloxacin-induced rash resolves spontaneously in 1 to 2 weeks, although some patients

require treatment with systemic glucocorticoids. If rash develops, gemifloxacin should be discontinued.

91.1.2.8.3 Drug Interactions.

As with ciprofloxacin, absorption of gemifloxacin can be reduced by compounds that contain cations. Among these are iron salts, zinc salts, sucralfate, aluminum- or magnesium-containing antacids, and milk and other dairy products, which contain calcium ions. To ensure adequate absorption, these cationic agents should be administered at least 6 hours before gemifloxacin or 2 hours after.

91.1.2.8.4 Preparations, Dosage, and Administration.

Gemifloxacin [Factive] is available in 320-mg tablets for oral dosing, with or without food. The dosage for CAP is 320 mg once a day for 7 days, and the dosage for ABECB is 320 mg once a day for 5 days. For patients with severe renal impairment, the dosage should be reduced to 160 mg once a day. To prevent high concentrations in the urine, all patients should consume liberal amounts of fluid.

91.2 ADDITIONAL ANTIBACTERIAL DRUGS

91.2.1 Metronidazole

Metronidazole [Flagyl, Protostat] is used for protozoal infections and infections caused by obligate anaerobic bacteria. The basic pharmacology of metronidazole is discussed in [Chapter 98](#), as is the drug's use against protozoal infections. Consideration here is limited to antibacterial applications.

91.2.1.1 Mechanism of Antibacterial Action.

Metronidazole is lethal to anaerobic organisms only. To exert bactericidal effects, metronidazole must first be taken up by cells and then converted into its active form; only anaerobes can perform the conversion. The active form interacts with DNA to cause strand breakage and loss of helical structure, effects that result in inhibition of nucleic acid synthesis and, ultimately, cell death. Since aerobic bacteria are unable to activate metronidazole, they are insensitive to the drug.

1054

1055

91.2.1.2 Antibacterial Spectrum.

Metronidazole is active against obligate anaerobes only. Sensitive bacterial pathogens include *Bacteroides fragilis* (and other *Bacteroides* species), *C. difficile* (and other *Clostridium* species), *Fusobacterium* species, *Gardnerella vaginalis*, *Peptococcus* species, and *Peptostreptococcus* species.

91.2.1.3 Therapeutic Uses.

Metronidazole is active against a variety of anaerobic bacterial infections, including infections of the CNS, abdominal organs, bones and joints, skin and soft tissues, and genitourinary tract. Frequently, such infections also involve aerobic bacteria, and hence therapy must include a drug active against them. Metronidazole is a drug of choice for antibiotic-associated colitis caused by *C. difficile*. In addition, the drug is employed for prophylaxis in surgical procedures associated with a high risk of infection by anaerobes (eg, colorectal surgery, abdominal surgery, vaginal surgery). Metronidazole is also used in combination with a tetracycline and bismuth subsalicylate to eradicate *Helicobacter pylori* in people with peptic ulcer disease. Development of resistance to metronidazole is rare.

91.2.1.4 Preparations, Dosage, and Administration.

For initial treatment of serious bacterial infections, metronidazole is administered by IV infusion. Under appropriate conditions, the patient may switch to oral therapy.

91.2.1.5 Intravenous Formulations.

Metronidazole is available in two formulations—powder and solution—for IV use. The powdered form [Flagyl IV] is supplied in 500-mg vials and must be reconstituted prior to use (see below). The solution (generic only) contains 5 mg of metronidazole per milliliter and is ready for IV use.

91.2.1.6 Preparation of Powdered Metronidazole for IV Infusion.

The powder is readied for infusion in three steps: (1) reconstitution, (2) dilution in IV solution, and (3) neutralization. These steps must be performed in the order given. The powder is reconstituted using 4.4 mL of any of the following liquids: sterile water for injection, bacteriostatic water for injection, 0.9% sodium chloride injection, or bacteriostatic 0.9%

sodium chloride injection. The resulting concentrated solution contains approximately 100 mg of metronidazole per milliliter. This solution is then diluted to a concentration of 8 mg/mL (or less) using any of the following IV solutions: 0.9% sodium chloride injection, 5% dextrose injection, or lactated Ringer's injection. Neutralization of the diluted solution is accomplished by adding 5 mEq of sodium bicarbonate injection for each 500 mg of metronidazole present; this procedure should elevate pH to a value between 6 and 7. Neutralized solutions should not be refrigerated, because cooling may cause metronidazole to precipitate.

91.2.1.7 Intravenous Dosage and Administration.

Infusions must be done slowly (over a 1-hour span). Therapy of anaerobic infections in adults is initiated with a loading dose of 15 mg/kg. After this, maintenance doses of 7.5 mg/kg are given every 6 to 8 hours. Treatment duration is usually 1 to 2 weeks. Patients with renal impairment and those receiving prolonged treatment may need a reduced dosage to avoid toxicity from drug accumulation.

91.2.1.8 Oral Preparations and Dosage.

Metronidazole [Flagyl, Flagyl ER, Flagyl 375, Protostat] is supplied in capsules (375 mg), standard tablets (250 and 500 mg), and extended-release tablets (750 mg). The adult dosage for anaerobic infections is 7.5 mg/kg every 6 hours. For bacterial vaginosis in adults, a dosage of 750 mg (extended-release formulation) once daily for 7 days is effective. Pseudomembranous colitis caused by *C. difficile* is treated with 500 mg 3 times a day for 7 to 15 days.

91.2.2 Daptomycin

Daptomycin [Cubicin] is the first representative of a new class of antibiotics, the *cyclic lipopeptides*. The drug has a unique mechanism of action and can rapidly kill virtually all clinically relevant gram-positive bacteria, including methicillin-resistant *Staph. aureus*. Daptomycin is devoid of significant drug interactions, and the only notable side effect is possible muscle injury. The drug is given once a day by IV infusion, and there is no need to monitor its plasma level.

91.2.2.1 Mechanism of Action.

Daptomycin has a novel mechanism of action. The drug inserts itself into the bacterial cell membrane, and thereby forms channels that permit efflux of intracellular potassium (and possibly other cytoplasmic ions). Loss of intracellular ions has two effects: it (1) depolarizes

the cell membrane, and (2) inhibits synthesis of DNA, RNA, and proteins, and thereby causes cell death.

91.2.2.2 Antibacterial Spectrum.

Daptomycin is active only against *gram-positive bacteria*. The drug cannot penetrate the outer membrane of gram-negative bacteria, and hence cannot harm them. Daptomycin is rapidly bactericidal to staphylococci (including methicillin- and vancomycin-resistant *Staph. aureus* and methicillin-resistant *Staph. epidermidis*), enterococci (including vancomycin-resistant *E. faecium* and *E. faecalis*), streptococci (including penicillin-resistant *Strep. pneumoniae*), and most other aerobic and anaerobic gram-positive bacteria. As a rule, daptomycin is more rapidly bactericidal than either vancomycin, linezolid, or quinupristin/dalfopristin.

91.2.2.3 Therapeutic Use.

Daptomycin has two approved indications: (1) bloodstream infection with *Staph. aureus*, and (2) complicated skin and skin structure infections caused by susceptible strains of the following gram-positive bacteria: *Staph. aureus* (including methicillin-resistant strains), *Strep. pyogenes*, *Strep. agalactiae*, *Strep. dysgalactiae* subspecies *equisimilis*, and *E. faecalis* (vancomycin-susceptible strains only). The drug is being tested for other possible uses, including endocarditis and infections caused by vancomycin-resistant enterococci. Daptomycin should *not* be used for CAP. Why? Because clinical trials have shown that, in patients receiving daptomycin, the rate of death and serious cardiorespiratory events is higher than in patients receiving equally effective alternatives.

91.2.2.4 Resistance.

Out of more than 1000 patients receiving daptomycin in clinical trials, only 2 had infections resistant to the drug. The mechanism of resistance has not been identified. There is no known mechanism by which resistance can be transferred from one bacterium to another. Also, there is no cross-resistance between daptomycin and drugs in any other class of antibiotics.

91.2.2.5 Pharmacokinetics.

Daptomycin is administered by IV infusion, and a significant fraction (92%) becomes bound to plasma proteins. The drug undergoes minimal metabolism, and most of each dose is excreted unchanged in the urine. In patients with normal renal function, the half-life is 9 hours.

However, in those with severe renal impairment (creatinine clearance less than 30 mL/min),

and in those on hemodialysis or continuous ambulatory peritoneal dialysis (CAPD), the half-life increases threefold. As a result, if the dosage is not reduced, plasma drug levels can rise dangerously high.

91.2.2.6 Adverse Effects.

Daptomycin is generally well tolerated. The most common adverse effects are constipation (6.2%), nausea (5.8%), diarrhea (5.2%), injection-site reactions (5.8%), headache (5.4%), insomnia (4.5%), and rash (4.3%).

Daptomycin may pose a small risk of *myopathy* (muscle injury). In clinical trials with doses that were larger and more frequent than those used now, patients often experienced muscle pain and weakness in association with increased levels of creatine phosphokinase (CPK), a marker for muscle injury. However, with currently approved doses, elevation of CPK is rare. Nonetheless, patients should be warned about possible muscle injury, and told to report any muscle pain or weakness. In addition, CPK levels should be measured weekly. If the level rises markedly (to more than 10 times the upper limit of normal), daptomycin should be discontinued. Daptomycin should also be discontinued in patients who report muscle pain or weakness in conjunction with a more moderate rise in CPK.

91.2.2.7 Drug Interactions.

Daptomycin appears devoid of significant drug interactions. It does not induce or inhibit cytochrome P450, and hence should not affect drugs that are metabolized by this enzyme system. In clinical studies, daptomycin did not affect the kinetics of warfarin, simvastatin, or aztreonam. Concurrent use of daptomycin plus tobramycin caused a moderate increase in daptomycin levels and a moderate decrease in tobramycin levels. Accordingly, caution is needed when these drugs are combined.

Like daptomycin, the HMG-CoA reductase inhibitors (eg, simvastatin [Zocor]) can cause myopathy. However, in clinical trials, no patient receiving simvastatin plus daptomycin developed signs of muscle injury. Nonetheless, given our limited experience with daptomycin, it may be prudent to suspend HMG-CoA reductase inhibitors when daptomycin is being used.

91.2.2.8 Preparations, Dosage, and Administration.

Daptomycin [Cubicin] is available as a powder in 500-mg single-use vials. Following reconstitution in 0.9% sodium chloride, the drug is given by a slow (30-minute) IV infusion.

1055

For patients with normal renal function, the dosage is 4 mg/kg once every 24 hours. For patients with severe renal impairment, and for those on hemodialysis or CAPD, the dosage is 4 mg/kg once every 48 hours. Daptomycin powder should be stored refrigerated at 2°C to 8°C (36°F to 46°F). After reconstitution, the solution may be stored at room temperature for 12 hours or refrigerated for 48 hours. Daptomycin is compatible with 0.9% sodium chloride solution and lactated Ringer's solution, but not with solutions that contain dextrose.

91.2.3 Rifampin

Rifampin [Rifadin, Rimactane] is a broad-spectrum antibacterial agent employed primarily for tuberculosis (see [Chapter 89](#)). However, the drug is also used against several nontuberculous infections. Rifampin is useful for treating *asymptomatic carriers of Neisseria meningitidis*, but is not given to treat active meningococcal infection. Unlabeled uses include treatment of leprosy, gram-negative bacteremia in infancy, and infections caused by *Staph. epidermidis* and *Staph. aureus* (eg, endocarditis, osteomyelitis, prostatitis). Rifampin has also been employed for prophylaxis of meningitis due to *H. influenzae*. Because resistance can develop rapidly, established bacterial infections should not be treated with rifampin alone. The basic pharmacology of rifampin and its use in tuberculosis are presented in [Chapter 89](#).

91.2.4 Rifaximin

Rifaximin [Xifaxan] is a nonabsorbable analog of rifampin approved for traveler's diarrhea caused by *E. coli* in patients at least 12 years old. The drug is not effective against severe diarrhea associated with fever or bloody stools, and hence should not be used if these are present. Like rifampin, rifaximin inhibits bacterial DNA-dependent RNA polymerase, and thereby inhibits RNA synthesis, resulting in inhibition of protein synthesis and subsequent bacterial death.

Rifaximin is administered by mouth, and very little (less than 0.4%) is absorbed. As a result, the drug achieves high concentrations in the intestinal tract, and then is excreted unchanged in the stool.

Rifaximin is well tolerated. Gastrointestinal effects—nausea, flatulence, defecation urgency—occur in some patients. Because so little drug is absorbed, systemic effects are minimal. However, studies in rats and rabbits indicate that rifaximin is teratogenic, and hence should not be used by pregnant women. There have been postmarketing reports of hypersensitivity reactions

(rash, allergic dermatitis, urticaria, pruritus, angioneurotic edema), but rifaximin has not been clearly identified as the cause.

Rifaximin is available in 200-mg tablets for oral use. The recommended dosage is 200 mg 3 times a day for 3 days. Rifaximin may be taken with or without food.

91.2.5 Bacitracin

Bacitracin is a polypeptide antibiotic produced by a strain of *Bacillus subtilis*. The drug is almost always employed topically. Because systemic administration can cause serious toxicity, and because superior systemic agents are available, bacitracin is no longer used for systemic infections.

91.2.5.1 Mechanism of Action and Antimicrobial Spectrum.

Bacitracin inhibits synthesis of the bacterial cell wall, thereby promoting cell lysis and death. The drug is active against most gram-positive bacteria, including staphylococci, streptococci, and *C. difficile*. *Neisseria* species and *H. influenzae* are also susceptible, but most other gram-negative bacteria are resistant. Acquisition of resistance by sensitive organisms is uncommon.

91.2.5.2 Adverse Effects.

Rarely, topical bacitracin causes local hypersensitivity reactions. Parenteral (IM) administration can produce severe nephrotoxicity.

91.2.5.3 Therapeutic Uses.

Bacitracin is used for topical treatment of bacterial infections. The drug is very active against staphylococci and group A streptococci, the pathogens that cause most acute infections of the skin. Because of this activity, bacitracin has been marketed in a variety of topical preparations for treatment of skin infections. Many of these preparations contain additional antibiotics, usually polymyxin B, neomycin, or both.

91.2.6 Polymyxin B

Polymyxin B is a bactericidal drug employed primarily for local effects. Because of serious systemic toxicity, parenteral administration is rare.

91.2.6.1 Antibacterial Spectrum and Mechanism of Action.

Polymyxin B is bactericidal to a broad spectrum of aerobic, gram-negative bacilli. Gram-positive bacteria and most anaerobes are resistant.

Bactericidal effects result from binding of polymyxin B to the bacterial cell membrane, an action that disrupts membrane structure and thereby increases membrane permeability. The increase in permeability leads to inhibition of cellular respiration and cell death. The resistance displayed by gram-positive bacteria has been attributed to the thick gram-positive cell wall, a structure that may block access of polymyxin B to the cell membrane.

91.2.6.2 Therapeutic Uses.

Polymyxin B is used primarily for topical treatment of the eyes, ears, and skin. Preparations designed for application to the skin frequently contain other antibiotics, such as bacitracin and neomycin. In addition to its topical uses, polymyxin B (together with neomycin) has been employed as a bladder irrigant to prevent infection in patients with indwelling catheters.

Parenteral use is extremely limited; polymyxin B is not a drug of choice for any systemic infection. The primary indication for parenteral polymyxin B is serious infection caused by *P. aeruginosa*. Polymyxin B may be given when preferred drugs have been ineffective or intolerable.

91.2.6.3 Adverse Effects.

The major adverse effects associated with parenteral therapy are neurotoxicity and nephrotoxicity. Both occur frequently and limit systemic use of the drug. Polymyxin B is not absorbed when applied topically, and hence topical use does not cause systemic effects. Rarely, topical polymyxin B produces hypersensitivity.

91.2.6.3.1

KEY POINTS

- Fluoroquinolones are broad-spectrum antibiotics with a wide variety of clinical applications.
- Patients who might otherwise require hospitalization for parenteral antibacterial therapy can often be treated as outpatients with an oral fluoroquinolone.

- Fluoroquinolones act by inhibiting bacterial DNA gyrase and topoisomerase IV.
- Because fluoroquinolones can cause tendon rupture, they should be discontinued at the first sign of tendon pain or inflammation. Also, the patient should not exercise until tendinitis has been ruled out.
- Fluoroquinolones pose a risk of phototoxicity. Accordingly, patients should avoid sunlight and sunlamps, and should use protective clothing and a sunscreen if they must go outdoors.
- Absorption of fluoroquinolones can be reduced by cationic substances, including milk products (calcium), aluminum- and magnesium-containing antacids, iron and zinc salts, and sucralfate.
- In addition to its use against protozoa, metronidazole is used against infections caused by obligate anaerobic bacteria (eg, *Bacteroides fragilis*, *C. difficile*).

⁹²CHAPTER 91 Antifungal Agents

The antifungal agents fall into two major groups: drugs for *systemic mycoses* (ie, systemic fungal infections) and drugs for *superficial mycoses*. A few drugs are used for both. Systemic infections occur much less frequently than superficial infections, but are much more dangerous. Accordingly, therapy of systemic mycoses is our main focus.

^{92.1}DRUGS FOR SYSTEMIC MYCOSES

Systemic mycoses can be subdivided into two categories: opportunistic infections and nonopportunistic infections. The opportunistic mycoses—*candidiasis*, *aspergillosis*, *cryptococcosis*, and *mucormycosis*—are seen primarily in debilitated or immunocompromised hosts. In contrast, nonopportunistic infections can occur in any host. These latter mycoses, which are relatively uncommon, include *sporotrichosis*, *blastomycosis*, *histoplasmosis*, and *coccidioidomycosis*. Treating systemic mycoses can be difficult: These infections often resist treatment and hence may require prolonged therapy with drugs that frequently prove toxic. Drugs of choice for systemic mycoses are summarized in [Table 91-1](#).

The systemic antifungal drugs fall into four classes: polyene antibiotics, azoles, echinocandins, and pyrimidine analogs. Class members and mechanisms of action are summarized in [Table 91-2](#).

^{92.1.1} Amphotericin B, a Polyene Antibiotic

Amphotericin B [Abelcet, Amphotec, AmBisome] belongs to a group of drugs known as *polyene antibiotics*, so named because their structures contain a series of conjugated double bonds. Nystatin, another antifungal drug, is in the same family.

Amphotericin B—an important but dangerous drug—is active against a broad spectrum of pathogenic fungi and a drug of choice for most systemic mycoses (see [Table 91-1](#)).

Unfortunately, amphotericin B is highly toxic: To varying degrees, infusion reactions and renal damage occur in all patients. Because of its potential for harm, amphotericin B should be employed only against infections that are progressive and potentially fatal.

Amphotericin B is available in four formulations: a conventional formulation (amphotericin B deoxycholate) and three lipid-based formulations. The lipid-based formulations are as effective as the conventional formulation and cause less toxicity—but are much more expensive. For treatment of systemic mycoses, all formulations are administered by IV infusion. Infusions are given daily or every other day for several months.

1057

1058

TABLE 91-1 Drugs of Choice for Systemic Mycoses

Infection	Causative Organism	Drugs of Choice	Alternative Drugs
Aspergillosis	<i>Aspergillus</i> species	Voriconazole	Amphotericin B, itraconazole, posaconazole, caspofungin, micafungin
Blastomycosis	<i>Blastomyces dermatitidis</i>	Amphotericin B <i>or</i> itraconazole	No alternative recommended
Candidiasis	<i>Candida</i> species	Amphotericin B <i>or</i> fluconazole, either one ± flucytosine	Itraconazole, voriconazole, caspofungin
Coccidioidomycosis	<i>Coccidioides immitis</i>	Amphotericin B <i>or</i> fluconazole	Itraconazole, ketoconazole
Cryptococcosis	<i>Cryptococcus neoformans</i>	Amphotericin B ± flucytosine	Itraconazole
Chronic suppression		Fluconazole	Amphotericin B
Histoplasmosis	<i>Histoplasma capsulatum</i>	Amphotericin B <i>or</i> itraconazole	Fluconazole, ketoconazole
Chronic suppression		Itraconazole	Amphotericin B
Mucormycosis	<i>Mucor</i>	Amphotericin B	No alternative recommended
Paracoccidioidomycosis	<i>Paracoccidioides brasiliensis</i>	Amphotericin B <i>or</i> itraconazole	Ketoconazole
Sporotrichosis	<i>Sporothrix schenckii</i>	Amphotericin B <i>or</i> itraconazole	Fluconazole

TABLE 91-2 Classes of Systemic Antifungal Drugs

Drug Class	Mechanism of Action	Class Members
Polyene Antibiotics	Bind to ergosterol, and thereby disrupt the fungal cell membrane	Amphotericin B
Azoles	Inhibit synthesis of ergosterol, and thereby disrupt the fungal cell membrane	Fluconazole Itraconazole Ketoconazole Posaconazole Voriconazole
Echinocandins	Inhibit synthesis of beta-1,3-D-glucan, and thereby disrupt the fungal cell wall	Anidulafungin Caspofungin Micafungin
Pyrimidine Analogs	Disrupt synthesis of RNA and DNA	Flucytosine

92.1.1.1

Mechanism of Action

Amphotericin B binds to components of the fungal cell membrane, thereby increasing permeability. The resultant leakage of intracellular cations (especially potassium) reduces viability. Depending on the concentration of amphotericin B and the susceptibility of the fungus, the drug may be fungistatic or fungicidal.

The component of the fungal membrane to which amphotericin B binds is *ergosterol*, a member of the *sterol* family of compounds. Hence, for a cell to be susceptible, its cytoplasmic membrane must contain sterols. Since bacterial membranes lack sterols, bacteria are not affected.

Much of the toxicity of amphotericin is attributable to the presence of sterols (principally cholesterol) in mammalian cell membranes. When amphotericin binds with cholesterol in mammalian membranes, the effect is similar to that seen in fungi. However, there *is* some degree of selectivity: Amphotericin binds more strongly to ergosterol than it does to cholesterol, and hence fungi are hurt more than we are.

92.1.1.2 Microbial Susceptibility and Resistance

Amphotericin B is active against a broad spectrum of fungi. Some protozoa (eg, *Leishmania braziliensis*) are also susceptible. As noted, bacteria are resistant.

Emergence of resistant fungi is extremely rare, and occurs only with long-term amphotericin use. In all cases of resistance, the fungal membranes had reduced amounts of ergosterol or none at all.

92.1.1.3 Therapeutic Uses

Amphotericin B is a drug of choice for most systemic mycoses (see [Table 91-1](#)). Before this drug became available, systemic fungal infections usually proved fatal. Treatment is prolonged; 6 to 8 weeks is common. In some cases, treatment may last for 3 or 4 months. In addition to its antifungal applications, amphotericin B is a drug of choice for leishmaniasis (see [Chapter 98](#)).

92.1.1.4 Pharmacokinetics

92.1.1.4.1 Absorption and Distribution.

Amphotericin is poorly absorbed from the GI tract, and hence oral therapy cannot be used for systemic infection. Rather, amphotericin must be administered IV. When the drug leaves the vascular system, it undergoes extensive binding to sterol-containing membranes of tissues. Levels about half those in plasma are achieved in aqueous humor and in peritoneal, pleural, and joint fluids. Amphotericin B does not readily penetrate to the cerebrospinal fluid (CSF).

92.1.1.4.2 Metabolism and Excretion.

Little is known about the elimination of amphotericin B. We do not know whether the drug is metabolized or how most of it is removed from the body. Renal excretion of unchanged amphotericin is minimal. Accordingly, there is no need to reduce the dosage in patients with pre-existing renal impairment. Complete elimination of amphotericin takes a long time; the drug has been detected in tissues more than a year after cessation of treatment.

92.1.1.5 Adverse Effects

Amphotericin can cause a variety of serious adverse effects. Patients should be under close supervision, preferably in a hospital.

92.1.1.5.1 Infusion Reactions.

Intravenous amphotericin frequently produces fever, chills, rigors, nausea, and headache. These reactions are caused by release of proinflammatory cytokines (tumor necrosis factor, interleukin-1, interleukin-6) from monocytes and macrophages. Symptoms begin 1 to 3 hours after starting the infusion and persist about 1 hour. Mild reactions can be reduced by pretreatment with diphenhydramine plus acetaminophen. Aspirin can also help, but it may increase kidney damage (see below). Intravenous meperidine or dantrolene can be given if rigors occur. If other measures fail, hydrocortisone (a glucocorticoid) can be used to decrease fever and chills. However, since glucocorticoids can reduce the patient's ability to fight infection, routine use of hydrocortisone should be avoided. Infusion reactions are less intense with lipid-based amphotericin formulations than with the conventional formulation.

Amphotericin infusion produces a high incidence of phlebitis. This can be minimized by changing peripheral venous sites often, administering amphotericin through a large central vein, and pretreatment with heparin.

92.1.1.5.2 Nephrotoxicity.

Amphotericin is toxic to cells of the kidney. Renal impairment occurs in practically all patients. The extent of kidney damage is related to the total dose administered over the full course of treatment. In most cases, renal function normalizes after amphotericin use stops. However, if the total dose exceeds 4 gm, residual impairment is likely. Kidney damage can be minimized by infusing 1 L of saline on the days of amphotericin administration. Other nephrotoxic drugs (eg, aminoglycosides, cyclosporine, nonsteroidal anti-inflammatory drugs [NSAIDs]) should be avoided. To evaluate renal injury, tests of kidney function should be performed every 3 to 4 days, and intake and output should be monitored. If plasma creatinine content rises above 3.5 mg/dL, amphotericin dosage should be reduced. Renal damage is less with lipid-based amphotericin than with the conventional formulation.

92.1.1.5.3 Hypokalemia.

Damage to the kidneys often causes hypokalemia. Potassium supplements may be needed to correct the problem. Potassium levels and serum creatinine should be monitored often.

1058

92.1.1.5.4 Hematologic Effects.

Amphotericin can cause bone marrow suppression, resulting in normocytic, normochromic anemia. Hematocrit determinations should be conducted to monitor red blood cell status.

1059

92.1.1.5.5 Effects Associated with Intrathecal Injection.

Intrathecal administration may cause nausea, vomiting, headache, and pain in the back, legs, and abdomen. Rare reactions include visual disturbances, impairment of hearing, and paresthesias (tingling, numbness, or pain in the hands and feet).

92.1.1.5.6 Other Adverse Effects.

Infusion of amphotericin may be associated with delirium, hypotension, hypertension, wheezing, and hypoxia. Rarely, amphotericin has caused rash, convulsions, anaphylaxis, dysrhythmias, acute liver failure, and nephrogenic diabetes insipidus.

92.1.1.6 Drug Interactions

92.1.1.6.1 Nephrotoxic Drugs.

Use of amphotericin with other nephrotoxic drugs (eg, aminoglycosides, cyclosporine, NSAIDs) increases the risk of injury to the kidneys. Accordingly, these combinations should be avoided if possible.

92.1.1.6.2 Flucytosine.

Amphotericin potentiates the antifungal actions of flucytosine, apparently by enhancing flucytosine entry into fungi. Because of this potentiative interaction, the combination of flucytosine with a relatively low dose of amphotericin can produce antifungal effects equivalent to those of a high dose of amphotericin alone. By allowing a reduction in amphotericin dosage, the combination decreases the risk of amphotericin-induced toxicity.

92.1.1.7 Preparations, Dosage, and Administration

92.1.1.7.1 Preparations.

Amphotericin B is available in a conventional formulation—*amphotericin B deoxycholate* (generic only)—and three lipid-based formulations: *liposomal amphotericin B* [AmBisome], *amphotericin B cholesteryl sulfate complex* [Amphotec], and *amphotericin B lipid complex* [Abelcet]. The lipid-based formulations cause less nephrotoxicity and fewer infusion reactions than the conventional formulation. However, these newer formulations are considerably more expensive.

92.1.1.7.2 Routes.

For treatment of systemic mycoses, amphotericin B is almost always administered IV. Infusions should be performed slowly (over 2 to 4 hours) to minimize phlebitis and cardiovascular reactions. Alternate-day dosing can reduce adverse effects. For most patients, several months of therapy are required. Because amphotericin B does not readily enter the CSF, intrathecal injection is used for fungal meningitis.

92.1.1.7.3 Intravenous Dosage and Administration.

Fungal Infections. Dosage is individualized and based on the severity of the disease and the patient's ability to tolerate treatment. Optimal dosage has not been established. A small test dose (1 mg) is often infused to assess patient reaction. After this, therapy is initiated with a dosage of 0.25 mg/kg/day. Maintenance dosages range from 1.5 to 6 mg/kg/day, depending on the severity of the infection and the form of amphotericin used. Dosage should be reduced in patients with renal impairment. The infusion solution should be checked periodically for a precipitate and, if one is seen, administration should be discontinued immediately. Because the treatment period is prolonged, the administration site should be rotated—so as to reduce the risk of phlebitis and help ensure continued availability of a suitable vein.

92.1.1.7.4 Leishmaniasis.

Leishmaniasis can be treated with *amphotericin B deoxycholate* or *liposomal amphotericin B* [AmBisome]. For conventional amphotericin, the dosage is 0.5 to 1 mg/kg daily every other day for up to 8 weeks. For AmBisome, the dosage is 3 mg/kg on days 1, 2, 3, 4, 5, 14, and 21.

92.1.2 Azoles

Like amphotericin B, the azoles are broad-spectrum antifungal drugs. As a result, azoles represent an alternative to amphotericin B for most systemic fungal infections (see [Table 91-1](#)). In contrast to amphotericin, which is highly toxic and must be given IV, the azoles have lower toxicity and can be administered by mouth. However, azoles do have one disadvantage: they inhibit hepatic P450 drug-metabolizing enzymes, and can thereby increase the levels of many other drugs. Of the fourteen azoles in current use, only five—itraconazole, ketoconazole, fluconazole, voriconazole, and posaconazole—are indicated for systemic mycoses. Azoles used for superficial mycoses are discussed separately below.

92.1.2.1 Itraconazole

Itraconazole [Sporanox] is an alternative to amphotericin B for several systemic mycoses (see [Table 91-1](#)), and will serve as our prototype for the azole family. The drug is safer than amphotericin B and has the added advantage of oral dosing. Principal adverse effects are cardiosuppression and liver injury. Like other azoles, itraconazole can inhibit drug-metabolizing enzymes, and can thereby raise levels of other drugs.

92.1.2.1.1 Mechanism of Action.

Itraconazole inhibits the synthesis of *ergosterol*, an essential component of the fungal cytoplasmic membrane. The result is increased membrane permeability and leakage of cellular components. Accumulation of ergosterol precursors may also contribute to antifungal actions. Itraconazole suppresses ergosterol synthesis by inhibiting fungal cytochrome P450-dependent enzymes.

92.1.2.1.2 Therapeutic Use.

Itraconazole is active against a broad spectrum of fungal pathogens. At this time, it is a drug of choice for *blastomycosis*, *histoplasmosis*, *paracoccidioidomycosis*, and *sporotrichosis*, and an alternative to amphotericin B for *aspergillosis*, *candidiasis*, and *coccidioidomycosis*. Itraconazole may also be used for superficial mycoses.

92.1.2.1.3 Pharmacokinetics.

Itraconazole is administered PO (in capsules or suspension); a formulation for IV use is no longer available. Food increases absorption of itraconazole *capsules*, but decreases absorption of itraconazole oral *suspension*. Interestingly, administration with a cola beverage enhances absorption. Once absorbed, the drug is widely distributed to lipophilic tissues. Concentrations in aqueous fluids (eg, saliva, CSF) are negligible. The drug undergoes extensive hepatic metabolism. About 40% of each dose is excreted in the urine as inactive metabolites.

92.1.2.1.4 Adverse Effects.

Itraconazole is well tolerated in usual doses. Gastrointestinal reactions (nausea, vomiting, diarrhea) are most common, occurring in about 10% of patients. Other common reactions include rash (8.6%), headache (3.8%), abdominal pain (3.3%), and edema (3.5%). In addition to these relatively benign effects, itraconazole may cause two potentially serious effects: cardiac suppression and liver injury.

92.1.2.1.4.1 Cardiac Suppression.

Itraconazole has negative inotropic actions that can cause a transient decrease in ventricular ejection fraction. Cardiac function returns to normal by 12 hours after dosing. Because of its negative inotropic actions, itraconazole should not be used for *superficial* fungal infections (dermatomycoses, onychomycosis) in patients with heart failure, a history of heart failure, or other indications of ventricular dysfunction. The drug may still be used to treat *serious* fungal infections in patients with heart failure, but only with careful monitoring, and only if the benefits clearly outweigh the risks. If signs and symptoms of heart failure worsen, itraconazole should be discontinued.

92.1.2.1.4.2 Liver Injury.

As of March 2001, the Food and Drug Administration (FDA) had received 24 reports of liver failure, including 11 deaths, in patients taking itraconazole. Although a causal link has not been established, caution is nonetheless advised. Patients should be informed about signs of liver dysfunction (persistent nausea, anorexia, fatigue, vomiting, right upper abdominal pain, jaundice, dark urine, pale stools) and, if they appear, should seek medical attention immediately.

1059

1060

TABLE 91-3 Some Drugs Whose Levels Can Be Increased by Azole Antifungal Drugs

Target Drug	Class	Consequence of Excessive Level
Pimozide [Orap]	Antipsychotic	Fatal dysrhythmias
Dofetilide [Tikosyn]	Antidysrhythmic	Fatal dysrhythmias
Quinidine	Antidysrhythmic	Fatal dysrhythmias
Cisapride [Propulsid]*	Prokinetic agent	Fatal dysrhythmias
Warfarin [Coumadin]	Anticoagulant	Bleeding
Sulfonylureas	Oral hypoglycemic	Hypoglycemia
Phenytoin [Dilantin]	Antiseizure drug	Central nervous system toxicity
Cyclosporine [Sandimmune]	Immunosuppressant	Increased nephrotoxicity
Tacrolimus [Prograf]	Immunosuppressant	Increased nephrotoxicity
Lovastatin [Mevacor]	Antihyperlipidemic	Rhabdomyolysis
Simvastatin [Zocor]	Antihyperlipidemic	Rhabdomyolysis

* In 2000, cisapride was voluntarily withdrawn from the U.S. market and is now available only through an investigational limited-access program.

92.1.2.1.5 Drug Interactions.

Inhibition of Hepatic Drug-Metabolizing Enzymes. Itraconazole inhibits CYP3A4 (the 3A4 isozyme of cytochrome P450) and can thereby increase levels of many other drugs ([Table 91-3](#)). The most important are cisapride, pimozide, dofetilide, and quinidine. Why? Because, when present at high levels, these drugs can cause potentially fatal ventricular dysrhythmias. Accordingly, concurrent use with itraconazole is contraindicated. Other drugs of concern include cyclosporine, digoxin, warfarin, and sulfonylurea-type oral hypoglycemics. In patients taking cyclosporine or digoxin, levels of these drugs should be monitored; in patients taking warfarin, prothrombin time should be monitored; and in patients taking sulfonylureas, levels of blood glucose should be monitored.

92.1.2.1.6 Drugs That Raise Gastric pH.

Drugs that decrease gastric acidity—antacids, histamine (H₂) antagonists, and proton pump inhibitors—can greatly reduce absorption of oral itraconazole. Accordingly, these agents should be administered at least 1 hour before itraconazole or 2 hours after. (Since proton pump inhibitors have a prolonged duration of action, patients using these drugs may have insufficient stomach acid for itraconazole absorption, regardless of when the proton pump inhibitor is given.)

92.1.2.1.7 Preparations, Dosage, and Administration.

Itraconazole [Sporanox] is available in suspension (10 mg/mL) and capsules (100 mg) for oral use. The capsules should be taken with food and/or a cola beverage to increase absorption. The recommended dosage is 200 mg once a day. If needed, the dosage may be increased to 200 mg twice a day.

92.1.2.2 Fluconazole

92.1.2.2.1 Actions and Uses.

Fluconazole [Diflucan], a member of the azole family, is an important antifungal drug. It has the same mechanism as itraconazole: inhibition of cytochrome P450-dependent synthesis of ergosterol, with resultant damage to the cytoplasmic membrane and accumulation of ergosterol precursors. The drug is primarily fungistatic. Fluconazole is used for blastomycosis; histoplasmosis; meningitis caused by *Cryptococcus neoformans* and

Coccidioides immitis; and vaginal, oropharyngeal, esophageal, and disseminated *Candida* infections. In addition, fluconazole is used investigationally for leishmaniasis (see [Chapter 98](#)).

92.1.2.2.2 Pharmacokinetics.

Fluconazole is well absorbed (90%) following oral administration, and undergoes wide distribution to tissues and body fluids, including the CSF. Most of each dose is eliminated unchanged in the urine. Fluconazole has a half-life of 30 hours, making once-a-day dosing sufficient.

92.1.2.2.3 Adverse Effects.

Fluconazole is generally well tolerated. The most common reactions are nausea (3.7%), headache (1.9%), rash (1.8%), vomiting (1.7%), abdominal pain (1.7%), and diarrhea (1.5%). Rarely, treatment has been associated with hepatic necrosis, Stevens-Johnson syndrome, and anaphylaxis. Fluconazole is teratogenic in animals and may be in humans; appropriate caution is needed.

92.1.2.2.4 Drug Interactions.

Like other azole antifungal drugs, fluconazole can inhibit CYP3A4, and can thereby increase levels of other drugs, including warfarin, phenytoin, cyclosporine, zidovudine, rifabutin, and sulfonylurea oral hypoglycemics.

92.1.2.2.5 Preparations, Dosage, and Administration.

Fluconazole [Diflucan] is available in solution (2 mg/mL) for IV infusion, and in tablets (50, 100, 150, and 200 mg) and suspension (10 and 40 mg/mL) for oral use. Because oral absorption is rapid and nearly complete, oral and IV dosages are the same. For treatment of *oropharyngeal* and *esophageal candidiasis*, the usual dosage is 200 mg on the first day, followed by 100 mg once daily thereafter. For treatment of *systemic candidiasis* and *cryptococcal meningitis*, the usual dosage is 400 mg on the first day, followed by 200 mg once daily thereafter. Duration of treatment ranges from 3 weeks to more than 3 months, depending on the infection being treated.

92.1.2.3 Voriconazole

92.1.2.3.1 Actions and Uses.

Voriconazole [Vfend], a member of the azole family, is an important drug for treating life-threatening fungal infections. Like other azoles, voriconazole inhibits cytochrome P450–dependent enzymes, and thereby suppresses synthesis of ergosterol, a critical component of the fungal cytoplasmic membrane. As a result, voriconazole is active against a broad spectrum of fungal pathogens, including *Aspergillus* species, *Candida* species, *Scedosporium* species, *Fusarium* species, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Cryptococcus neoformans*. At this time, voriconazole has four approved indications: (1) candidemia, (2) invasive aspergillosis, (3) esophageal candidiasis, and (4) serious infections caused by *Scedosporium apiospermum* or *Fusarium* species in patients unresponsive to or intolerant of other drugs.

According to Infectious Disease Society of America guidelines, voriconazole has replaced amphotericin B as the drug of choice for invasive aspergillosis. Voriconazole is just as effective as amphotericin B and poses a much lower risk of kidney damage. However, voriconazole does have its own set of adverse effects, including hepatotoxicity, visual disturbances, hypersensitivity reactions, hallucinations, and fetal injury. In addition, like other azoles, voriconazole can interact with many drugs.

92.1.2.3.2 Pharmacokinetics.

Voriconazole may be administered IV or PO. With oral administration, bioavailability is high (96%), but can be reduced by food. Plasma levels peak 2 hours after ingestion. The drug's half-life is dose dependent, and can range from 6 hours up to 24 hours. Voriconazole undergoes extensive metabolism by hepatic P450 enzymes.

92.1.2.3.3 Adverse Effects.

The most common adverse effects are visual disturbances, fever, rash, nausea, vomiting, diarrhea, headache, sepsis, peripheral edema, abdominal pain, and respiratory disorders.

During clinical trials, the effects that most often led to discontinuing treatment were liver damage, visual disturbances, and rash.

1060

1061

92.1.2.3.3.1 Hepatotoxicity.

Voriconazole can cause hepatitis, cholestasis, and fulminant hepatic failure. Fortunately, these events are both uncommon and generally reversible. To monitor for injury, liver function tests should be obtained before treatment and periodically thereafter.

92.1.2.3.3.2 Visual Disturbances.

Reversible, dose-related visual disturbances develop in 30% of patients. Symptoms include reduced visual acuity, increased brightness, altered color perception, and photophobia. As a rule, these begin within 30 minutes of dosing and then greatly diminish over the next 30 minutes. Owing to the risk of photophobia and blurred vision, patients should be warned against driving at night.

92.1.2.3.3.3 Hypersensitivity Reactions.

Voriconazole may cause dermatologic reactions, ranging from rash to life-threatening Stevens-Johnson syndrome. During infusion, anaphylactoid reactions have occurred, manifesting with tachycardia, chest tightness, dyspnea, faintness, flushing, fever, and sweating. If these symptoms develop, the infusion should be stopped.

92.1.2.3.3.4 Teratogenicity.

Voriconazole is teratogenic in rats and can cause fetal harm in humans. The drug is classified in FDA Pregnancy Risk Category D, and hence should not be used during pregnancy unless the potential benefits are deemed to outweigh the risk to the fetus. Women taking the drug should use effective contraception.

92.1.2.3.4 Drug Interactions.

Voriconazole can interact with many other drugs. Several mechanisms are involved. Voriconazole is both a substrate for and inhibitor of hepatic P450 enzymes. As a result, drugs that inhibit P450 can raise voriconazole levels, and drugs that induce P450 can lower voriconazole levels. On the other hand, because voriconazole itself can inhibit P450, voriconazole can raise levels of other drugs. Therefore

- To ensure that voriconazole levels are adequate, voriconazole should not be combined with powerful P450 inducers, including rifampin, rifabutin, carbamazepine, and phenobarbital.

- To avoid excessive voriconazole levels, voriconazole should not be combined with powerful P450 inhibitors.
- To avoid toxicity from accumulation of other drugs, voriconazole should not be combined with some agents that are P450 substrates, including cisapride, pimozide, and sirolimus.

92.1.2.3.5 Preparations, Dosage, and Administration.

Voriconazole [Vfend] is available in 200-mg, single-use vials for IV infusion, and in two oral formulations: tablets (50 and 200 mg) and a powder for oral suspension (40 mg/mL after reconstitution). Treatment is initiated with IV voriconazole and later can be switched to oral voriconazole as appropriate.

Intravenous therapy consists of two loading doses (6 mg/kg each given 12 hours apart) followed by maintenance doses of 4 mg/kg every 12 hours. All IV doses should be infused slowly, over 1 to 2 hours (maximum rate is 3 mg/kg/hr). If the response is inadequate, maintenance doses can be increased by 50%. Patients with *mild to moderate* hepatic cirrhosis should receive the standard two loading doses, but maintenance doses should be halved. (There are no data on dosing in patients with *severe* cirrhosis.) Patients with significant renal impairment (creatinine clearance less than 50 mL/min), should use *oral* voriconazole, not IV voriconazole. Why? Because, in the absence of adequate kidney function, the solubilizing agent (not voriconazole itself) in the IV formulation can accumulate to dangerous levels.

After receiving their IV loading doses, patients who can tolerate oral therapy may be switched to voriconazole tablets. The usual dosage is 200 mg every 12 hours for patients over 40 kg and 100 mg every 12 hours for patients under 40 kg. If the response is inadequate, doses can be increased by 50%. Oral dosing should be done 1 hour before meals or 1 hour after.

92.1.2.4 Ketoconazole

92.1.2.4.1 Actions and Antifungal Spectrum.

Ketoconazole (formerly available as Nizoral) belongs to the azole family of antifungal agents. Benefits derive from inhibiting synthesis of ergosterol, an essential component of the fungal cytoplasmic membrane. Ketoconazole is active against most fungi that cause systemic mycoses, as well as fungi that cause superficial infections (dermatophytes and *Candida* species).

92.1.2.4.2 Therapeutic Use.

Ketoconazole is an alternative to amphotericin B for systemic mycoses. The drug is much less toxic than amphotericin and only somewhat less effective. Specific indications are listed in [Table 91-1](#). Responses to ketoconazole are slow. Accordingly, the drug is less useful for severe, acute infections than for long-term suppression of chronic infections. Ketoconazole is also a valuable drug for treating superficial mycoses.

92.1.2.4.3 Pharmacokinetics. Absorption.

Ketoconazole is a weak base and hence requires an acidic environment for dissolution and absorption. Oral ketoconazole is well absorbed from the GI tract, provided that gastric acid levels are normal. In patients with achlorhydria (absence of gastric acid), absorption is low. Drugs that reduce gastric acidity (eg, antacids, H₂ blocking agents, proton pump inhibitors) decrease absorption.

92.1.2.4.3.1 Distribution.

Most ketoconazole in the blood is bound to plasma proteins. The drug crosses the blood-brain barrier poorly, and concentrations in the CSF remain low. In contrast, high levels of ketoconazole are achieved in the skin, making oral ketoconazole useful against superficial mycoses.

92.1.2.4.3.2 Elimination.

Ketoconazole is eliminated by hepatic metabolism. Its half-life is approximately 3 hours. In patients with liver dysfunction, the half-life can be substantially prolonged. Because elimination is hepatic, renal impairment does not influence the intensity or duration of effects. Hence, no dosage adjustment is needed in patients with kidney disease.

92.1.2.4.4 Adverse Effects.

Ketoconazole is generally well tolerated. The most common adverse reactions—nausea and vomiting—can be reduced by giving the drug with food. The most serious effects involve the liver.

92.1.2.4.4.1 Hepatotoxicity.

Effects of ketoconazole on the liver are rare but potentially severe. Fatal hepatic necrosis has occurred. Liver function should be evaluated prior to treatment and at least monthly

thereafter. Ketoconazole should be discontinued at the first sign of liver injury. The drug should be employed with caution in patients with a history of hepatic disease. Patients should be advised to notify the physician if they experience symptoms suggesting liver injury (eg, unusual fatigue, anorexia, nausea, vomiting, jaundice, dark urine, pale stools).

92.1.2.4.4.2 Effects on Sex Hormones.

Just as ketoconazole inhibits steroid synthesis in fungi, the drug can inhibit steroid synthesis in humans. In males, inhibition of testosterone synthesis has caused gynecomastia, decreased libido, and reduced potency; reversible sterility has occurred with high doses. In females, reduction of estradiol synthesis has caused menstrual irregularities.

92.1.2.4.4.3 Other Adverse Effects.

Ketoconazole can produce a variety of relatively mild adverse effects, including rash, itching, dizziness, fever, chills, constipation, diarrhea, photophobia, and headache. Rarely, ketoconazole has caused anaphylaxis, severe epigastric pain, and altered function of the adrenals.

92.1.2.4.5 Drug Interactions.

Drugs that decrease gastric acidity—antacids, H₂ antagonists, proton pump inhibitors—can greatly reduce ketoconazole absorption. Accordingly, these agents should be administered no sooner than 2 hours after ingestion of ketoconazole.

Like other azoles, ketoconazole inhibits CYP3A4, and can thereby increase levels of other drugs.

Rifampin reduces plasma levels of ketoconazole, apparently by enhancing hepatic metabolism. If these drugs are used concurrently, ketoconazole dosage should be increased—and even then it may be impossible to achieve therapeutic levels.

92.1.2.4.6 Preparations, Dosage, and Administration.

Ketoconazole is supplied in 200-mg tablets for oral administration. The recommended adult dosage is 200 mg once a day. To treat severe infection, daily doses of 400 to 800 mg may be required. The dosage for children over 2 years old is 3.3 to 6.6 mg/kg/day in a single dose. Duration of treatment is 6 months or longer. Since an acidic environment is needed for ketoconazole absorption, patients with achlorhydria should dissolve the tablets in 4 mL of 0.2 N hydrochloric acid; the solution should be sipped through a plastic or glass straw to avoid damaging the teeth.

92.1.2.5 Posaconazole

92.1.2.5.1 Actions and Uses.

Posaconazole [Noxafil] was approved in 2006, making it the newest member of the azole family. Like other azoles, the drug binds with ergosterol in the fungal cell membrane, and thereby compromises membrane integrity. *In vitro*, posaconazole has strong activity against *Aspergillus* and *Candida*, and good activity against several other fungi. Currently, the drug has only two indications: (1) *treatment* of oropharyngeal candidiasis, including infections resistant to itraconazole and/or fluconazole; and (2) *prophylaxis* of invasive *Aspergillus* and *Candida* infection in immunocompromised patients.

92.1.2.5.2 Pharmacokinetics.

Posaconazole is administered by mouth, and food greatly enhances absorption. For example, when dosing is done with a low-fat meal or liquid nutritional supplement, peak plasma levels are 3 times higher than when dosing is done on an empty stomach. In the blood, posaconazole is highly (over 98%) protein bound. In the liver, posaconazole undergoes a process known as UDP glucuronidation, rather than metabolism by P450 enzymes (although it *can* inhibit CYP3A4). Elimination is mainly fecal (71%) and partly urinary (13%). The mean elimination half-life is 35 hours.

92.1.2.5.3 Adverse Effects.

Posaconazole can cause a variety of adverse effects, but these are usually mild. In clinical trials, adverse effects were similar to those seen with itraconazole and fluconazole. The most common reactions were nausea (38%), vomiting (29%), and headache (28%). Like other azoles, posaconazole can cause liver dysfunction. In addition, there have been reports of QT prolongation and dysrhythmias.

1061

1062

92.1.2.5.4 Drug Interactions.

Like other azoles, posaconazole inhibits CYP3A4, and can thereby increase levels of many other drugs. Two immunosuppressants—cyclosporine [Neoral] and tacrolimus [Prograf]—are of particular concern. If posaconazole is combined with cyclosporine or tacrolimus, their dosages should be reduced by 25% and 66%, respectively. Combined use of posaconazole with pimozide, halofantrine, or quinidine is *contraindicated* (because raising levels of these drugs can lead to QT prolongation and dysrhythmias), as is combined use with ergot alkaloids (because raising their levels can lead to ergotism).

Two drugs—rifabutin and phenytoin—can induce UDP glucuronidase (the hepatic enzyme that metabolizes posaconazole) and can thereby reduce posaconazole levels by nearly 50%. Accordingly, an increase in posaconazole dosage may be needed.

92.1.2.5.5 Preparations, Dosage, and Administration.

Posaconazole [Noxafil] is supplied as a 40-mg/mL oral suspension. To promote absorption, each dose should be taken with a full meal or a liquid nutritional supplement. Dosages are as follows:

- *Prophylaxis of invasive fungal infections*—200 mg 3 times a day for as long as neutropenia or immunosuppression persists
- *Oropharyngeal candidiasis*—200 mg twice daily on day 1, followed by 100 mg once daily for 13 days
- *Oropharyngeal candidiasis refractory to itraconazole and/or fluconazole*—400 mg twice daily for as long as indicated

92.1.3 Echinocandins

The echinocandins are the newest class of antifungal drugs. In contrast to amphotericin B and the azoles, which disrupt the fungal *cell membrane*, the echinocandins disrupt the fungal *cell wall*. Echinocandins cannot be dosed orally, and their antifungal spectrum is narrow, being limited mainly to *Aspergillus* and *Candida* species. Three echinocandins are currently available: caspofungin, micafungin, and anidulafungin. When dosage is appropriate, all three drugs appear therapeutically equivalent.

92.1.3.1 Caspofungin

92.1.3.1.1 Actions and Uses.

Caspofungin [Cancidas], introduced in 2001, was the first echinocandin available. Antifungal effects result from inhibiting the biosynthesis of beta-1,3-D-glucan, an essential component of the cell wall of some fungi, including *Candida* and *Aspergillus*. Caspofungin is approved for IV therapy of (1) invasive aspergillosis in patients unresponsive to or intolerant of traditional agents (eg, amphotericin B, itraconazole), and (2) systemic *Candida* infections, including candidemia and *Candida*-related peritonitis, pleural space infections, and intra-abdominal abscesses. The drug is better tolerated than amphotericin B, and appears just as effective.

92.1.3.1.2 Pharmacokinetics.

Caspofungin is not absorbed from the GI tract, and hence must be given parenterally (by IV infusion). In the blood, most (97%) of the drug is protein bound. Caspofungin is cleared from the blood with a half-life of 9 to 11 hours. The principal mechanism of plasma clearance is redistribution to tissues, not metabolism or excretion. Over time, the drug undergoes gradual metabolism followed by excretion in the urine and feces.

92.1.3.1.3 Adverse Effects.

Caspofungin is generally well tolerated. The most common adverse effects are fever (3.6% to 26%) and phlebitis at the injection site (11.3% to 15.7%). Less common reactions include headache (6% to 11.3%), rash (4.6%), nausea (2.5% to 6%), and vomiting (1.2% to 3.1%). In addition, caspofungin can cause effects that appear to be mediated by histamine release. Among these are rash, facial flushing, pruritus, and a sense of warmth. One case of anaphylaxis has been reported.

92.1.3.1.4 Use in Pregnancy.

Caspofungin is embryotoxic in rats and rabbits. To date, there are no adequate data on effects in pregnant women. Currently, the drug is classified in FDA Pregnancy Risk Category C, and hence should be avoided during pregnancy unless the potential benefits outweigh the potential risks to the fetus.

92.1.3.1.5 Drug Interactions.

Drugs that induce cytochrome P450 may decrease levels of caspofungin. Powerful inducers include efavirenz [Sustiva], nelfinavir [Viracept], rifampin [Rifadin], carbamazepine [Tegretol], and phenytoin [Dilantin]. Patients taking these drugs with caspofungin may need to increase caspofungin dosage.

Caspofungin can decrease levels of *tacrolimus* [Prograf], an immunosuppressant. If these drugs are taken concurrently, levels of tacrolimus should be monitored and dosage increased as needed.

Combining caspofungin with *cyclosporine* [Sandimmune] increases the risk of liver injury, as evidenced by a transient elevation in plasma levels of liver enzyme. Accordingly, the combination should generally be avoided.

92.1.3.1.6 Preparations, Dosage, and Administration.

Caspofungin [Cancidas] is supplied as a powder (50 and 70 mg) to be reconstituted in sterile saline for IV infusion. Treatment for adults consists of a 70-mg loading dose followed by daily maintenance doses of 50 mg each. All doses should be infused slowly (over 1 hour). Duration of treatment depends on the severity of the infection and the clinical response. For patients with *moderate* liver impairment, maintenance doses should be reduced to 35 mg. There are no data on dosage for patients with *severe* liver impairment.

92.1.3.2 Micafungin

92.1.3.2.1 Actions and Uses.

Micafungin [Mycamine], approved in 2005, was the second echinocandin antifungal agent available for general use. Like caspofungin, micafungin inhibits synthesis of beta-1,3-D-glucan, an essential component of the cell wall of *Candida*. Micafungin, administered IV, is indicated for (1) *prevention* of *Candida* infection in patients undergoing a bone marrow transplant; (2) *treatment* of esophageal candidiasis; (3) *treatment* of candidemia, the fourth most common bloodstream infection among hospitalized patients in the United States; and (4) *treatment* of disseminated infection, peritonitis, or abscesses caused by *Candida*. For all four indications, fluconazole and itraconazole are preferred.

92.1.3.2.2 Pharmacokinetics.

Like caspofungin, micafungin is not absorbed from the GI tract, and hence is given IV. Protein binding in blood is high (greater than 99%). Micafungin undergoes hepatic metabolism—mainly by pathways that do not involve cytochrome P450—followed by excretion in the feces. The elimination half-life is 11 to 17 hours.

92.1.3.2.3 Adverse Effects.

Micafungin is generally well tolerated. The most common adverse effects are headache, nausea, vomiting, diarrhea, fever, and phlebitis at the infusion site. Elevation of liver enzymes has also occurred, suggesting injury to the liver. Patients may also experience histamine-mediated reactions, including rash, itching, facial swelling, and vasodilation. There have been isolated reports of severe allergic reactions, including life-threatening anaphylaxis.

92.1.3.2.4 Drug Interactions.

Micafungin appears largely devoid of significant drug interactions. Of note, micafungin does not alter the kinetics of the following immunosuppressants: mycophenolate [CellCept], cyclosporine [Sandimmune, others], tacrolimus [Prograf], and prednisolone—nor do those drugs alter the kinetics of micafungin. Micafungin can intensify the effects of sirolimus [Rapamune] (an immunosuppressant) and nifedipine [Procardia, others] (a calcium channel blocker). Accordingly, patients treated with sirolimus or nifedipine should be monitored closely for signs of toxicity. Because micafungin does not interact very much with the cytochrome P450 system, it is unlikely to alter the effects of drugs that do.

92.1.3.2.5 Preparations, Dosage, and Administration.

Micafungin [Mycamine] is supplied as a lyophilized powder (50 and 100 mg) in single-use, light-protected vials, and must be reconstituted prior to infusion. The recommended dosage is 50 mg once a day to prevent *Candida* infection, 100 mg once a day to treat candidemia, and 150 mg once a day to treat esophageal candidiasis. All doses are given by a 1-hour IV infusion. Faster infusion rates increase the risk of a histamine reaction.

92.1.3.3 Anidulafungin

92.1.3.3.1 Actions and Uses.

Anidulafungin [Eraxis], approved in 2006, has good activity against *Candida* species, and poor activity against most other fungi. Indications are limited to IV therapy of esophageal candidiasis, candidemia, and other serious *Candida* infections. Like caspofungin and micafungin, anidulafungin inhibits synthesis of beta-1,3-D-glucan, and thereby disrupts the *Candida* cell wall.

92.1.3.3.2 Pharmacokinetics.

Like other echinocandins, anidulafungin is not absorbed from the GI tract, and hence must be given by IV infusion. In the blood, 84% of the drug is protein bound. Clearance is the result of slow, spontaneous chemical degradation, followed by excretion in the feces. The plasma half-life is 40 to 50 hours.

92.1.3.3.3 Adverse Effects.

Anidulafungin is generally well tolerated. The most common adverse effects are diarrhea (3.1%), hypokalemia (3.1%), and headache (1.3%). Possible histamine-mediated reactions

(rash, urticaria, pruritus, flushing, dyspnea, hypotension) have been reported, especially at higher infusion rates. Accordingly, the infusion rate should not exceed 1.1 mg/min. A few patients have developed signs of liver damage (hepatitis, elevation of circulating liver enzymes, worsening of hepatic failure).

92.1.3.3.4 Drug Interactions.

No clinically relevant drug interactions have been reported. Anidulafungin is neither a substrate for, inducer of, nor inhibitor of hepatic P450 drug-metabolizing enzymes, and hence will not interact with other drugs affected by this system.

92.1.3.3.5 Preparations, Dosage, and Administration.

Anidulafungin [Eraxis] is available as a powder (50 and 100 mg) to be reconstituted in the supplied diluent, and then further diluted prior to infusion. To minimize histamine-related reactions, the infusion rate should not exceed 1.1 mg/min. Dosages are as follows:

- *Esophageal candidiasis*—Infuse a single 100-mg loading dose on day 1, followed by 50 mg once a day thereafter, continuing for at least 14 days and at least 7 days after the last positive culture.
- *Candidemia and other serious Candida infections*—Infuse a single 200-mg loading dose on day 1, followed by 100 mg once a day thereafter, continuing for at least 14 days after the last positive culture.

92.1.4 Flucytosine, a Pyrimidine Analog

Flucytosine [Ancobon], a pyrimidine analog, is employed for serious infections caused by susceptible strains of *Candida* and *Cryptococcus neoformans*. Because development of resistance is common, flucytosine is almost always used in combination with amphotericin B. Extreme caution is needed in patients with renal impairment and hematologic disorders.

92.1.4.1 Mechanism of Action.

Flucytosine is taken up by fungal cells, which then convert it to 5-fluorouracil (5-FU), a powerful antimetabolite. The ultimate effect of 5-FU is disruption of fungal DNA and RNA synthesis. Flucytosine is relatively harmless to us because mammalian cells lack cytosine deaminase, the enzyme that converts flucytosine to 5-FU.

92.1.4.2 Fungal Resistance.

Development of resistance during therapy is common and constitutes a serious clinical problem. Several mechanisms have been described, including (1) a reduction in cytosine permease (needed for fungal uptake of flucytosine) and (2) loss of cytosine deaminase (needed to convert flucytosine to its active form).

92.1.4.3 Antifungal Spectrum and Therapeutic Uses.

Flucytosine has a narrow antifungal spectrum. Fungicidal activity is highest against *Candida* species and *Cryptococcus neoformans*. Most other fungi are resistant. Because of this narrow spectrum, flucytosine is indicated only for candidiasis and cryptococcosis. For treatment of serious infections (eg, cryptococcal meningitis, systemic candidiasis), flucytosine should be combined with amphotericin B. This combination offers two advantages over flucytosine alone: (1) antifungal activity is enhanced and (2) emergence of resistant fungi is reduced.

92.1.4.4 Pharmacokinetics.

Flucytosine is readily absorbed from the GI tract and is well distributed throughout the body. The drug has good access to the central nervous system; levels in the CSF are about 80% of those in plasma. Flucytosine is eliminated by the kidneys, principally as unchanged drug. The half-life is about 4 hours in patients with normal renal function. However, in patients with renal insufficiency, the half-life is greatly prolonged, and hence dosage must be reduced.

92.1.4.5 Adverse Effects.

Hematologic Effects. Bone marrow suppression is the most serious complication of treatment. Marrow suppression usually manifests as reversible neutropenia or thrombocytopenia. Rarely, fatal agranulocytosis develops. Platelet and leukocyte counts should be determined weekly. Adverse hematologic effects are most likely when plasma levels of flucytosine exceed 100 mcg/mL. Accordingly, the dosage should be adjusted to keep drug levels below this value. Flucytosine should be used with caution in patients with pre-existing bone marrow suppression.

92.1.4.5.1 Hepatotoxicity.

Mild and reversible liver dysfunction occurs frequently, but severe hepatic injury is rare. Liver function should be monitored (by making weekly determinations of serum transaminase and alkaline phosphatase levels).

92.1.4.6 Drug Interactions.

Flucytosine is often combined with *amphotericin B*. As noted, this combination offers several advantages. However, the combination can also be detrimental. Since amphotericin B is nephrotoxic, and since flucytosine is eliminated by the kidneys, amphotericin B–induced kidney damage may suppress flucytosine excretion, and may thereby promote flucytosine toxicity. Therefore, *it is important to monitor renal function and flucytosine levels when amphotericin B and flucytosine are combined.*

Like itraconazole, flucytosine inhibits hepatic drug-metabolizing enzymes, and can thereby raise levels of several other drugs. With at least four drugs—*cisapride*, *pimozide*, *dofetilide*, and *quinidine*—elevated levels can lead to potentially fatal cardiac dysrhythmias. Accordingly, flucytosine must not be combined with these drugs.

92.1.4.7 Preparations, Dosage, and Administration.

Flucytosine [Ancobon] is available in 250- and 500-mg capsules for oral administration. The usual dosage for patients with normal kidney function is 50 to 150 mg/kg/day administered in divided doses at 6-hour intervals. At this dosage, some patients must ingest 10 or more capsules 4 times a day. Dosages must be reduced for patients with renal insufficiency. Nausea and vomiting associated with drug administration can be decreased by taking flucytosine capsules over a 15-minute interval.

92.2 DRUGS FOR SUPERFICIAL MYCOSES

The superficial mycoses are caused by two groups of organisms: (1) *Candida* species and (2) dermatophytes (species of *Epidermophyton*, *Trichophyton*, and *Microsporum*). *Candida* infections usually occur in mucous membranes and moist skin; chronic infections may involve the scalp, skin, and nails. Dermatophytoses are generally confined to the skin, hair, and nails. Superficial infections with dermatophytes are more common than superficial infections with *Candida*.

92.2.1 Overview of Drug Therapy

Superficial mycoses can be treated with a variety of topical and oral drugs. For mild to moderate infections, topical agents are generally preferred. Specific indications for the drugs used against superficial mycoses are summarized in [Tables 91-4](#) and [91-5](#). Some of these drugs are also used for systemic mycoses.

92.2.1.1 Dermatophytic Infections (Ringworm)

Dermatophytic infections are commonly referred to as ringworm (because of the characteristic ring-shaped lesions). There are four principal dermatophytic infections, defined by their location: *tinea pedis* (ringworm of the foot, or “athlete's foot”), *tinea corporis* (ringworm of the body), *tinea cruris* (ringworm of the groin, or “jock itch”), and *tinea capitis* (ringworm of the scalp).

92.2.1.1.1 Tinea Pedis.

Tinea pedis, the most common fungal infection, generally responds well to topical therapy. Available agents are listed in [Table 91-4](#). Patients should be advised to wear absorbent cotton socks, change their shoes often, and dry their feet after bathing.

92.2.1.1.2 Tinea Corporis.

Tinea corporis usually responds to a topical azole or allylamine (see [Table 91-4](#)). Treatment should continue for at least 1 week after symptoms have cleared. Severe infection may require a systemic antifungal agent (eg, griseofulvin).

92.2.1.1.3 Tinea Cruris.

Tinea cruris responds well to topical therapy. Treatment should continue for at least 1 week after symptoms have cleared. If the infection is severely inflamed, a systemic antifungal drug (eg, clotrimazole) may be needed; topical or systemic glucocorticoids may be needed as well.

92.2.1.1.4 Tinea Capitis.

Tinea capitis is difficult to treat. Topical drugs are not likely to work. Oral griseofulvin, taken for 6 to 8 weeks, is considered standard therapy. However, oral terbinafine, taken for only 2 to 4 weeks, may be more effective.

1063

TABLE 91-4 Drugs for Superficial Fungal Infections*

Drug	Route	Ringworm†	Candida Infection		
			Skin	Mouth	Onychomycosis‡

* Vulvovaginal candidiasis is addressed in [Table 91-5](#).

† *Ringworm* is a popular term for dermatophytic infections, including tinea pedis (ringworm of the foot, “athlete's foot”), tinea cruris (ringworm of the groin, “jock

itch”), tinea corporis (ringworm of the body), and tinea capitis (ringworm of the scalp).

‡ *Onychomycosis* is a clinical term for fungal infection of the toenails and fingernails.

92.2.1.2 Candidiasis

92.2.1.2.1 Vulvovaginal Candidiasis.

Vulvovaginal candidiasis is very common, occurring in 75% of women at least once in their lives. Most cases are caused by *Candida albicans*, and many of the rest are caused by *Candida glabrata*, especially in patients with HIV/AIDS. Factors that predispose to *Candida* infection include pregnancy, obesity, diabetes, debilitation, HIV infection, and use of certain drugs, including oral contraceptives, systemic glucocorticoids, anticancer agents, immunosuppressants, and systemic antibiotics. In the past, most regimens required daily application of a topical drug for 1 to 2 weeks. However, with current drugs, just 1 to 3 days of *topical* therapy can be curative. In addition, *oral* therapy may be used: A single 150-mg dose of fluconazole can be curative—but it causes more side effects (headache, rash, GI disturbance) than the topical agents. For women with recurrent vulvovaginal candidiasis, weekly prophylaxis with oral fluconazole is highly effective—but relapse is common when treatment is stopped. The drugs used for vulvovaginal candidiasis are summarized in [Table 91-5](#). All appear equally effective. Hence, drug selection is largely a matter of patient preference. The longer regimens have no demonstrated advantage over the shorter ones.

92.2.1.2.2 Oral Candidiasis.

Oral candidiasis, also known as *thrush*, is seen often. Topical agents—*nystatin*, *clotrimazole*, and *amphotericin B*—are generally effective. In the immunocompromised host, oral therapy with *fluconazole* or *ketoconazole* is usually required.

92.2.1.3 Onychomycosis (Fungal Infection of the Nails)

Fungal infection of the nails, known as onychomycosis, is difficult to eradicate and requires prolonged therapy. Infections may be caused by dermatophytes or *Candida* species. Because onychomycosis is largely a cosmetic concern, treatment is usually optional.

Onychomycosis may be treated with oral antifungal drugs or with topical ciclopirox. Success rates with oral therapy are quite low, and rates with topical therapy are even lower.

92.2.1.3.1 Oral Therapy.

The drugs used most often are *terbinafine* [Lamisil] and *itraconazole* [Sporanox]. Both are active against *Candida* species and dermatophytes. Once in the body, these drugs become incorporated into keratin as the nails grow. Drug may also diffuse into the nails from the tissue below. Side effects include GI disturbances (eg, nausea, vomiting, abdominal pain), headache, and skin reactions (eg, itching, rash). Treatment generally lasts 3 to 6 months.

1064

Unfortunately, even with this prolonged therapy, the cure rate is relatively low (about 50%).

1065

TABLE 91-5 Some Preferred Products for Vulvovaginal Candidiasis

Generic Name	Trade Name	Formulation	Dosage
Oral Preparation			
Fluconazole	Diflucan	150-mg oral tablet	1 tablet once
Topical Preparations			
Butoconazole	Gynazole-1	2% vaginal cream, SR	5 gm once
	Femstat 3	2% vaginal cream	5 gm at bedtime × 3 days
	Mycelex-3	2% vaginal cream	5 gm at bedtime × 3 days
Clotrimazole	Gyne-Lotrimin 3	200-mg vaginal suppository	1 suppository at bedtime × 3 days
	Mycelex-7	1% vaginal cream	5 gm at bedtime × 7–14 days
Miconazole	Femizol-M	2% vaginal cream	5 gm at bedtime × 7 days
	Monistat 7	2% vaginal cream	5 gm at bedtime × 7 days
	(a component of Monistat Dual Pack)	1200-mg vaginal suppository	1 suppository once, day or night
	(a component of Monistat 3 Combination Pack)	200-mg vaginal suppository	1 suppository at bedtime × 3 days
	(a component of Monistat 7 Combination Pack)	100-mg vaginal suppository	1 suppository at bedtime × 7 days
Terconazole	Terazol 3	80-mg vaginal suppository	1 suppository at bedtime × 3 days
	Terazol 3	0.8% vaginal cream	5 gm at bedtime × 3 days
	Terazol 7	0.4% vaginal cream	5 gm at bedtime × 7 days
Tioconazole	Monistat 1	6.5% vaginal ointment	4.6 gm at bedtime once
	Vagistat-1	6.5% vaginal ointment	4.6 gm at bedtime once
SR = sustained-release formulation.			

92.2.1.3.2 Topical Therapy with Ciclopirox.

Ciclopirox [Penlac Nail Lacquer] is the only topical agent for onychomycosis. In contrast to oral terbinafine or itraconazole, which are active against *Candida* species and several dermatophytes, topical ciclopirox is active against only one dermatophyte—*Trichophyton rubrum*—and has no activity against *Candida*. Ciclopirox is applied once a day to the nails and immediately adjacent skin. New coats are applied over old ones. Once a week, all coats are removed with alcohol. Side effects are minimal and localized. Unfortunately, despite prolonged use (up to 48 weeks), ciclopirox confers only modest benefits: Complete cure occurs in less than 12% of patients and, even when complete cure *does* occur, the recurrence rate is high—about 40%. Compared with oral therapy, topical ciclopirox is safer and cheaper, but much less effective.

Use of ciclopirox for superficial fungal infections of the *skin* is discussed below.

92.2.2 Azoles

Twelve members of the azole family are used for superficial mycoses (see [Tables 91-4](#) and [91-5](#)). The usual route is topical. Three of the twelve—itraconazole, fluconazole, and ketoconazole—are also used for systemic mycoses (see above).

The azoles are active against a broad spectrum of pathogenic fungi, including dermatophytes and *Candida* species. Antifungal effects result from inhibiting the biosynthesis of ergosterol, an essential component of the fungal cytoplasmic membrane.

92.2.2.1 Clotrimazole

92.2.2.1.1 Therapeutic Uses.

Topical clotrimazole is a drug of choice for dermatophytic infections and candidiasis of the skin, mouth, and vagina.

92.2.2.1.2 Adverse Effects.

When applied to the skin, clotrimazole can cause stinging, erythema, edema, urticaria, pruritus, and peeling. However, the incidence is low. Intravaginal administration occasionally causes a burning sensation and lower abdominal cramps. Oral clotrimazole can cause GI distress.

92.2.2.1.3 Preparations, Dosage, and Administration.

Clotrimazole is available as an oral troche, as a cream or suppository for intravaginal use, and in three formulations for application to the skin: cream, lotion, and solution. For fungal infections of the skin, the drug is applied twice daily for 2 to 4 weeks. For vulvovaginal candidiasis, several dosing schedules have been employed, including (1) intravaginal insertion of one 200-mg suppository nightly for 7 days, (2) intravaginal insertion of one 500-mg suppository once at bedtime, and (3) intravaginal application of 5 gm of 1% cream once a day for 7 days. Trade names for dermatologic products are Desenex, Cruex, and Lotrimin, and trade names for vaginal products are Gyne-Lotrimin and Mycelex.

92.2.2.2 Ketoconazole

Ketoconazole [Kuric, Extina, Nizoral, Xolegel] is approved for oral and topical therapy of superficial mycoses. Oral ketoconazole provides effective treatment of dermatophytic infections as well as candidiasis of the skin, mouth, and vagina. However, because of the toxicity associated with oral use, this route should be reserved for infections that have failed to respond to topical agents. Ketoconazole for topical use is available in five formulations: 2% foam [Extina] and 2% gel [Xolegel] for seborrheic dermatitis, 1% shampoo [Nizoral-AD] for dandruff, 2% shampoo [Nizoral] for tinea versicolor, and 2% cream [Kuric] for dermatophytic infections and candidiasis of the skin. The basic pharmacology of ketoconazole is discussed above under *Drugs for Systemic Mycoses*.

92.2.2.3 Miconazole

92.2.2.3.1 Therapeutic Uses.

Miconazole [Micatin, Monistat 3, Monistat 7, others] is an azole antifungal drug available for topical and systemic administration. Topical miconazole is a drug of choice for dermatophytic infections and for cutaneous and vulvovaginal candidiasis.

1065

92.2.2.3.2 Adverse Effects.

1066

Adverse effects of topical miconazole are generally mild. Intravaginal administration causes burning, itching, and irritation in about 7% of users. When applied to the skin, miconazole occasionally causes irritation, burning, and maceration. Topical application is not associated with systemic toxicity.

92.2.2.3.3 Drug Interactions.

Intravaginal miconazole can intensify the anticoagulant effects of warfarin. One woman using the combination reported bruising, bleeding gums, and a nosebleed. We have long known that *systemic* miconazole can inhibit metabolism of warfarin, thereby causing warfarin levels to rise. Apparently, intravaginal miconazole can be absorbed in amounts sufficient to do the same. Because of this interaction, women taking warfarin should not use intravaginal miconazole. If the drugs must be used concurrently, anticoagulation should be monitored closely and warfarin dosage reduced as indicated.

92.2.2.3.4 Preparations, Dosage, and Administration.

Miconazole is available in cream, liquid, and powder formulations for application to the skin, and in cream and suppository formulations for intravaginal application. Cutaneous mycoses are treated with twice-daily applications for 2 to 4 weeks. For vulvovaginal candidiasis, 2% miconazole cream or a 100-mg suppository is administered nightly for 1 week. Alternatively, a 200-mg suppository can be inserted on three consecutive nights.

92.2.2.4 Fluconazole

Fluconazole [Diflucan] can be used for *oral* therapy of vulvovaginal candidiasis, oropharyngeal candidiasis, and onychomycosis. For vulvovaginal candidiasis, the dosage for *treating ongoing* infection is 150 mg once, and the dosage for *preventing recurrent* infection is 150 mg once a week for 6 months. The dosage for oropharyngeal candidiasis is 200 mg on day 1 followed by 100 mg daily for 2 weeks. The dosage for onychomycosis is 100 mg daily for 3 to 12 weeks. The basic pharmacology of fluconazole is discussed above under *Drugs for Systemic Mycoses*.

92.2.2.5 Newer Azole Drugs

92.2.2.5.1 Econazole.

Econazole [Spectazole] is available for topical application only. The drug is indicated for ringworm infections and superficial candidiasis. Local adverse effects (burning, erythema, stinging, itching) occur in about 3% of patients. Less than 1% of topical econazole is absorbed, and systemic toxicity has not been reported. Econazole, supplied in a 1% cream, is applied twice daily for 2 to 4 weeks.

92.2.2.5.2 Oxiconazole and Sulconazole.

Oxiconazole [Oxistat] and sulconazole [Exelderm] are broad-spectrum antifungal drugs. Both are approved for topical treatment of tinea infections. Local adverse effects (itching, burning, irritation, erythema) occur in less than 3% of patients. Neither drug is absorbed to a significant degree. Systemic toxicity has not been reported. Oxiconazole is supplied as a cream and lotion, and sulconazole is supplied as a cream and solution. Both drugs are applied once daily for 2 to 4 weeks.

92.2.2.5.3 Butoconazole, Terconazole, and Tioconazole.

These azole drugs are approved only for topical treatment of vulvovaginal candidiasis. All three are fungicidal. Local adverse effects (burning, itching) occur in 2% to 6% of users. Absorption following intravaginal administration is low, and systemic reactions are rare (except for headache from terconazole). Because of a small risk of fetal injury, these drugs are not recommended for use during the first trimester of pregnancy. Trade names, formulations, and dosages are presented in [Table 91-5](#).

92.2.2.5.4 Sertaconazole.

Sertaconazole [Ertaczo], available by prescription, is the ninth azole approved for topical therapy of tinea pedis. The 2% cream is applied twice daily for 4 weeks. Mild local reactions (itching, burning, irritation, erythema) occur in 2% of patients. Blood levels are undetectable following repeated applications, and systemic effects have not been reported. Cure rates are like those seen with generic clotrimazole and miconazole—older azoles that are much cheaper and can be purchased without a prescription.

92.2.3 Griseofulvin

Griseofulvin [Grifulvin, Gris-PEG] is administered orally to treat superficial mycoses. The drug is inactive against organisms that cause systemic mycoses.

92.2.3.1 Mechanism of Action.

Following absorption, griseofulvin is deposited in the keratin precursor cells of skin, hair, and nails. Because griseofulvin is present, newly formed keratin is resistant to fungal invasion. Hence, as infected keratin is shed, it is replaced by fungus-free tissue.

Griseofulvin kills fungi by inhibiting fungal mitosis. How? By binding to components of microtubules, the structures that form the mitotic spindle. Because griseofulvin acts by disrupting mitosis, the drug only affects fungi that are actively growing.

92.2.3.2 Pharmacokinetics.

Griseofulvin is administered by mouth. Absorption can be enhanced by taking the drug with a fatty meal. As noted, griseofulvin is deposited in the keratin precursor cells of skin, hair, and nails. Elimination is by hepatic metabolism and renal excretion.

92.2.3.3 Therapeutic Uses.

Griseofulvin is employed orally to treat dermatophytic infections of the skin, hair, and nails. The drug is not active against *Candida* species, nor is it useful against systemic mycoses. Dermatophytic infections of the skin respond relatively quickly (in 3 to 8 weeks). However, infections of the palms may require 2 to 3 months of treatment, and a year or more may be needed to eliminate infections of the toenails.

92.2.3.4 Adverse Effects.

Most untoward effects are not serious. Transient headache is common, occurring in about 15% of patients. Other mild reactions include rash, insomnia, tiredness, and GI effects (nausea, vomiting, diarrhea). Griseofulvin may cause hepatotoxicity and photosensitivity in patients with porphyria. The drug is contraindicated for individuals with a history of porphyria or hepatocellular disease.

92.2.3.5 Drug Interactions.

Griseofulvin induces hepatic drug-metabolizing enzymes and can thereby decrease the effects of *warfarin*. When this combination is used, the dosage of warfarin may need to be increased.

92.2.3.6 Preparations, Dosage, and Administration.

Griseofulvin is formulated in two particle sizes: microsize and ultra-microsize. The microcrystalline form [Grifulvin V] is supplied in tablets (250 and 500 mg), capsules (250 mg), and a suspension (25 mg/mL). The ultra-microcrystalline form [Gris-PEG] is supplied in tablets (125, 165, 250, and 330 mg).

Dosage depends to some degree upon the formulation (microsize or ultra-microsize). With microsize formulations, the usual adult dosage is 500 mg to 1 gm/day, and the usual pediatric dosage is 11 mg/kg/day. The ultra-microsize particles are better absorbed than the microsize

particles. As a result, doses of ultra-microcrystalline griseofulvin are about 30% lower than doses of microcrystalline griseofulvin.

92.2.4 Polyene Antibiotics

92.2.4.1 Nystatin

92.2.4.1.1 Actions, Uses, and Adverse Effects.

Nystatin [Mycostatin, Nilstat, others] is a polyene antibiotic used only for candidiasis. Nystatin is the drug of choice for intestinal candidiasis, and is also employed to treat candidal infections of the skin, mouth, esophagus, and vagina. Nystatin can be administered orally and topically. There is no significant absorption from either route. Oral nystatin occasionally causes GI disturbance (nausea, vomiting, diarrhea). Topical application may produce local irritation.

92.2.4.1.2 Preparations, Dosage, and Administration.

For oral administration, nystatin is supplied as a suspension and in tablets and lozenges; dosages range from 100,000 to 1 million units 3 to 4 times a day. Vaginal tablets are employed for vaginal candidiasis; the usual dosage is 100,000 units once a day for 2 weeks. Nystatin is supplied as a cream, ointment, and powder to treat candidiasis of the skin. The cream and ointment formulations are applied twice daily; the powder is applied 3 times daily. Trade names for nystatin include Mycostatin and Nilstat.

92.2.5 Allylamines

92.2.5.1 Naftifine

Naftifine [Naftin] was the first allylamine available. Although approved only for topical treatment of dermatophytic infections, naftifine is active against a broad spectrum of pathogenic fungi. The drug works by inhibiting squalene epoxidase, and thereby inhibits synthesis of ergosterol, a key component of the fungal cell membrane. The most common adverse effects are burning and stinging. Absorption following topical administration is low (about 6%). Systemic effects have not been reported. Naftifine is supplied in two formulations: 1% cream and 1% gel. The cream is applied once daily, the gel twice daily. The usual duration of treatment is 4 weeks.

1066

92.2.5.2 Terbinafine**92.2.5.2.1 Actions and Uses.**

Terbinafine [Lamisil] belongs to the same chemical family as naftifine and has the same mechanism of action: inhibition of squalene epoxidase with resultant inhibition of ergosterol synthesis. The drug is highly active against dermatophytes, and less active against *Candida* species. Terbinafine is available in topical and oral formulations. Topical therapy is used for ringworm infections (eg, tinea corporis, tinea cruris, tinea pedis). Oral therapy is used for ringworm and onychomycosis (fungal infection of the nails).

92.2.5.2.2 Adverse Effects.

Adverse effects with *topical* terbinafine are minimal. The discussion that follows applies to *oral* therapy. The most common side effects are headache, diarrhea, dyspepsia, and abdominal pain. Oral terbinafine may also cause skin reactions and disturbance of taste. Of much greater concern, terbinafine may pose a risk of *liver failure*. As of April 2001, the FDA had received 16 reports of liver failure—including 11 deaths and 2 liver transplantations—in patients taking oral terbinafine. Although a causal link has not been established, caution is nonetheless advised. Baseline tests for serum alanine and aspartate aminotransferases (ALT and AST) are recommended. In addition, patients should be informed about signs of liver dysfunction (persistent nausea, anorexia, fatigue, vomiting, jaundice, right upper abdominal pain, dark urine, pale stools) and, if they appear, should discontinue terbinafine immediately and undergo evaluation of liver function. Terbinafine is not recommended for patients with pre-existing liver disease.

92.2.5.2.3 Preparations, Dosage, and Administration.

Terbinafine for oral therapy is available in 250-mg tablets sold as Lamisil. The dosage for nail infections is 250 mg/day for 6 to 12 weeks, and the dosage for ringworm is 250 mg/day for 2 to 6 weeks. Terbinafine for topical therapy is available in two formulations: 1% cream [Lamisil] and 1% gel [Lamisil DermGel]. Topical therapy typically lasts 1 to 2 weeks.

92.2.5.3 Butenafine

Butenafine [Lotrimin Ultra, Mentax] is chemically similar to naftifine and terbinafine, although the drug is not a true allylamine. However, it does have the same mechanism of action: inhibition of squalene epoxidase with resultant inhibition of ergosterol synthesis. Butenafine is indicated for topical therapy of tinea pedis (athlete's foot), tinea corporis (ringworm), tinea

cruris (jock itch), and tinea versicolor. Absorption is minimal, and systemic side effects have not been reported. Local reactions include burning, stinging, erythema, irritation, and itching. Butenafine 1% cream is applied once daily for 2 to 4 weeks.

92.2.6 Other Drugs for Superficial Mycoses

92.2.6.1 Tolnaftate

Tolnaftate is employed topically to treat a variety of superficial mycoses. The drug is active against dermatophytes, but not against *Candida* species. The mechanism of antifungal action is unknown. Adverse effects (sensitization, irritation) are extremely rare. Tolnaftate is available in several formulations. Creams, gels, and solutions are most effective; powders are used adjunctively. The drug is applied twice daily for 2 to 4 weeks. Trade names include Aftate, Tinactin, and Ting.

92.2.6.2 Undecylenic Acid

Undecylenic acid [Desenex, Cruex, others] is a topical agent used to treat superficial mycoses. The drug is active against dermatophytes but not *Candida* species. Its major indication is tinea pedis (athlete's foot). However, other drugs (tolnaftate, the azoles) are more effective.

92.2.6.3 Ciclopirox

Ciclopirox [Loprox, Penlac Nail Lacquer] is a broad-spectrum, topical antifungal drug. Benefits derive from chelating iron and aluminum present in metal-dependent enzymes that protect fungi from peroxides. Ciclopirox is used for infections of the skin (discussed here) and for infections of the fingernails and toenails (discussed above under *Onychomycosis*). The formulations used for skin infections are marketed as *Loprox*. The formulation used for nail infections is marketed as *Penlac Nail Lacquer*.

When applied to the skin, ciclopirox is active against dermatophytes and *Candida* species. The drug is effective against superficial candidiasis and tinea pedis, tinea cruris, and tinea corporis. Ciclopirox penetrates the epidermis to the dermis, but systemic absorption is minimal, and hence no significant systemic accumulation occurs. There is no toxicity from local application. For treatment of skin infections, ciclopirox is available as a 1% shampoo and as a 0.77% cream, gel, or suspension. The shampoo is used twice weekly for 4 weeks. The cream, gel, and suspension are applied twice daily for 2 to 4 weeks.

92.2.6.3.1

KEY POINTS

- Amphotericin B is a drug of choice for most systemic mycoses—despite its potential for serious harm.
- Amphotericin B binds to ergosterol in the fungal cell membrane, thereby making the membrane more permeable. The resultant leakage of intracellular cations reduces viability.
- Much of the toxicity of amphotericin B results from binding to cholesterol in host cell membranes.
- Because absorption of oral amphotericin B is poor, treatment of systemic mycoses requires intravenous administration.
- Amphotericin B infusion frequently causes fever, chills, rigors, nausea, and headache. Pretreatment with diphenhydramine plus an analgesic (eg, acetaminophen) can reduce mild symptoms. A glucocorticoid can be used for severe reactions. Meperidine or dantrolene can reduce rigors.
- Amphotericin B causes renal injury in most patients. Kidney damage can be minimized by infusing 1 L of saline on the day amphotericin is infused.
- If possible, amphotericin B should not be combined with other nephrotoxic drugs (eg, aminoglycosides, cyclosporine, NSAIDs).
- Itraconazole, our prototype for the azole antifungal agents, is active against a broad spectrum of fungi.
- Itraconazole inhibits cytochrome P450, and thereby inhibits synthesis of ergosterol, an essential component of the fungal cell membrane. As a result, cell membrane permeability increases, causing cellular components to leak out.
- Itraconazole is an alternative to IV amphotericin for many fungal infections. Advantages are lower toxicity and oral usability.
- Itraconazole has two major adverse effects: cardiosuppression and liver damage.
- Itraconazole inhibits CYP3A4, and can thereby raise levels of many drugs. High levels of cisapride, pimozide, dofetilide, and quinidine can cause fatal dysrhythmias, and hence use of these drugs with itraconazole is contraindicated.

- Drugs that reduce gastric acidity (eg, H₂ antagonists, proton pump inhibitors) can greatly reduce absorption of itraconazole.
- Topical clotrimazole, a member of the azole family of antifungals, is a drug of choice for many superficial mycoses caused by dermatophytes and *Candida* species.
- Onychomycosis (fungal infection of the fingernails and toenails) is difficult to treat and requires prolonged therapy. Preferred treatments are terbinafine and itraconazole.
- Vulvovaginal candidiasis can be treated with a single oral dose of fluconazole or with short-term topical therapy (eg, one 500-mg vaginal suppository of clotrimazole).

1067

1068

92.2.6.3.2

Summary of Major Nursing Implications*

The implications summarized below pertain only to use of antifungal drugs against *systemic* mycoses.

92.2.6.3.2.1

AMPHOTERICIN B

92.2.6.3.2....

Preadministration Assessment

92.2.6.3.2....

Therapeutic Goal

Treatment of progressive and potentially fatal systemic fungal infections. Flucytosine may be given to enhance therapeutic effects.

92.2.6.3.2....

Identifying High-Risk Patients

When used as it should be (ie, for life-threatening infections), amphotericin has no contraindications.

92.2.6.3.2....

Implementation: Administration

92.2.6.3.2....

Routes

Intravenous, intrathecal.

92.2.6.3.2....

Intravenous Administration

Use aseptic technique when preparing infusion solutions. Infuse slowly (over 2 to 4 hours). Check the solution periodically for a precipitate and, if one forms, discontinue the infusion immediately. Therapy lasts several months; rotate the infusion site to reduce phlebitis and ensure availability of a usable vein. Dosage must be individualized. Alternate-day dosing may be ordered to reduce adverse effects.

92.2.6.3.2....

Ongoing Evaluation and Interventions

92.2.6.3.2....

Minimizing Adverse Effects

92.2.6.3.2....

General Considerations.

Amphotericin B can produce serious adverse effects. The patient should be under close supervision, preferably in a hospital.

92.2.6.3.2....

Infusion Reactions.

Amphotericin can cause fever, chills, rigors, nausea, and headache. Pretreatment with diphenhydramine plus acetaminophen can minimize these reactions. Give meperidine or dantrolene if rigors develop. If other measures fail, give hydrocortisone to suppress symptoms. Rotate the infusion site and pretreat with heparin to minimize phlebitis. Infusion reactions can be reduced by using a lipid-based formulation rather than conventional amphotericin.

92.2.6.3.2....

Nephrotoxicity.

Almost all patients experience renal impairment. Monitor and record intake and output. Kidney function should be tested every 3 to 4 days; if plasma creatinine content rises above 3.5 mg/dL, amphotericin dosage should be reduced. The risk of renal damage can be decreased by infusing 1 L of saline on the day of amphotericin administration, avoiding other nephrotoxic drugs (eg, aminoglycosides, cyclosporine, NSAIDs), and using a lipid-based formulation instead of conventional amphotericin.

92.2.6.3.2....

Hypokalemia.

Renal injury may cause hypokalemia. Serum potassium should be measured frequently. Correct hypokalemia with potassium supplements.

92.2.6.3.2....

Hematologic Effects.

Normocytic, normochromic anemia has occurred secondary to amphotericin-induced suppression of bone marrow. Hematocrit determinations should be performed to monitor for this anemia.

92.2.6.3.2....

Minimizing Adverse Interactions

92.2.6.3.2....

Nephrotoxic Drugs.

Unless clearly required, amphotericin should not be combined with other nephrotoxic drugs, such as the aminoglycosides, cyclosporine, and NSAIDs.

92.2.6.3.2.2

ITRACONAZOLE

92.2.6.3.2....

Preadministration Assessment

92.2.6.3.2....

Therapeutic Goal

Treatment of systemic and superficial mycoses.

92.2.6.3.2....

Baseline Data

Assess for heart disease or a history thereof. The physician may order baseline tests of liver function.

92.2.6.3.2....

Identifying High-Risk Patients

Itraconazole is *contraindicated* for patients taking pimozide, quinidine, dofetilide, or cisapride.

Use with *great caution*, if at all, in patients with cardiac disease, significant pulmonary disease, active liver disease, or a history of liver injury with other drugs.

92.2.6.3.2....

Implementation: Administration

92.2.6.3.2....

Route

Oral.

92.2.6.3.2....

Administration

Advise patients to take itraconazole *capsules* with food and/or a cola beverage to enhance absorption.

Advise patients using antacids and other drugs that reduce gastric acidity to take them at least 1 hour before itraconazole or 2 hours after.

92.2.6.3.2....

Ongoing Evaluation and Interventions

92.2.6.3.2....

Minimizing Adverse Effects

92.2.6.3.2....

Liver Injury.

Rarely, itraconazole has been associated with fatal liver failure. If signs of liver injury appear, discontinue itraconazole and obtain tests of liver function. Inform patients about signs of liver dysfunction (persistent nausea, anorexia, fatigue, vomiting, right upper abdominal pain, jaundice, dark urine, pale stools), and instruct them to notify the prescriber if these occur.

92.2.6.3.2....

Cardiac Suppression.

Itraconazole can suppress ventricular function, posing a risk of heart failure. Monitor for signs and symptoms of heart failure, and discontinue itraconazole if they develop. Inform patients about signs of heart failure (fatigue, cough, dyspnea, edema, jugular distention), and instruct them to seek immediate medical attention if they occur.

92.2.6.3.2....

Minimizing Adverse Interactions

92.2.6.3.2....

Pimozide, Quinidine, Dofetilide, and Cisapride.

By inhibiting CYP3A4, itraconazole can raise levels of these drugs, posing a risk of fatal dysrhythmias. Accordingly, concurrent use of these drugs with itraconazole is contraindicated.

92.2.6.3.2....	Cyclosporine, Digoxin, Warfarin, and Sulfonyleureas.	1068
	By inhibiting CYP3A4, itraconazole can raise levels of these drugs. Monitor cyclosporine and digoxin blood levels. Monitor prothrombin time in patients taking warfarin. Monitor blood glucose in patients taking a sulfonyleurea.	1069
92.2.6.3.2....	Drugs That Raise Gastric pH.	
	Antacids, H ₂ antagonists, proton pump inhibitors, and other drugs that decrease gastric acidity can reduce itraconazole absorption. Advise patients using these agents to take them at least 1 hour before itraconazole or 2 hours after.	
92.2.6.3.2.3	FLUCYTOSINE	
92.2.6.3.2....	Preadministration Assessment	
92.2.6.3.2....	Therapeutic Goal	
	Treatment of serious infections caused by <i>Candida</i> species and <i>Cryptococcus neoformans</i> . Flucytosine is usually combined with amphotericin B.	
92.2.6.3.2....	Baseline Data	
	Obtain baseline tests of renal function, hematologic status, and serum electrolytes.	
92.2.6.3.2....	Identifying High-Risk Patients	
	Use with <i>extreme caution</i> in patients with kidney disease or bone marrow suppression.	
92.2.6.3.2....	Implementation: Administration	
92.2.6.3.2....	Route	
	Oral.	
92.2.6.3.2....	Dosage and Administration	
	Treatment may require ingestion of 10 or more capsules 4 times a day. Advise patients to take capsules a few at a time over a 15-minute interval to minimize nausea and vomiting. Dosage must be reduced in patients with renal impairment.	

92.2.6.3.2....

Ongoing Evaluation and Interventions

92.2.6.3.2....

Monitoring Summary

Obtain weekly tests of liver function (serum transaminase and alkaline phosphatase levels) and hematologic status (leukocyte counts). In patients receiving amphotericin B concurrently, and in those with pre-existing renal impairment, monitor kidney function and flucytosine levels.

92.2.6.3.2....

Minimizing Adverse Effects

92.2.6.3.2....

Hematologic Effects.

Flucytosine-induced bone marrow suppression can cause neutropenia, thrombocytopenia, and fatal agranulocytosis. Risk can be minimized by adjusting the dosage to keep plasma flucytosine levels below 100 mcg/mL. Obtain weekly leukocyte counts to monitor hematologic effects.

92.2.6.3.2....

Hepatotoxicity.

Mild and reversible liver dysfunction occurs frequently; severe hepatic damage is rare. Obtain weekly determinations of serum transaminase and alkaline phosphatase levels to evaluate liver function.

92.2.6.3.2....

Minimizing Adverse Interactions

92.2.6.3.2....

Amphotericin B.

Kidney damage from amphotericin B may decrease flucytosine excretion, thereby increasing toxicity secondary to flucytosine accumulation. When these drugs are combined, renal function and flucytosine levels must be monitored.

* Patient education information is highlighted as blue text.

⁹³CHAPTER 92 Antiviral Agents I: Drugs for Non-HIV Viral Infections

JACK LE FROCK

RICH LEHNE

Antiviral drugs are discussed in this chapter and the one that follows. In this chapter, we consider drugs used to treat infections caused by viruses other than HIV. In [Chapter 93](#), we consider drugs used against HIV infection. Drugs for non-HIV infections are summarized in [Table 92-1](#).

Although antiviral therapy has made significant advances in the last decade, our ability to treat viral infections remains limited. Compared with the dramatic advances made in antibacterial therapy over the past half-century, efforts to develop safe and effective antiviral drugs have been less successful. A major reason for this lack of success resides in the process of viral replication: Viruses are obligate intracellular parasites that use the biochemical machinery of host cells to reproduce. Because the viral growth cycle employs host-cell enzymes and substrates, it is difficult to suppress viral replication without doing significant harm to the host. The antiviral drugs used clinically act by suppressing biochemical processes unique to viral reproduction. As our knowledge of viral molecular biology expands, additional virus-specific processes will be discovered, giving us new targets against which to direct drugs.

TABLE 92-1 Major Drugs for Non-HIV Viral Infections

Drug	Antiviral Spectrum
Drugs for Herpes Simplex Virus and Varicella-Zoster Virus Infections	
Acyclovir	HSV, VZV
Famciclovir	HSV, VZV
Valacyclovir	HSV, VZV
Vidarabine	HSV, VZV
Penciclovir	HSV
Trifluridine	HSV keratitis
Idoxuridine	HSV keratitis
Drugs for Hepatitis	
Adefovir	HBV
Entecavir	HBV
Peginterferon alfa-2a	HBV
Interferon alfa-2b	HBV, HCV
Lamivudine	HBV*
Telbivudine	HBV
Drugs for Cytomegalovirus Infection	
Ganciclovir	CMV
Valganciclovir	CMV
Cidofovir	CMV
Fomivirsen†	CMV
Foscarnet	CMV, HSV resistant to acyclovir, VZV
Drugs for Influenza	
Oseltamivir	Influenza A and B
Zanamivir	Influenza A and B
Drugs for Respiratory Syncytial Virus Infection	
Ribavirin	RSV, influenza A and B
Palivizumab	RSV
CMV = cytomegalovirus, HBV = hepatitis B virus, HCV = hepatitis C virus, HSV = herpes simplex virus, RSV = respiratory syncytial virus, VZV = varicella-zoster virus.	

* Also active against HIV-1 and HIV-2.

† Withdrawn from the United States market.

1070

TABLE 92-2 Treatment of Herpes Simplex Virus and Varicella-Zoster Virus Infections

Infection	Drug	Route	Dosage	Duration
Herpes Simplex Virus Infections				
Primary genital	Acyclovir	PO	400 mg 3 times/day	7–10 days
	Valacyclovir	PO	1 gm 2 times/day	7–10 days
	Famciclovir	PO	250 mg 3 times/day	7–10 days
Recurrent genital, single episode suppression	Acyclovir	PO	400 mg 3 times/day	3–5 days
	Valacyclovir	PO	500 mg 2 times/day	3 days
	Famciclovir	PO	1000 mg 2 times/day	1 day
Recurrent genital, chronic suppression	Acyclovir	PO	400 mg 2 times/day	Up to 1 yr
	Valacyclovir	PO	500–1000 mg/day	Up to 1 yr
	Famciclovir	PO	250 mg 2 times/day	Up to 1 yr
Encephalitis	Acyclovir	IV	10–15 mg/kg every 8 hr	14–21 days
Mucocutaneous in ICH	Acyclovir	IV	5 mg/kg every 8 hr	7–10 days
		PO	400 mg 5 times/day	7–14 days
	Valacyclovir	PO	50 mg 2 times/day	7–10 days
	Famciclovir	PO	500 mg 2 times/day	7–10 days
	Foscarnet*	IV	400 mg 2–3 times/day	7–21 days
Neonatal	Acyclovir	IV	10–15 mg/kg every 8 hr	14 days
Oralabial	Acyclovir	Topical	5% cream 5 times/day	4 days
	Penciclovir	Topical	1% cream every 2 hr	4 days
	Docosanol	Topical	10% cream 5 times/day	4 days
Varicella-Zoster Virus Infections				
Varicella	Acyclovir	PO	20 mg/kg (800 mg max) 4 times/day	5 days
Varicella in ICH*	Acyclovir	IV	10 mg/kg every 8 hr	7 days
Herpes zoster	Acyclovir	PO	800 mg 5 times/day	7–10 days
	Valacyclovir	PO	1 gm 3 times/day	7 days
	Famciclovir	PO	500 mg 3 times/day	7 days
Herpes zoster in ICH*	Acyclovir	IV	10 mg/kg every 8 hr	7 days
Acyclovir-resistant zoster	Foscarnet	IV	40 mg/kg every 28 hr	10 days

Pharmacology for Nursing Care, 7th Edition

Keratoconjunctivitis	Trifluridine	Topical	1 drop every 2 hr while awake (max 9 drops/day) until healed, then 1 drop every 4 hr while awake for 7 days	Up to 21 days
ICH = immunocompromised host.				

* Reserve foscarnet for acyclovir-resistant infection.

93.1 DRUGS FOR INFECTION WITH HERPES SIMPLEX VIRUSES AND VARICELLA-ZOSTER VIRUS

Herpes simplex virus (HSV) and *varicella-zoster virus* (VZV) are members of the herpesvirus group. HSV causes infection of the genitalia, mouth and face, and other sites. VZV is the cause of *varicella* (chickenpox) and *herpes zoster* (shingles), a painful condition resulting from reactivation of VZV that had been dormant within sensory nerve roots. Both conditions are discussed further in [Chapter 67](#) (Childhood Immunization), along with the vaccine used to prevent VZV infection. Drugs for infection with HSV and VZV are summarized in [Table 92-2](#). Genital herpes is discussed in [Chapter 94](#).

93.1.1 Acyclovir

Acyclovir [Zovirax] is the agent of first choice for most infections caused by herpes simplex viruses and varicella-zoster virus. The drug can be administered topically, orally, and intravenously. Serious side effects are uncommon.

93.1.1.1 Antiviral Spectrum

Acyclovir is active only against members of the herpesvirus family, a group that includes *herpes simplex viruses* (HSVs), *varicella-zoster virus* (VZV), and *cytomegalovirus* (CMV). Of these, HSVs are most sensitive, VZV is moderately sensitive, and most strains of CMV are resistant.

93.1.1.2 Mechanism of Action

Acyclovir inhibits viral replication by suppressing synthesis of viral DNA. To exert antiviral effects, acyclovir must first undergo activation. The critical step in activation is conversion of acyclovir to acyclo-GMP by *thymidine kinase*. Once formed, acyclo-GMP is converted to acyclo-GTP, the compound directly responsible for inhibiting DNA synthesis. Acyclo-GTP suppresses DNA synthesis by (1) inhibiting viral DNA polymerase and (2) becoming incorporated into the growing strand of viral DNA, which blocks further strand growth.

The selectivity of acyclovir is based in large part on the ability of certain viruses to activate the drug. HSVs are especially sensitive to acyclovir because the drug is a much better substrate for thymidine kinase produced by HSVs than it is for mammalian thymidine kinase. Hence, formation of acyclo-GMP, the limiting step in the activation of acyclovir, occurs almost exclusively in cells infected with HSV. Cytomegalovirus is inherently resistant to the drug because acyclovir is a poor substrate for the form of thymidine kinase produced by this virus.

1071

1072

93.1.1.3 Resistance

Herpesviruses develop resistance to acyclovir by three mechanisms: (1) decreased production of thymidine kinase, (2) alteration of thymidine kinase such that it no longer converts acyclovir to acyclo-GMP, and (3) alteration of viral DNA polymerase such that it is less sensitive to inhibition. Of these mechanisms, thymidine kinase deficiency is the most common. Resistance is rare in immunocompetent patients, but many cases have been reported in transplant patients and patients with AIDS. Lesions caused by resistant HSVs can be extensive and severe, progressing despite continued acyclovir therapy. Acyclovir-resistant HSVs and VZV usually respond to IV foscarnet or cidofovir, which are primarily used for treatment of cytomegalovirus infection (see below).

93.1.1.4 Therapeutic Uses

93.1.1.4.1 Herpes Simplex Genitalis.

Most genital herpes infections are caused by *type 2 HSV* (HSV-2). For patients with *initial* infection, *topical* acyclovir reduces the duration of viral shedding, but does not accelerate healing. Topical acyclovir is not effective for *recurrent* genital infections. *Oral* acyclovir is superior to topical therapy for initial genital infections and for recurrent infections. For patients with initial infection, oral therapy decreases formation of additional lesions and decreases the duration and severity of the initial episode. For patients with recurrent herpes genitalis, continuous oral therapy reduces the frequency at which lesions appear. When initial genital infection is especially severe, *intravenous* acyclovir may be indicated. Patients with primary or recurrent herpes genitalis should be informed that, although acyclovir can decrease symptoms, the drug does not eliminate the virus and does not produce cure. Patients should be advised to avoid all sexual contact when lesions are present, and should use a condom even when lesions are absent.

In pregnant women with recurrent genital herpes, infection can be transmitted to the newborn during delivery. Treatment with acyclovir near term can suppress recurrence, and may

thereby eliminate the need for a cesarean section, which would otherwise be required to prevent neonatal HSV exposure.

93.1.1.4.2 Mucocutaneous Herpes Simplex Infections.

Herpes infections of the face and oropharynx are usually caused by HSV-2. For immunocompetent patients, *oral* acyclovir can be used to treat primary infections of the gums and mouth. Oral acyclovir can also be taken *prophylactically* to prevent episodes of *recurrent* herpes labialis (cold sores). However, there is no truly effective treatment for active herpes labialis. Mucocutaneous herpes infections can be especially severe in immunocompromised patients. For these people, *intravenous* acyclovir is the treatment of choice.

93.1.1.4.3 Varicella-Zoster Infections.

High doses of *oral* acyclovir are effective for herpes zoster (shingles) in older adults. Oral therapy is also effective for varicella (chickenpox) in children, adolescents, and adults, provided that dosing is begun early (within 24 hours of rash onset). *Intravenous* acyclovir is the treatment of choice for varicella-zoster infection in the immunocompromised host.

93.1.1.5 Pharmacokinetics

Acyclovir may be administered topically, orally, or intravenously. Oral bioavailability is low, ranging from 15% to 30%. No significant absorption occurs with topical use. Once in the blood, acyclovir is distributed widely to body fluids and tissues. Levels achieved in cerebrospinal fluid are 50% of those in plasma. Elimination is renal, primarily as the unchanged drug. In patients with normal kidney function, acyclovir has a half-life of 2.5 hours. The half-life is prolonged by renal impairment, reaching 20 hours in anuric patients. Accordingly, dosages should be reduced in patients with kidney disease.

93.1.1.6 Adverse Effects

93.1.1.6.1 Intravenous Therapy.

Intravenous acyclovir is generally well tolerated. The most common reactions are *phlebitis* and *inflammation* at the site of infusion. Reversible *nephrotoxicity*, manifested as elevations in serum creatinine and blood urea nitrogen, occurs in some patients. The cause of nephrotoxicity is deposition of acyclovir in renal tubules. The risk of renal injury is increased by dehydration and by use of other nephrotoxic drugs. Kidney damage can be minimized by

infusing acyclovir slowly (over 1 hour) and by ensuring adequate hydration during the infusion and for 2 hours after.

Neurologic toxicity—agitation, tremors, delirium, hallucinations, and myoclonus—occurs rarely, primarily in patients with renal impairment. In patients on dialysis, very low doses can cause severe neurotoxicity, characterized by delirium and coma.

93.1.1.6.2 Oral and Topical Therapy.

Oral acyclovir is devoid of serious adverse effects. Renal impairment has not been reported. The most common reactions to oral therapy are nausea, vomiting, diarrhea, headache, and vertigo. Topical acyclovir frequently causes transient burning or stinging; systemic reactions do not occur. Oral acyclovir is safe during pregnancy, and hence can be used to suppress recurrent genital herpes near term.

93.1.1.7 Preparations, Dosage, and Administration

93.1.1.7.1 Topical: Ointment.

Acyclovir [Zovirax] is supplied as a 5% ointment for topical therapy of *herpes genitalis* and *mild mucocutaneous HSV infection in the immunocompromised host*. Application is done 6 times a day at 3-hour intervals for 7 days. Patients should use a finger cot or rubber glove to avoid viral transfer to other parts of the body or to other people.

93.1.1.7.2 Topical: Cream.

Acyclovir [Zovirax] is supplied as a 5% cream for topical therapy of recurrent *herpes labialis* (cold sores) in patients at least 12 years old. Application is done 5 times a day for 4 days.

93.1.1.7.3 Oral.

Oral acyclovir [Zovirax] is available in capsules (200 mg), tablets (400 and 800 mg), and a suspension (200 mg/5 mL). Dosages for patients with normal kidney function are given below. Dosages must be reduced for patients with renal impairment.

- For *initial episodes of herpes genitalis*, the usual dosage is 400 mg 3 times a day for 7 to 10 days.

- For *episodic recurrences of herpes genitalis*, the usual dosage is 400 mg 3 times a day for 5 days.
- For *long-term suppressive therapy of recurrent genital infections*, the usual dosage is 400 mg twice daily for up to 12 months.
- For *acute therapy of herpes zoster*, the dosage is 800 mg 5 times a day (at 4-hour intervals) for 7 to 10 days.
- For *varicella* (chickenpox), the dosage is 20 mg/kg (but no more than 800 mg) 4 times a day for 5 days. Treatment should begin at the earliest sign of rash.

1072

93.1.1.7.4

Intravenous.

1073

Acyclovir [Zovirax] for IV use is available (1) in solution (25 and 50 mg/mL) and (2) as a powder (500 mg/10-mL vial, 1000 mg/20-mL vial) to be reconstituted in sterile water to a final concentration of 50 mg/mL. Administration is by slow IV infusion (over 1 hour or more). Acyclovir must not be given by IV bolus or by IM or subQ injection. To minimize the risk of renal damage, hydrate the patient during the infusion and for 2 hours after. Dosages for patients with normal kidney function are given below. Dosages should be reduced for patients with renal impairment.

- For *mucocutaneous herpes simplex infection in the immunocompromised host*, the adult dosage is 5 mg/kg infused every 8 hours for 7 days. The dosage for children under 12 years is 250 mg/m² infused every 8 hours for 7 days.
- For *varicella-zoster infection in the immunocompromised host*, the adult dosage is 10 mg/kg infused every 8 hours for 7 days. The dosage for children under 12 years is 500 mg/m² infused every 8 hours for 7 days.
- For *severe episodes of herpes genitalis in the immunocompetent host*, the adult dosage is 5 to 10 mg/kg infused every 8 hours for 5 to 7 days (or until symptoms resolve). The dosage for children under 12 years is 250 mg/m² infused every 8 hours for 5 days.

93.1.2 Valacyclovir

93.1.2.1 Actions and Uses.

Valacyclovir [Valtrex], a prodrug form of acyclovir, has three approved indications: (1) herpes zoster (shingles), (2) herpes simplex genitalis, and (3) herpes labialis (cold sores). In all three infections, benefits depend on conversion of valacyclovir to acyclovir, its active form. In a clinical trial in patients with *herpes zoster*, valacyclovir (1000 mg 3 times a day for 7 or 14 days) was somewhat more effective than acyclovir (800 mg 5 times a day for 7 days) in reducing the duration of pain and the duration of postherpetic neuralgia. In clinical trials in patients with initial or recurrent *herpes genitalis*, valacyclovir (1000 mg twice a day) and acyclovir (200 mg 5 times a day) produced similar results. In a recent study, valacyclovir was shown to reduce—but not eliminate—the risk of transmitting genital herpes between monogamous heterosexual partners.

In patients receiving immunosuppressive drugs following a kidney transplant, prophylaxis with valacyclovir (2 gm 4 times a day for 90 days) can reduce the risk of CMV disease, a major complication of transplant surgery.

93.1.2.2 Pharmacokinetics.

After oral dosing, valacyclovir undergoes rapid absorption followed by rapid and essentially complete conversion to acyclovir. When acyclovir itself is given PO, bioavailability is only 15% to 30%. In contrast, when valacyclovir is given PO, the effective bioavailability of acyclovir is greatly increased—to about 55%. Hence, valacyclovir represents a more efficient way of getting acyclovir into the body. Following conversion of valacyclovir to acyclovir, the kinetics are the same as if acyclovir itself had been given.

93.1.2.3 Adverse Effects.

In some immunocompromised patients, valacyclovir has produced a syndrome known as *thrombotic thrombocytopenic purpura/hemolytic uremic syndrome* (TTP/HUS). This syndrome, which is potentially fatal, has not occurred in immunocompetent patients. Valacyclovir is not approved for use in immunocompromised hosts. Aside from causing TTP/HUS, valacyclovir is generally well tolerated, producing the same side effects seen with oral acyclovir (eg, nausea, vomiting, diarrhea, headache, vertigo).

93.1.2.4 Preparations, Dosage, and Administration.

Valacyclovir [Valtrex] is available in 500- and 1000-mg oral capsules. Dosing may be done without regard to meals. In patients with renal impairment, dosages should be reduced.

For patients with *herpes zoster*, the recommended dosage is 1000 mg 3 times a day for 7 days. Therapy should begin as soon as possible after symptom onset.

For patients with *herpes simplex genitalis*, the dosage is 1 gm twice daily for 10 days (for the initial episode), 500 mg twice daily for 3 days (for episodic recurrences), and 500 to 1000 mg once daily (for long-term suppression).

For patients with *herpes labialis*, the dosage is 2 gm twice, taken 12 hours apart. Dosing should begin as soon as possible after onset of symptoms.

93.1.3 Famciclovir

Famciclovir [Famvir] is a prodrug used to treat acute herpes zoster and genital herpes infection. Benefits are equivalent to those of acyclovir. Adverse effects are minimal.

93.1.3.1 Pharmacokinetics.

Famciclovir undergoes rapid absorption from the GI tract followed by enzymatic conversion to *penciclovir*, its active form. Food decreases the rate of famciclovir absorption but not the extent. As a result, the amount of penciclovir produced is the same whether famciclovir is taken with or without food. Penciclovir is excreted in the urine, largely unchanged. The *plasma* half-life of penciclovir is about 2.5 hours. However, the half-life of penciclovir *within cells* is much longer. In patients with renal impairment, the plasma half-life of penciclovir is prolonged.

93.1.3.2 Mechanism of Action and Antiviral Spectrum.

Penciclovir undergoes intracellular conversion to penciclovir triphosphate, a compound that inhibits viral DNA polymerase, and thereby prevents replication of viral DNA. Under clinical conditions, formation of penciclovir triphosphate requires viral thymidine kinase. As a result, inhibition of DNA synthesis is limited to cells that are infected, leaving the vast majority of host cells unharmed. *In vitro*, penciclovir is active against HSV type 1 (HSV-1), HSV-2, and VZV.

93.1.3.3 Therapeutic Use.

Famciclovir is approved for treatment of acute herpes zoster (shingles) and herpes simplex genitalis. In patients with herpes zoster, the drug can decrease the time to full crusting from 7 days down to 5 days. Famciclovir does not decrease the *incidence* of postherpetic neuralgia, but can decrease the *duration* (from 112 days down to 61 days). In a trial comparing famciclovir with acyclovir, both drugs had equivalent effects against herpes zoster.

In patients with genital herpes simplex infection, famciclovir is active against the first episode and recurrent episodes. In addition, it can be used for long-term suppression.

93.1.3.4 Adverse Effects.

Famciclovir is very well tolerated. In clinical trials, the incidence of side effects was the same as with placebo. Safety for use during pregnancy or breast-feeding and in children under the age of 18 has not been established.

93.1.3.5 Preparations, Dosage, and Administration. Preparations.

Famciclovir [Famvir] is supplied in tablets (125, 250, and 500 mg) for oral use. Dosing can be done without regard to meals.

93.1.3.5.1 Acute Herpes Zoster.

The recommended dosage is 500 mg every 8 hours for 7 days. Treatment should start no later than 72 hours after symptom onset. In patients with renal impairment, the interval between doses should be increased to 12 hours or 24 hours, depending on the degree of impairment.

93.1.3.5.2 Herpes Simplex Genitalis.

For initial episodes, the dosage is 250 mg 3 times a day for 5 to 10 days. For episodic recurrence, the dosage is 125 mg twice a day for 5 days (or two 1000-mg doses 12 hours apart). For long-term suppression, the dosage is 250 mg twice daily.

93.1.4 Topical Drugs for Herpes Labialis

We have three topical drugs for recurrent herpes labialis (cold sores). Two of these drugs—penciclovir and docosanol—are discussed below. The third drug—acyclovir—is discussed above.

93.1.4.1 Penciclovir Cream

Penciclovir [Denavir] is a topical drug indicated for recurrent herpes labialis (cold sores), an infection caused by HSV-1 and HSV-2. The drug suppresses viral replication by inhibiting DNA polymerase, the enzyme that makes DNA. Penciclovir is supplied as a 1% cream to be applied every 2 hours (except when sleeping) for 4 days. In clinical trials, benefits were modest: The average time to healing and duration of pain were decreased by just half a day, from 5 days down to 4.5 days. The only common adverse effect is mild local erythema.

93.1.4.2 Docosanol Cream

Docosanol [Abreva] is a topical preparation indicated for recurrent herpes labialis. The drug is available over the counter as a 10% cream. Application is done 5 times a day, beginning at the first sign of recurrence. Benefits are modest. In one clinical trial, treatment reduced the time to healing from 4.8 days down to 4.1 days—about the same response seen with penciclovir. Docosanol cream appears devoid of adverse effects.

Docosanol has a broad antiviral spectrum and a unique mechanism of action. Unlike penciclovir, which inhibits viral DNA synthesis (and thereby suppresses replication), docosanol blocks viral entry into host cells. The drug does not kill viruses and does not prevent them from binding to cells. As a result, viable virions can remain attached to the cell surface for a long time. Because docosanol does not affect processes of replication, it is unlikely to promote resistance.

93.1.5 Topical Drugs for Ocular Herpes Infections

93.1.5.1 Trifluridine Ophthalmic Solution

Trifluridine [Viroptic] is indicated only for topical treatment of ocular infections caused by HSV-1 and HSV-2. The drug is given to treat acute keratoconjunctivitis and recurrent epithelial keratitis. Antiviral actions result from inhibiting DNA synthesis. The most common side effects are localized burning and stinging. Edema of the eyelid occurs in about 3% of patients. Systemic absorption is minimal following topical administration, and hence the drug is devoid of systemic toxicity. Trifluridine is supplied as a 1% ophthalmic solution. Treatment consists of placing 1 drop on the cornea every 2 hours while the patient is awake, for a maximum of 9 drops/day. Once re-epithelialization of the cornea has occurred, the dosage is reduced to 1 drop every 4 hours. Treatment continues for 7 days.

1073

1074

93.1.5.2 Vidarabine Ointment

Like trifluridine, topical vidarabine [Vira-A] is indicated for acute keratoconjunctivitis and recurrent epithelial keratitis caused by HSV-1 and HSV-2. Antiviral effects result from inhibition of viral DNA polymerase and from premature termination of the growing viral DNA chain. The most frequent side effects are burning sensations, photophobia, and lacrimation. Absorption of topical vidarabine is insignificant, and systemic toxicity has not been reported. Vidarabine is available in a 3% ointment for application to the eye. About ½ inch of ointment is administered into the lower conjunctival sac 5 times a day at 3-hour intervals. As a rule, treatment lasts for no more than 3 weeks.

93.2 DRUGS FOR CYTOMEGALOVIRUS INFECTION

Cytomegalovirus (CMV) is a member of the herpesvirus group, which includes herpes simplex virus types 1 and 2, varicella-zoster virus (the cause of chickenpox), and Epstein-Barr virus (the cause of infectious mononucleosis). Transmission of CMV occurs person to person—through direct contact with saliva, urine, blood, tears, breast milk, semen, and other body fluids. Infection can also be acquired by way of blood transfusion or organ transplantation. Infection with CMV is very common: Between 50% and 85% of Americans age 40 and older harbor the virus. After the initial infection, which has minimal symptoms in healthy people, the virus remains dormant within cells for life, without causing detectable injury or clinical illness. Hence, for most healthy people, CMV infection is of little concern. By contrast, people who are immunocompromised—owing to HIV infection, cancer chemotherapy, or use of immunosuppressive drugs—are at high risk of serious morbidity and even death, both from initial CMV infection and from reactivation of dormant CMV. Common sites for infection are the lungs, eyes, and GI tract. Among people with AIDS, CMV retinitis is the principal reason for loss of vision (see [Chapter 93](#)). The five drugs used against CMV are discussed below.

93.2.1 Ganciclovir

Ganciclovir [Cytovene, Vitrasert] is a synthetic antiviral agent with activity against herpesviruses, including CMV. Because the drug can cause serious adverse effects, especially granulocytopenia and thrombocytopenia, use should be restricted to prevention and treatment of CMV infection in the immunocompromised host.

93.2.1.1 Mechanism of Action.

Ganciclovir is converted to its active form, ganciclovir triphosphate, inside infected cells. As ganciclovir triphosphate, it suppresses replication of viral DNA by (1) inhibiting viral DNA polymerase and (2) undergoing incorporation into the growing DNA chain, which causes premature chain termination.

93.2.1.2 Pharmacokinetics.

Bioavailability of oral ganciclovir is low: only 5% under fasting conditions and 9% when taken with food. Once in the blood, the drug is widely distributed to body fluids and tissues. Ganciclovir is excreted unchanged in the urine. In patients with normal renal function, the half-life is about 3 hours. In patients with renal impairment, the half-life is prolonged. Accordingly, dosages should be reduced in patients with kidney disease.

93.2.1.3 Therapeutic Use.

Ganciclovir is used only for prevention and treatment of CMV infection in immunocompromised patients, including those with HIV infection and those receiving immunosuppressive drugs. Specific uses include:

- Treatment of sight-threatening CMV retinitis
- Treatment of CMV pneumonitis
- Treatment of acute CMV colitis
- Prevention of CMV infection in transplant recipients
- Preemptive treatment of patients with CMV antigenemia or viremia

In patients with AIDS, CMV retinitis has an incidence of 15% to 40%. Although most AIDS patients respond initially, the relapse rate is high. Accordingly, for most patients, maintenance therapy should continue indefinitely. The risk of relapse is higher with oral ganciclovir than with IV ganciclovir. Since viral resistance can develop during treatment, this possibility should be considered if the patient responds poorly.

93.2.1.4 Adverse Effects.

Granulocytopenia and Thrombocytopenia. The adverse effect of greatest concern is bone marrow suppression, which can result in granulocytopenia (40%) and thrombocytopenia (20%). These effects, which are usually reversible, are more likely with IV therapy than with oral therapy. These hematologic responses can be exacerbated by concurrent therapy with zidovudine. Conversely, granulocytopenia can be reduced with granulocyte colony-stimulating factors (see [Chapter 55](#)). Because of the risk of adverse hematologic effects, blood cell counts must be monitored. Treatment should be interrupted if the absolute neutrophil count falls below $500/\text{mm}^3$ or if the platelet count falls below $25,000/\text{mm}^3$. Cell counts usually begin to recover within 3 to 5 days. Ganciclovir should be used with caution in patients with pre-existing cytopenias, in those with a history of cytopenic reactions to other drugs, and in those taking other bone marrow suppressants (eg, zidovudine, trimetrexate).

93.2.1.4.1 Reproductive Toxicity

Ganciclovir is teratogenic and embryotoxic in laboratory animals and probably in humans. Women should be advised to avoid pregnancy during therapy and for 90 days after ending treatment. At doses equivalent to those used therapeutically, ganciclovir inhibits spermatogenesis in mice; sterility is reversible with low doses and irreversible with high doses. Female infertility may also occur. Patients should be forewarned of these effects.

93.2.1.4.2 Other Adverse Effects.

Incidental effects include nausea, fever, rash, anemia, liver dysfunction, and confusion and other central nervous system (CNS) symptoms. In mice, very high doses (1000 mg/kg) have caused cancer.

93.2.1.5 Preparations, Dosage, and Administration.

Intravenous. Ganciclovir [Cytovene] is available as a powder to be reconstituted for IV infusion. Solutions are alkaline and must be infused into a freely flowing vein to avoid local injury. For treatment of CMV retinitis, the *initial dosage* for adults with normal renal function is 5 mg/kg (infused over 1 hour) every 12 hours for 14 to 21 days. Two *maintenance dosages* can be used: (1) 5 mg/kg infused over 1 hour once every day or (2) 6 mg/kg infused over 1 hour once a day, 5 days each week. Dosages must be reduced for patients with renal impairment. Since many patients with AIDS must continue maintenance therapy for life, they

need a permanent IV line and equipment for home infusion. Adequate hydration must be maintained in all patients to ensure renal excretion of ganciclovir.

1074

93.2.1.5.1 Oral.

1075

Oral ganciclovir [Cytovene] is indicated for maintenance therapy in patients with CMV retinitis. The dosage is 1000 mg 3 times daily with food.

93.2.1.5.2 Intraocular.

The ganciclovir intraocular implant [Vitrasert] is indicated for CMV retinitis in patients with AIDS. Surgical implantation, which takes about 1 hour, is performed under local anesthesia on an outpatient basis. Vision is usually blurred for 2 to 4 weeks after the procedure. The implant must be replaced every 5 to 8 months. Clinical trials indicate that CMV retinitis progresses more slowly in patients who receive intraocular ganciclovir compared with those on IV ganciclovir.

93.2.2 Valganciclovir

93.2.2.1 Basic and Clinical Pharmacology.

Valganciclovir [Valcyte] is a prodrug version of ganciclovir [Cytovene] with greater oral bioavailability (60% vs. 9%). Like ganciclovir, valganciclovir is indicated for CMV retinitis. Following absorption from the GI tract, valganciclovir is rapidly metabolized to ganciclovir, its active form—and eventually undergoes excretion as unchanged ganciclovir in the urine. When compared with *intravenous* ganciclovir in patients with active CMV retinitis, oral valganciclovir was just as effective—and much more convenient. Recently, valganciclovir was shown to reduce transmission of genital herpes (see [Chapter 94](#)).

Adverse effects are the same as with ganciclovir. The principal concern is blood dyscrasias—granulocytopenia (27%), anemia (26%), and thrombocytopenia (6%)—secondary to bone marrow suppression. In addition, valganciclovir frequently causes diarrhea (41%), nausea (30%), vomiting (21%), fever (31%), and headache (22%). Valganciclovir is presumed to pose the same risks of mutagenesis, aspermatogenesis, and carcinogenesis as ganciclovir.

93.2.2.2 Preparations, Dosage, and Administration.

Valganciclovir [Valcyte] is available in 450-mg tablets for oral use. The dosage for *induction* (treatment of active CMV retinitis) is 900 mg (2 tablets) twice daily for 21 days. The dosage

for *maintenance* is 900 mg once daily. All doses should be taken with food to enhance bioavailability. Dosage must be reduced for patients with renal impairment.

Because valganciclovir has the potential for mutagenesis and carcinogenesis, it should be handled carefully. Tablets should be ingested intact, without crushing or chewing. Direct contact with broken tablets should be avoided. If contact does occur, the area should be washed with soap and water. When handling or disposing of the drug, healthcare workers should follow the same guidelines established for cytotoxic anticancer drugs.

93.2.3 Cidofovir

Cidofovir [Vistide] is an IV drug with just one indication: CMV retinitis in patients with AIDS who have failed on ganciclovir or foscarnet. Alternative drugs for this infection are foscarnet, which is given IV, and ganciclovir, which may be administered IV, PO, or by ocular insert. Compared with IV foscarnet or IV ganciclovir, cidofovir has the distinct advantage of needing fewer infusions: Whereas foscarnet and ganciclovir must be infused daily, cidofovir is infused just once a week or every other week. The major adverse effect of the drug is kidney damage.

93.2.3.1 Mechanism of Action.

Once inside cells, cidofovir is converted to cidofovir diphosphate, its active form. As the diphosphate, cidofovir causes selective inhibition of viral DNA polymerase, and thereby inhibits viral DNA synthesis. Intracellular concentrations of cidofovir diphosphate are too low to inhibit human DNA polymerases. Hence, host cells are spared.

93.2.3.2 Antiviral Spectrum and Therapeutic Use.

Cidofovir is active against herpesviruses, including CMV, HSV-1, HSV-2, and VZV. At this time, the drug is approved only for CMV retinitis in patients with AIDS. Whether cidofovir is active against CMV infections in other patients or at other sites (eg, GI tract, lungs) is unknown. In clinical trials in patients with AIDS and established CMV retinitis, cidofovir significantly delayed progression of retinitis.

93.2.3.3 Pharmacokinetics.

Cidofovir is administered by IV infusion and is excreted by the kidneys. Probenecid competes with cidofovir for renal tubular secretion, and thereby delays elimination. Cidofovir has a prolonged *intracellular* half-life (17 to 65 hours), and hence a long interval (2 weeks) can separate doses. In contrast, IV foscarnet and ganciclovir must be infused daily.

93.2.3.4 Adverse Effects. Nephrotoxicity.

The principal adverse effect is dose-dependent nephrotoxicity, manifesting as decreased renal function and symptoms of a Fanconi-like syndrome (proteinuria, glucosuria, bicarbonate wasting). To reduce the risk of renal injury, all patients must receive probenecid and IV hydration therapy with each infusion. Also, serum creatinine and urine protein should be checked within 48 hours prior to each dose and, if these values indicate kidney damage, cidofovir should be withheld or the dosage reduced. Cidofovir is contraindicated for patients taking other drugs that can injure the kidney, and for patients with proteinuria (2+ or greater) or baseline serum creatinine greater than 1.5 mg/dL.

93.2.3.5 Other Adverse Effects.

Neutropenia develops in about 20% of patients, and hence neutrophil counts should be monitored. *Ocular disorders*—iritis, uveitis, or ocular hypotony (low intraocular pressure)—can also occur. Adverse effects are more common in patients taking antiretroviral drugs. In animal studies, cidofovir was carcinogenic and teratogenic, and caused hypospermia. Adverse effects are more likely in patients taking antiretroviral drugs (ie, drugs for HIV).

93.2.3.6 Preparations, Dosage, and Administration.

Cidofovir [Vistide] is supplied in solution (75 mg/mL) in 5-mL ampules. To reduce the risk of renal injury, cidofovir infusions must be accompanied by IV hydration therapy and PO probenecid.

Each cidofovir dose—for induction or maintenance—consists of 5 mg/kg infused IV over 1 hour. For induction, two doses are given 1 week apart. For maintenance, one dose is given every 2 weeks. The size of each dose must be reduced for patients with renal impairment. If impairment is severe, cidofovir should be withheld.

Oral probenecid must accompany each infusion. The dosage is 2 gm given 3 hours before the infusion, 1 gm given 1 hour after the infusion, and 1 gm more given 8 hours after that. Ingesting food before each dose can decrease probenecid-induced nausea and vomiting. An antiemetic may also be used.

Hydration is accomplished by infusing 1 L of 0.9% saline solution over 1 to 2 hours immediately before infusing cidofovir. For patients who can tolerate it, 1 L more can be infused over 1 to 3 hours, beginning when the cidofovir infusion begins or as soon as it is over.

93.2.4 Foscarnet

Foscarnet [Foscavir] is an IV drug active against all known herpesviruses, including CMV, HSV-1, HSV-2, and VZV. Compared with ganciclovir, foscarnet is more difficult to administer, less well tolerated, and much more expensive (the cost to the pharmacy is about \$20,000 a year). The major adverse effect is renal injury.

93.2.4.1 Mechanism of Action.

Foscarnet, an analog of pyrophosphate, inhibits viral DNA polymerases and reverse transcriptases, and thereby inhibits synthesis of viral nucleic acids. At the concentrations achieved clinically, the drug does not inhibit host DNA replication. Unlike many other antiviral drugs, which must undergo conversion to an active form, foscarnet is active as administered.

93.2.4.2 Therapeutic Use.

Foscarnet has two approved indications: (1) CMV retinitis in patients with AIDS and (2) acyclovir-resistant mucocutaneous HSV and VZV infection in the immunocompromised host. CMV retinitis resistant to ganciclovir may respond to foscarnet.

93.2.4.3 Pharmacokinetics.

Foscarnet has low oral bioavailability and must be administered IV. The drug is poorly soluble in water and does not penetrate cells easily. As a result, it must be given in large doses with large volumes of fluid. Between 10% and 28% of each dose is deposited in bone; the remainder is excreted unchanged in the urine. Because foscarnet is eliminated by the kidneys, dosages must be reduced in patients with renal impairment. The plasma half-life is 3 to 5 hours.

93.2.4.4 Adverse Effects and Interactions.

Foscarnet is generally less well tolerated than ganciclovir. However, unlike ganciclovir, foscarnet does not cause granulocytopenia or thrombocytopenia.

93.2.4.4.1 Nephrotoxicity.

Renal injury, as evidenced by a rise in serum creatinine concentration, is the most common dose-limiting toxicity. Most patients develop some degree of renal impairment. Renal injury occurs most often during the second week of therapy. The risk of nephrotoxicity is increased by concurrent use of other nephrotoxic drugs, including amphotericin B, aminoglycosides

(eg, gentamicin), and pentamidine. Prehydration with IV saline may reduce the risk of renal injury. Renal function (creatinine clearance) should be monitored closely and the dosage should be reduced if renal impairment develops.

93.2.4.4.2 Electrolyte and Mineral Imbalances.

Foscarnet frequently causes hypocalcemia, hypokalemia, hypomagnesemia, and hypo- or hyperphosphatemia. Ionized serum calcium may be reduced despite normal levels of total serum calcium. Patients should be informed about symptoms of low ionized calcium (eg, paresthesias, numbness in the extremities, perioral tingling) and instructed to report these. Severe hypocalcemia can result in dysrhythmias, tetany, and seizures. Serum levels of calcium, magnesium, potassium, and phosphorus should be measured frequently. Special caution is required in patients with pre-existing electrolyte, cardiac, or neurologic abnormalities. The risk of hypocalcemia is increased by concurrent use of pentamidine.

93.2.4.4.3 Other Adverse Effects.

Common reactions include fever (65%), nausea (47%), anemia (33%), diarrhea (30%), vomiting (26%), and headache (26%). In addition, foscarnet can cause fatigue, tremor, irritability, genital ulceration, abnormal liver function tests, neutropenia, and seizures.

1075

1076

93.2.4.5 Preparations, Dosage, and Administration.

Foscarnet [Foscavir] is dispensed in solution (24 mg/mL) for IV infusion. An infusion pump is essential to reduce the risk of accidental overdose. Infusions may be administered through a central venous line or a peripheral vein. When a central line is used, a concentrated (24 mg/mL) solution may be given. When a peripheral vein is used, the solution should be diluted to 12 mg/mL. For patients with normal kidney function, the *initial* dosage is 60 mg/kg (for CMV infection) or 40 mg/kg (for HSV infection) infused over 1 hour (or longer) every 8 hours for 2 to 3 weeks. The *maintenance* dosage (for CMV or HSV infection) is 90 to 120 mg/kg infused over 2 hours once daily. All dosages must be reduced for patients with renal impairment.

93.2.5 Fomivirsen

93.2.5.1 Clinical Pharmacology.

Fomivirsen [Vitravene] is a unique drug approved for treating CMV retinitis in HIV-infected patients who are intolerant of or unresponsive to other drugs. Administration is by direct injection into the vitreous humor. The dosage is 0.05 mL (0.33 mg) on days 1 and 14, and

every 4 weeks thereafter. Enzymes within the eye degrade fomivirsen to inactive mononucleotide fragments over a span of 7 to 10 days. The most common adverse effect is ocular inflammation, which develops in 25% of patients. Inflammation can be suppressed with topical glucocorticoids. Other common reactions include vision changes and elevated intraocular pressure. In 2009, fomivirsen was withdrawn from the United States market.

93.2.5.2 Mechanism of Action.

Fomivirsen is the first representative of a new class of drugs, known as “antisense” agents. Antisense drugs consist of a single strand of DNA designed to bind to specific molecules of messenger RNA and thereby block synthesis of disease-causing proteins. Benefits of fomivirsen derive from blocking production of viral proteins required by CMV for replication.

93.3 DRUGS FOR HEPATITIS

Viral hepatitis is the most common liver disorder. Millions of Americans are infected. Viral hepatitis can be caused by six different hepatitis viruses, labeled A, B, C, D, E, and G. All six can cause *acute* hepatitis, but only B, C, and D also cause *chronic* hepatitis. Acute hepatitis lasts for 6 months or less and is characterized by liver inflammation, jaundice, and elevation of serum alanine aminotransferase (ALT) activity. In most cases, acute hepatitis resolves spontaneously, and hence intervention is generally unnecessary. In contrast, chronic hepatitis can lead to cirrhosis, hepatocellular carcinoma, and life-threatening liver failure, and hence treatment should be considered.

Most cases (90%) of chronic hepatitis are caused by either hepatitis B virus (HBV) or hepatitis C virus (HCV). Accordingly, our discussion focuses on hepatitis B and hepatitis C. About 1.5% of Americans are infected with HBV or HCV, which is 5 times more than the number infected with HIV. Comparisons between hepatitis A, B, and C are summarized in [Table 92-3](#). Vaccines for hepatitis A and B are discussed in [Chapter 67](#). Drugs for hepatitis B and C are discussed below.

93.3.1 Hepatitis C

About 2.7 million Americans have chronic hepatitis C. Transmission occurs primarily through exchange of blood. Whether sexual transmission occurs is controversial. Furthermore, if sexual transmission *does* occur, the risk of transmission between monogamous heterosexual partners is extremely low. Among people who acquire HCV, 75% to 85% develop active infection. However, most people with chronic hepatitis C have no symptoms, although they can transmit HCV to others. Chronic HCV infection undergoes slow progression, and, in some people, eventually causes liver failure, cancer, and death. Chronic hepatitis C is the leading reason for

liver transplants, and kills about 12,000 Americans each year. Currently, treatment is recommended only for patients with HCV viremia, persistent elevation of ALT, and evidence of hepatic fibrosis and inflammation upon liver biopsy. The most effective treatment for hepatitis C is *pegylated interferon alfa (peginterferon alfa) combined with ribavirin*. There is no vaccine for hepatitis C.

It is important to note that not all hepatitis C viruses are the same. There are 6 genotypes of HCV, and more than 50 subtypes. In the United States, 75% of HCV infections are caused by HCV genotype 1, which, unfortunately, is less responsive to treatment than other HCV genotypes. Before drug therapy is initiated, HCV genotype should be determined.

93.3.1.1 Interferon Alfa Preparations

Human interferons are naturally occurring compounds with complex antiviral, immunomodulatory, and antineoplastic actions. The interferon family has three major classes, designated alpha, beta, and gamma. All of the interferons used for hepatitis belong to the alpha class ([Table 92-4](#)). In the discussion below, these compounds are referred to collectively as *interferon alfa*. None of these agents can be used orally, and hence administration is parenteral—almost always subQ. Commercial production is by recombinant DNA technology.

TABLE 92-3 Characteristics of Hepatitis A, Hepatitis B, and Hepatitis C

Point of Comparison	Hepatitis A	Hepatitis B	Hepatitis C
Causative agent	Hepatitis A virus	Hepatitis B virus	Hepatitis C virus
Infections that become chronic	None	3–5%	Over 70%
Acute infections each year in the United States	179,000	185,000	38,000
U.S. residents with chronic infection	None	1.25 million	2.7 million
Annual deaths in the United States from chronic infection	None	6000	8000–10,000
People worldwide with chronic infection	None	350 million	170 million
Method of prevention	Hepatitis A vaccine	Hepatitis B vaccine	None available
Preferred treatment	None	Interferon alfa <i>or</i> lamivudine	Peginterferon alfa <i>plus</i> ribavirin

93.3.1.1.1 Mechanism of Action.

Interferon alfa has multiple effects on the viral replication cycle. After binding to receptors on host cell membranes, the drug blocks viral entry into cells, synthesis of viral messenger RNA and viral proteins, and viral assembly and release.

93.3.1.1.2 Conventional Versus Long-Acting Interferons.

The alfa interferons can be divided into two groups—conventional and long acting—based on their time course of action (see [Table 92-4](#)). The conventional preparations have short half-lives, and hence must be administered frequently—at least *3 times a week*. In contrast, the long-acting preparations are administered less frequently—just *once a week*—making them more convenient. In addition, with the long-acting preparations, blood levels remain high between doses, and hence clinical responses are better.

How are long-acting interferons made? By conjugating a conventional interferon (eg, interferon alfa-2a) with polyethylene glycol (PEG), in a process known as *pegylation*. Therapeutic effects of the pegylated product are due solely to its interferon component. The PEG component serves only to delay elimination. At this time, two long-acting interferons are available: *pegylated interferon (peginterferon) alfa-2a* [Pegasys] and *peginterferon alfa-2b* [PEG-Intron]. Because of their convenience and superior efficacy, these products are preferred to conventional interferons. However, please note that several side effects— injection-site reactions, dose-related neutropenia, and thrombocytopenia—are more common with pegylated interferon than with the conventional formulation.

93.3.1.1.3 Effects in Chronic Hepatitis C.

In patients with chronic hepatitis C, responses are equally modest with all forms of interferon alfa. After 12 months of treatment, serum ALT normalizes in 40% to 50% of patients, and serum levels of HCV RNA (a marker for HCV in blood) become undetectable in 30% to 40%. Unfortunately, about half of these people relapse when treatment is stopped; sustained responses are maintained in only 5% to 15% of patients. As discussed below, combining interferon alfa with ribavirin can improve response rates.

93.3.1.1.4 Adverse Effects.

All formulations of interferon alfa produce the same spectrum of adverse effects. However, the incidence is higher with the long-acting preparations.

The most common side effect is a *flu-like syndrome* characterized by fever, fatigue, myalgia, headache, and chills. The incidence is about 50%. Fortunately, symptoms tend to diminish with continued therapy. Some symptoms (fever, headache, myalgia) can be reduced with acetaminophen.

Interferon alfa frequently causes *neuropsychiatric effects*—especially *depression*. Suicidal ideation and suicide have occurred. The risk of depression is increased by large doses and prolonged treatment. The mechanism underlying depression is unknown. In many patients, depression responds to antidepressant drugs (eg, paroxetine). If depression persists, a reduction in dosage or cessation of treatment is indicated.

Prolonged or high-dose therapy can cause fatigue, thyroid dysfunction, heart damage, and bone marrow suppression, manifesting as neutropenia and thrombocytopenia.

Other adverse effects include alopecia and GI effects: nausea, diarrhea, anorexia, and vomiting. Injection-site reactions (inflammation, bruising, itching, irritation) are common, especially with long-acting formulations. Also, interferon may induce or exacerbate autoimmune diseases, such as thyroiditis and autoimmune chronic hepatitis.

93.3.1.2 Ribavirin (Oral)

93.3.1.2.1 Actions and Therapeutic Use.

Oral ribavirin [Rebetol, Copegus], combined with subQ peginterferon alfa, is the treatment of choice for chronic hepatitis C. When used alone against HCV, ribavirin is not effective: Treatment produces a transient normalization of serum ALT, but does not reduce serum HCV RNA. Combining ribavirin with interferon alfa greatly improves response rates. Ribavirin was originally approved for combined use with conventional interferon alfa. However, combined use with peginterferon alfa is more effective, and hence is now preferred. Ribavirin has a broad spectrum of antiviral activity, but its mechanism of action remains unclear.

In addition to its use against HCV, ribavirin is available as an aerosol for treating children infected with respiratory syncytial virus. This use is discussed below under *Ribavirin (Inhaled)*.

TABLE 92-4 Interferon Alfa Preparations: Dosages for Chronic Hepatitis

		Dosage	
Generic Name	Trade Name	Chronic Hepatitis B	Chronic Hepatitis C
Conventional Alfa Interferons			
Interferon alfa-2a	Roferon-A	(not used)	3 million IU subQ 3 times/wk
Interferon alfa-2b	Intron A	5 million IU/day subQ or 10 million IU subQ 3 times/wk	3 million IU subQ 3 times/wk
Interferon alfacon-1	Infergen	(not used)	9 mcg subQ 3 times/wk
Long-Acting Alfa Interferons			
Peginterferon alfa-2a	Pegasys	180 mcg subQ once/wk	180 mcg subQ once/wk
Peginterferon alfa-2b	PEG-Intron	(not used)	Monotherapy: 1 mcg/kg subQ once/wk With ribavirin: 1.5 mcg/kg subQ once/wk
IU = international units.			

1077

1078

93.3.1.2.2

Clinical Trials.

The objective of hepatitis C therapy is to elicit a sustained virologic response (SVR), defined as loss of detectable serum HCV RNA that persists for at least 6 months after treatment. By this criterion, treatment with ribavirin plus conventional interferon alfa for 24 to 48 weeks produces a SVR in 30% to 40% of previously untreated patients. In trials using peginterferon alfa, response rates were even higher. For example, in one trial, the response rate was 68% with peginterferon alfa plus ribavirin versus only 51% with conventional interferon alfa plus ribavirin.

93.3.1.2.3 Adverse Effects.

Although ribavirin and interferon alfa are generally well tolerated, both drugs can cause significant adverse effects. As noted, interferon alfa frequently causes *flu-like symptoms*, and occasionally *severe depression*.

The principal concerns with ribavirin are *hemolytic anemia* and *birth defects*. Because anemia can develop rapidly, blood counts should be made before treatment, 2 weeks and 4 weeks into treatment, and periodically thereafter. In laboratory animals, ribavirin is teratogenic and embryolethal when taken by females, and causes sperm abnormalities when taken by males. Accordingly, *ribavirin is classified in Food and Drug Administration (FDA) Pregnancy Risk Category X, and therefore is contraindicated for use during pregnancy*. Before initiating treatment, pregnancy must be ruled out. During treatment, pregnancy must be avoided—both by females taking ribavirin, and by female partners of men taking ribavirin. To avoid pregnancy, couples should use *two* reliable forms of birth control during treatment and for 6 months after.

93.3.1.2.4 Preparations, Dosage, and Administration.

For treatment of chronic hepatitis C, ribavirin *must be combined with interferon alfa*; the drug is not effective when used alone. Ribavirin is approved specifically for combined use with interferon alfa-2b; however, combined use with a pegylated interferon is now preferred. Duration of therapy is prolonged, typically 24 to 48 weeks.

93.3.1.2.4.1 Preparations.

Ribavirin is available (1) in 200-mg *capsules* and a 40-mg/mL oral solution, both marketed as *Rebetol*; (2) in *tablets* (200, 400, 500, and 600 mg), marketed as *Copegus*; and (3) in a kit, marketed as *Rebetron*, that contains ribavirin capsules plus interferon alfa-2b [Intron A].

93.3.1.2.4.2 Dosage for Ribavirin Capsules and Oral Solution (Rebetol).

Rebetol is administered PO, and dosage depends on the patient's weight. For patients weighing 75 kg or less, the dosage is 1000 mg/day (400 mg in the morning and 600 mg in the evening). For patients weighing more than 75 kg, the dosage is 1200 mg/day (600 mg in the morning and 600 mg in the evening).

93.3.1.2.4.3 Dosage for Ribavirin Tablets (Copegus).

Copegus is administered PO with food. Dosage depends on (1) patient weight and (2) the strain (genotype) of the hepatitis C virus.

- *For Genotype 1 or 4.* For patients weighing 75 kg or less, the dosage is 1000 mg/day (400 mg in the morning and 600 mg in the evening). For patients weighing more than 75 kg, the dosage is 1200 mg/day (600 mg in the morning and 600 mg in the evening).
- *For Genotype 2 or 3.* For all patients, regardless of weight, the dosage is 800 mg/day (400 mg in the morning and 400 mg in the evening).

93.3.1.2.4.4 Dosage for Interferon Alfa Used with Ribavirin.

Dosage of interferon alfa depends on the specific preparation employed. For example, the dosage for peginterferon alfa-2a [Pegasys] is 180 mcg subQ once a week, and the dosage for peginterferon alfa-2b [PEG-Intron] is 1.5 mcg/kg subQ once a week.

93.3.2 Hepatitis B

In the United States, about 1.25 million people have chronic hepatitis B. Transmission is primarily through exchange of blood or semen. Between 45% and 60% of exposed adults develop acute hepatitis. Of these, about 11,000 require hospitalization for deep fatigue, muscle pain, and jaundice. In adults, acute infection usually leads to viral clearance by the immune system. As a result, only 3% to 5% of infected adults develop chronic infection. However, when chronic infection does develop, it can lead to cirrhosis, hepatic failure, hepatocellular carcinoma, and death. The best strategy against HBV is prevention: All children should receive HBV vaccine before entering school (see [Chapter 67](#)).

Six drugs are used for chronic HBV. Two are alfa interferons—*interferon alfa-2b* [Intron A] and *peginterferon alfa-2a* [PEG-Intron]—and four are nucleoside analogs—*lamivudine* [Epivir HBV], *adefovir* [Hepsera], *entecavir* [Baraclude], and *telbivudine* [Tyzeka]. The alfa interferons are administered subQ; the nucleoside analogs are administered by mouth. The interferons are more effective than the nucleoside analogs, but are also more expensive and less well tolerated. Development of resistance is common with lamivudine and telbivudine, and relatively rare with the other four drugs. Two agents—lamivudine and adefovir—are active against HIV, and hence may promote emergence of resistant HIV in people co-infected with that virus.

With all six drugs—and especially the nucleoside analogs—the rate of relapse following cessation of treatment is high. As a result, treatment is usually prolonged, thereby amplifying concerns about adverse effects and drug costs. To decrease unnecessary drug exposure and expense, current guidelines recommend treatment only for patients at highest risk, indicated by elevated aminotransferase levels, or histologic evidence of moderate or severe hepatic inflammation or advanced fibrosis. We do not yet know if treatment should continue lifelong, or if clinical benefit can be maintained if treatment is stopped after several years. Given that relapse is common, patients should be followed closely if these drugs *are* withdrawn. Comparisons between the six drugs are summarized in [Table 92-5](#).

93.3.2.1 Interferon Alfa

Only two forms of interferon alfa—interferon alfa-2b [Intron A] and peginterferon alfa-2b [PEG-Intron]—are approved for chronic hepatitis B. Both preparations are given by subQ injection (see [Table 92-4](#)). In clinical trials, treatment for 4 months reduced serum ALT and improved liver histology in about 40% of recipients. Remissions have been prolonged in some patients, and resistance has not been reported. Unfortunately, although alfa interferons are effective, they are also expensive, and adverse effects—flu-like syndrome, depression, fatigue, and leukopenia—are common. The basic pharmacology of interferon alfa and its use in hepatitis C are discussed above.

93.3.2.2 Lamivudine

Lamivudine [Epivir HBV] is a nucleoside analog approved for infections caused by HIV or HBV. The drug was originally developed to treat HIV infection, and was later proved effective against HBV. Formulations and dosages for treating HIV and HBV infections differ, and hence must not be thought of as interchangeable. The basic pharmacology of lamivudine is discussed in [Chapter 93](#). Discussion here is limited to treatment of HBV.

Lamivudine suppresses HBV replication by inhibiting viral DNA synthesis. The process begins with intracellular conversion of lamivudine to lamivudine triphosphate, the drug's active form.

As the triphosphate, lamivudine undergoes incorporation into the growing DNA chain, and thereby causes premature chain termination.

TABLE 92-5 Drugs for Chronic Hepatitis B

Drug	Route	Relapse Rate*	Adverse Effects	Resistance Rate	Active Against HIV
Alfa Interferons					
Interferon alfa-2b [Intron A]	SubQ	Moderate	Flu-like symptoms, fatigue, neutropenia, depression	Zero	No
Peginterferon alfa-2a [PEG-Intron]	SubQ	Moderate	Same as interferon alfa-2b	Zero	No
Nucleoside Analogs					
Lamivudine [Epivir HBV]	PO	High	Well tolerated; lactic acidosis and hepatomegaly are possible	15–30% in yr 1; 70% by yr 5	Yes
Adefovir [Hepsera]	PO	High	Nephrotoxic at high doses; lactic acidosis and hepatomegaly are possible	Zero in yr 1; 29% by yr 5	Yes
Entecavir [Baraclude]	PO	High	Well tolerated; lactic acidosis and hepatomegaly are possible	Zero in yr 1; ≤1% by yr 3	No
Telbivudine [Tyzeka]	PO	Moderate	Myopathy, lactic acidosis, hepatomegaly are possible	6–12% in yr 1; 9–22% by yr 2	No

* Following discontinuation of treatment.

Lamivudine offers at least some benefit to most patients. In one trial, 52 weeks of daily lamivudine normalized serum ALT in 72% of patients, and reduced liver inflammation and fibrosis in 56%. Unfortunately, the rate of relapse is high when treatment stops. Also, emergence of resistance is a concern: Resistant isolates appear in 24% of patients after 1 year of continuous treatment, 42% after 2 years, 53% after 3 years, and 70% after 4 years.

At the dosage employed to treat hepatitis B, side effects are minimal. In clinical trials, the incidence of most side effects was no greater than with placebo. *Lactic acidosis*, *pancreatitis*, and *severe hepatomegaly* are rare but dangerous complications. If one of these conditions develops, lamivudine should be discontinued.

For treatment of HBV, lamivudine [Epivir HBV] is formulated in 100-mg tablets and a 5-mg/mL oral solution. The dosage is 100 mg once a day (compared with 150 mg twice a day for HIV). Since lamivudine is eliminated primarily by renal excretion, dosage must be reduced in patients with renal impairment.

93.3.2.3 Adefovir

93.3.2.3.1 Therapeutic Use.

Adefovir [Hepsera] is indicated for oral therapy of chronic hepatitis B. The drug was originally developed to fight HIV infection, but was not approved owing to a high incidence of nephrotoxicity at the doses required. The doses used for hepatitis B are much lower, and hence the risk of renal injury is lower too.

Approval for chronic hepatitis B was based on two randomized, placebo-controlled trials, both lasting 48 weeks. In one trial, significant improvement was seen in 53% of those taking adefovir, compared with only 25% of those taking placebo. Results of the second trial were similar: Improvement was seen in 64% of those taking adefovir, compared with 35% of those taking placebo.

93.3.2.3.2 Mechanism of Action.

Adefovir is a nucleoside analog with a mechanism similar to that of acyclovir. Both drugs inhibit viral DNA synthesis, and both must be converted to their active form within the body. Activation of adefovir is mediated by cellular kinases—enzymes that convert the drug into adefovir diphosphate, a compound with two actions: (1) it directly inhibits viral DNA polymerase (by competing with deoxyadenosine triphosphate, a natural substrate for the enzyme); and (2) it undergoes incorporation into the growing strand of viral DNA, and thereby causes premature strand termination. Host cells are spared because adefovir diphosphate is a poor inhibitor of human DNA polymerase.

93.3.2.3.3 Pharmacokinetics.

Bioavailability is about 60% following oral administration, both in the presence and absence of food. Plasma levels peak about 2 hours after dosing. Elimination is renal, by a combination of glomerular filtration and active tubular secretion. In patients with normal kidney function, the half-life is 7.5 hours. In patients with renal impairment, the half-life is significantly increased.

93.3.2.3.4 Adverse Effects.

Nephrotoxicity is the principal concern. Increased serum creatinine, a sign of kidney damage, was seen in 4% of patients who received 48 weeks of therapy, and in 9% of patients who received 96 weeks of therapy. To reduce risk, kidney function should be assessed at baseline and periodically thereafter, paying special attention to patients at high risk (ie, patients with pre-existing renal impairment and those taking nephrotoxic drugs [eg, cyclosporine, tacrolimus, aminoglycosides, vancomycin, aspirin and other nonsteroidal anti-inflammatory drugs]).

When adefovir is discontinued, patients may experience *acute exacerbation of hepatitis B*. In clinical trials, serum ALT levels rose dramatically in 25% of patients when treatment was stopped. Hepatic function should be assessed periodically following adefovir withdrawal.

93.3.2.3.5 Drug Interactions.

Drugs that are eliminated by active tubular secretion can compete with adefovir for renal excretion. As a result, if one of these agents were to be combined with adefovir, excretion of adefovir, the other drug, or both could be decreased, causing their plasma levels to rise.

93.3.2.3.6 Precautions.

Because adefovir is related to the nucleoside analogs used against HIV, there is a concern that, if the patient were infected with HIV, giving adefovir in the low doses employed against HBV could allow emergence of HIV viruses resistant to nucleoside analogs. Accordingly, HIV infection should be ruled out before adefovir is used.

The nucleoside analogs used to treat HIV infection can cause lactic acidosis and severe hepatomegaly. Hence, there is concern that adefovir can cause these effects too. If the patient develops clinical or laboratory findings that suggest lactic acidosis or pronounced hepatotoxicity, adefovir should be withdrawn.

93.3.2.3.7 Preparations, Dosage, and Administration.

Adefovir [Hepsera] is supplied in 10-mg tablets. For patients with good kidney function, the dosage is 10 mg once a day, taken with or without food. For patients with impaired kidney function, as indicated by reduced creatinine clearance (CrCl), the dosing *interval* should be increased. Adjusted dosages are as follows:

- CrCl 20 to 49 mL/min—10 mg every 48 hours
- CrCl below 20 mL/min (not requiring dialysis)—10 mg every 72 hours
- Patients on hemodialysis—10 mg once a week, taken after dialysis

1079

93.3.2.4 Entecavir

1080

93.3.2.4.1 Therapeutic Use.

Entecavir [Baraclude], approved in 2005, is indicated for oral therapy of chronic hepatitis B. Candidates for treatment should have evidence of active viral replication along with persistently elevated serum aminotransferases or histologic evidence of active disease. In clinical trials, entecavir was more effective than lamivudine. In patients with lamivudine-resistant HBV, responses to entecavir were somewhat reduced, but were still better than responses to lamivudine. There is no published information comparing entecavir with adefovir.

93.3.2.4.2 Mechanism of Action.

Entecavir is a nucleoside analog that undergoes conversion to entecavir triphosphate (its active form) within the body. As entecavir triphosphate, the drug inhibits HBV DNA polymerase, and thereby prevents viral replication. Entecavir triphosphate is a weak inhibitor of human DNA polymerases, both nuclear and mitochondrial, and hence host cells are spared. In contrast to lamivudine and adefovir, entecavir does not impede HIV replication, and hence should not promote emergence of resistant HIV.

93.3.2.4.3 Pharmacokinetics.

Entecavir is available in tablets and solution for oral administration. Bioavailability with both formulations is the same. Plasma levels peak 0.5 to 1.5 hours after dosing. Entecavir undergoes extensive distribution to body tissues, with little binding to plasma proteins. Metabolism is minimal. Entecavir is neither a substrate for, inhibitor of, nor inducer of cytochrome P450 enzymes. Excretion is via the urine, primarily as unchanged drug. The half-life is about 5.5 days.

93.3.2.4.4 Adverse Effects and Precautions.

Entecavir is very well tolerated. The most common adverse effects are dizziness, headache, fatigue, and nausea—and even these occur in less than 5% of patients.

Patients treated with other nucleoside analogs have developed lactic acidosis and severe hepatomegaly, and hence there is concern that entecavir may cause these effects too. If the patient develops clinical or laboratory findings that suggest lactic acidosis or pronounced hepatotoxicity, entecavir should be withdrawn.

Acute severe exacerbations of hepatitis B have developed following discontinuation of entecavir and other drugs for hepatitis B. Accordingly, if entecavir is discontinued, liver function should be monitored closely for several months.

93.3.2.4.5 Preparations, Dosage, and Administration.

Entecavir [Baraclude] is available in tablets (0.5 and 1 mg) and an oral solution (0.05 mg/mL). Dosing is done once a day, either 2 hours before eating or 2 hours after. Dosage depends on renal function (as indicated by CrCl) and on the infection's sensitivity to lamivudine.

If the infection is *lamivudine sensitive*, daily dosages are as follows:

- CrCl 50 mL/min or higher—0.5 mg
- CrCl 30 to 49 mL/min—0.25 mg
- CrCl below 30 mL/min (not requiring dialysis)—0.15 mg
- Patients on hemodialysis—0.05 mg taken after dialysis

If the infection is *lamivudine resistant*, daily dosages are as follows:

- CrCl 50 mL/min or higher—1 mg
- CrCl 30 to 49 mL/min—0.5 mg
- CrCl below 30 mL/min (not requiring dialysis)—0.3 mg
- Patients on hemodialysis—0.05 mg taken after dialysis

93.3.2.5 Telbivudine

93.3.2.5.1 Therapeutic Use.

Telbivudine [Tyzeka], approved in 2006, is a nucleoside analog indicated for chronic HBV infection in adults and adolescents 16 years of age or older. Patients must have evidence of active HBV replication, plus either persistent elevations in serum aminotransferases (ALT or AST) or histologic evidence of active liver disease. In nucleoside-naïve patients, telbivudine is at least as effective as lamivudine (as indicated by suppression of HBV DNA and either normalization of ALT or loss of serum HBeAg, a hepatitis B antigen). At this time, we don't know if telbivudine will improve long-term outcomes (eg, less hepatocellular carcinoma or decompensated cirrhosis). As with lamivudine, resistance can be significant: After 2 years of treatment with telbivudine, resistance develops in 9% to 22% of patients. Patients resistant to telbivudine show cross-resistance to lamivudine. In contrast to lamivudine and adefovir, telbivudine is not active against HIV.

93.3.2.5.2 Mechanism of Action.

Telbivudine is a thymidine nucleoside analog that undergoes intracellular conversion to its active form: telbivudine triphosphate. As the triphosphate, it inhibits HBV replication in two ways. First, it directly inhibits HBV DNA polymerase (by competing with the natural substrate, thymidine triphosphate). Second, it undergoes incorporation in the growing viral DNA chain, and thereby causes chain termination.

93.3.2.5.3 Adverse Effects.

The most common adverse effects are fever, fatigue/malaise, arthralgia, myalgia, cough, headache, and GI symptoms (eg, abdominal pain, nausea, vomiting, diarrhea, dyspepsia). Some patients have developed symptomatic myopathy, characterized by persistent muscle pain, tenderness, or weakness. Lactic acidosis and severe hepatomegaly have occurred with other nucleoside analogs, but have not been reported with telbivudine. As with other drugs for hepatitis B, severe exacerbations can occur when treatment is discontinued.

93.3.2.5.4 Drug Interactions.

No significant interactions have been reported. However, since telbivudine is eliminated primarily by renal excretion, drugs that impair renal function may raise its level. Also, other drugs that cause muscle injury may increase risk in patients taking telbivudine. Telbivudine

is neither a substrate for nor inhibitor of CYP isozymes, and hence will not be affected by drugs that inhibit or induce CYP isozymes, nor will it affect drugs that are metabolized by these isozymes.

93.3.2.5.5 Preparations, Dosage, and Administration.

Telvivudine [Tyzeka] is supplied in 600-mg tablets. The usual dosage is 600 mg once a day, taken with or without food. For patients with renal impairment, as indicated by reduced CrCl, the dosing interval should be increased. For patients with hepatic impairment, no dosage adjustment is required. Dosages are as follows:

- CrCl 50 mL/min or higher—600 mg once daily
- CrCl 30 to 49 mL/min—600 mg once every 48 hours
- CrCl below 30 mL/min (not requiring dialysis)—600 mg once every 72 hours
- Patients on hemodialysis—600 mg once every 96 hours, taken after hemodialysis

93.4 DRUGS FOR INFLUENZA

Influenza is a serious respiratory tract infection that constitutes a major cause of morbidity and mortality worldwide. During the 1918–1919 global pandemic, more than 500,000 people died in the United States and up to 50 million people died worldwide. In the United States today, complications of influenza (eg, bronchitis, pneumonia) cause up to 300,000 hospitalizations and 36,000 deaths each year. The cost of influenza is huge: Direct and indirect expenses total between \$3 billion and \$5 billion annually.

Influenza is caused by influenza viruses, of which there are two major types: *influenza A* and *influenza B*. Type A influenza viruses cause far more infections than type B influenza viruses (about 96% vs. 4%). The influenza viruses are highly variable and undergo constant evolution. Because of this ongoing evolution, the World Health Organization (WHO) has established a global network of laboratories to monitor the emergence and spread of new variants.

Influenza is a highly contagious infection spread via aerosolized droplets produced by coughing or sneezing. The virus enters the body through mucous membranes of the nose, mouth, or eyes. Viral replication takes place in the respiratory tract. Symptoms begin 2 to 4 days after exposure, and last 5 to 6 days. Influenza is characterized by fever, cough, chills, sore throat, headache, and myalgia (muscle pain). For typical patients, infection results in 5 to 6 days of restricted activity, 3 to 4 days

of bed disability, and 3 days of absence from work or school. In the United States, the influenza “season” begins in November and extends through March or April.

Influenza is managed by vaccination and with drugs. Vaccination is the primary management strategy; drug therapy is secondary. The drugs for influenza fall into two groups: *adamantanes*, which have been used for decades, and *neuraminidase inhibitors*, which are relatively new. The adamantanes are active against influenza A only, whereas the neuraminidase inhibitors are active against influenza A *and* influenza B.

1080
1081

TABLE 92-6 Influenza Vaccines

Vaccine	Route	Formulation	Mercury/Dose*	Approved Age Group
Inactivated Influenza Vaccines				
Afluria	IM	0.5-mL syringe	None	18 yr and older
Fluarix	IM	0.5-mL syringe	Under 1.25 mcg	18 yr and older
FluLaval	IM	5-mL multidose vial	25 mcg/dose	18 yr and older
Fluvirin	IM	0.5-mL syringe	Under 1 mcg	4 yr and older
		5-mL multidose vial	24.5 mcg/0.5-mL dose	4 yr and older
Fluzone	IM	0.25-mL syringe	None	6–35 months
		0.5-mL syringe	None	3 yr and older
		5-mL multidose vial	24 mcg/0.5-mL dose	6 months and older
Live, Attenuated Influenza Vaccine				
FluMist	Nasal	Single-dose sprayer†	None	2–49 yr

* Mercury, in the form of thimerosal, is used as a preservative in some vaccines.

† Each syringe-like sprayer contains one 0.5-mL dose, given as 0.25 mL in each nostril.

93.4.1 Influenza Vaccines

Annual vaccination is the best protection against influenza. Because influenza viruses are constantly evolving, influenza vaccines must continuously change too. Each year, manufacturers produce a new vaccine directed against the three strains of influenza virus deemed most likely to cause disease during the upcoming flu season. Identification of the three strains is done jointly by the Centers for Disease Control and Prevention (CDC), the FDA, and the WHO.

93.4.1.1 Types of Influenza Vaccines.

Two basic kinds of flu vaccine are available: (1) *inactivated influenza vaccine* and (2) *live, attenuated influenza vaccine*, also known as LAIV. The inactivated vaccine, which has been available for many years, is administered by *IM injection*. The live, attenuated vaccine, approved in 2003, is administered by *intranasal spray*. Both kinds of vaccine are directed at the same three influenza strains, and both are reformulated annually.

At this time, there are six influenza vaccines on the market ([Table 92-6](#)). Five of these vaccines—Afluria, Fluarix, FluLaval, Fluvirin, and Fluzone—are given IM, and one—FluMist—is given intranasally. As indicated in [Table 92-6](#), some of the IM products contain trace amounts of mercury. The table also shows that the six vaccines differ regarding the age groups for which they are approved. Of importance, the intranasal vaccine is approved only for people 2 to 49 years old, and hence cannot be used by two large groups considered at high risk, namely, the very young and the elderly.

93.4.1.2 Efficacy.

Protection begins 1 to 2 weeks after vaccination and generally lasts 6 months or longer. However, among elderly vaccinees, protection may be lost in 4 months or even less. Efficacy of vaccination depends on the age and health status of the vaccinee, and on how well the vaccine matches the strains of influenza virus in circulation that year. Efficacy of the inactivated vaccine and the LAIV is about equal.

93.4.1.3 Adverse Effects.

Adverse effects differ for the inactivated vaccine versus the LAIV. However, with both vaccines, significant adverse effects are rare.

93.4.1.3.1 Inactivated Influenza Vaccine

Adverse effects are uncommon, except for possible soreness at the injection site. People who have not been vaccinated previously may experience fever, myalgia, and malaise lasting 1 or 2 days.

Influenza vaccination may carry a very small risk of *Guillain-Barré syndrome* (GBS), a severe, paralytic illness. In 1976, swine flu vaccine was associated with GBS. However, there has been no clear link between GBS and influenza vaccines used since then. If there is

a risk, it is very small, estimated at 1 to 2 cases per million vaccinees—much smaller than the risk posed by severe influenza.

93.4.1.3.2 Live, Attenuated Influenza Vaccine

LAIV has been given to millions of people, and reports of serious adverse events have been very rare. As of August 16, 2005, the Vaccine Adverse Event Reporting System had received 460 reports regarding LAIV. Among these were seven cases of possible anaphylaxis, two cases of GBS, and one case of Bell's palsy. More commonly, vaccinees experience mild, transient effects. Among children 5 to 17 years old, the most common reactions have been runny nose, nasal congestion, cough, headache, vomiting, muscle aches, and fever. Among adults 18 to 49 years old, the most common reactions have been runny nose, headache, sore throat, and cough.

93.4.1.4 Precautions and Contraindications.

People with acute febrile illness should defer vaccination until symptoms abate. Minor illnesses (eg, common cold), with or without fever, do not preclude vaccination.

Influenza vaccines are contraindicated for persons with hypersensitivity to eggs. Why? Because the vaccines are produced from viruses grown in eggs, and hence may contain trace amounts of egg proteins. Individuals suspected of egg hypersensitivity should undergo a skin test before receiving the vaccine. If the test is positive, the vaccine should be withheld.

93.4.1.5 Who Should Be Vaccinated?

As of the 2008–2009 flu season, the Advisory Committee on Immunization Practices (ACIP) recommends annual vaccination for:

1. All children 6 months and older and all older adults
 - All children ages 6 months to 18 years of age
 - All people age 50 and older
2. All people at high risk of complications from the flu
 - Women who will be pregnant during the flu season
 - All residents of nursing homes and other facilities where persons with chronic medical conditions live

- Children 6 months to 18 years old receiving long-term therapy with aspirin (because they are at risk of developing Reye's syndrome if they get influenza)
- Anyone with a weakened immune system due to HIV infection, immunosuppressant therapy, or other causes

1081

- Anyone with certain muscle or nerve disorders, such as seizure disorders or cerebral palsy, that can lead to breathing or swallowing problems
- People who have long-term health problems, including asthma; heart, kidney, or lung disease; anemia and other blood disorders; and diabetes and other metabolic diseases

1082

3. People who can transmit flu to others at high risk for complications. This includes

- Healthcare workers
- Household members and other close contacts of infants or children up to 5 years of age
- Household members and other close contacts of people age 50 and older, and people with medical conditions that put them at higher risk for severe complications from influenza.

4. Annual vaccination is also recommended for

- People who provide essential community services
- People living in dormitories or other crowded conditions (to prevent outbreaks of influenza)
- People at high risk of influenza complication who travel to the Southern hemisphere between April and September, or to the tropics or in organized tourist groups at any time

93.4.1.6 Who Should NOT Be Vaccinated?

Some people should not be vaccinated without a physician's approval. In this group are

- People who have a severe allergy to chicken eggs
- People who have had a severe reaction to influenza vaccination in the past

- People who have experienced GBS
- People who have a moderate or severe illness with a fever (these individuals should wait until symptoms abate)

93.4.1.7 When Should Influenza Vaccine Be Administered?

The best time is October or November. However, the vaccine should be offered until the end of influenza season in April.

93.4.1.8 Dosage and Administration: Inactivated Influenza Vaccine.

Inactivated influenza vaccines are available under five trade names: Afluria, Fluarix, FluLaval, Fluvirin, and Fluzone. Afluria, Fluarix, and FluLaval are approved for people ages 18 years and older, Fluvirin for people 4 years and older, and Fluzone for people 6 months and older. Because the influenza virus evolves rapidly, all five products are reformulated annually. Accordingly, to maintain protection, revaccination is required each year.

Vaccination is done by IM injection into the anterolateral aspect of the thigh (for infants and young children) or into the deltoid muscle (for older children, adolescents, and adults).

Dosage is a function of age and vaccination history. Most vaccinees require just 1 injection a year. However, children under 9 years old who have not been vaccinated before require 2 injections, administered at least 4 weeks apart. The dosage size is 0.25 mL for vaccinees ages 6 months through 35 months, and 0.5 mL for vaccinees over the age of 3 years.

93.4.1.9 Dosage and Administration: Live, Attenuated Influenza Vaccine.

LAIV [FluMist] is supplied in a single-dose sprayer for intranasal administration. Vaccinees must be 2 to 49 years old. FluMist is unstable at room temperature, and hence must be stored frozen. As with the inactivated flu vaccine, dosing with LAIV is a function of age and vaccination history. Most vaccinees get just one dose a year. However, children 5 through 8 years old who have not been vaccinated before require two doses, administered 46 to 74 days apart. For all vaccinees, the size of each dose is the same: 0.5 mL (administered as a 0.25-mL spray in each nostril).

93.4.1.10 Avian Influenza.

The FDA has approved an inactivated vaccine against avian H5N1 influenza. It is not available commercially in the United States, but is being included in the CDC's Strategic National

Stockpile in case H5N1 avian influenza strains become able to spread efficiently between humans. The vaccine is given as 2 IM injections, 1 month apart.

93.4.2 Neuraminidase Inhibitors

The neuraminidase inhibitors, introduced in 1999, are active against influenza A and influenza B. In contrast, the adamantanes are active against influenza A only (see below). Neuraminidase inhibitors cost more than adamantanes, but are more effective and better tolerated, and pose a lower risk of resistance. As with the adamantanes, these drugs should not be viewed as an alternative to vaccination. At this time, two neuraminidase inhibitors are available: oseltamivir and zanamivir.

93.4.2.1 Oseltamivir

93.4.2.1.1 Therapeutic Effects.

Oseltamivir [Tamiflu] is an oral drug approved for prevention and treatment of influenza. When used for *treatment*, dosing must begin early—no later than 2 days after symptom onset, and preferably much sooner. Why? Because benefits decline greatly when treatment is delayed: When treatment is started within 12 hours of symptom onset, symptom duration is reduced by more than 3 days; when started within 24 hours, symptom duration is reduced by less than 2 days; and when started within 36 hours, symptom duration is reduced by only 29 hours. In addition to reducing symptom duration, oseltamivir can reduce symptom severity and the incidence of complications (sinusitis, bronchitis). Unfortunately, treatment is expensive (about \$60 for a 5-day course). Furthermore, in the real world, patients may be unable to obtain and fill a prescription soon enough for the drug to be of significant benefit.

Oseltamivir has been studied for its ability to *prevent* influenza in residents of nursing homes, in family members of someone with the flu, and in the community at large. When used in nursing homes, most of whose residents had been vaccinated, oseltamivir decreased the incidence of influenza from 4.4% down to 0.4%. When used to protect family members, the drug decreased the incidence of influenza from 12% down to 1%. And when given to unvaccinated individuals during a community outbreak of influenza, it reduced the incidence of infection from 4.8% down to 1.2%.

Oseltamivir is active against most isolates of influenza A type H5N1, the cause of *avian flu*, as well as the variants of type H1N1 that cause “swine flu.”

93.4.2.1.2 Mechanism of Action.

Antiviral effects derive from inhibiting neuraminidase, a viral enzyme required for replication. As a result of neuraminidase inhibition, newly formed viral particles are unable to bud off from the cytoplasmic membrane of infected host cells. Hence, viral spread is stopped. Oseltamivir is active against all strains of influenza A and influenza B. Emergence of resistance over the course of treatment is rare.

93.4.2.1.3 Pharmacokinetics.

Oseltamivir is well absorbed following oral administration. In the liver, the drug undergoes conversion to oseltamivir carboxylate, its active form. Bioavailability of the carboxylate is 80%. Plasma levels of active drug peak 2.5 to 6 hours after dosing. The plasma half-life is 6 to 10 hours. The drug is eliminated in the urine, primarily as the carboxylate form.

93.4.2.1.4 Adverse Effects and Interactions.

Oseltamivir is generally well tolerated. The most common side effects are nausea (9.9%) and vomiting (9.4%). Nausea can be reduced by giving oseltamivir with food. No interactions with other drugs have been reported.

93.4.2.1.5 Preparations, Dosage, and Administration.

Oseltamivir [Tamiflu] is available in tablets (30, 45, and 75 mg) and as a powder to be reconstituted to a 12-mg/mL oral suspension. The drug may be administered without regard to meals, although taking it with food can reduce nausea.

For *treatment* of influenza, the dosage for patients *age 13 years and older* is 75 mg twice daily for 5 days, beginning no later than 2 days after the onset of symptoms. Dosage should be reduced to 75 mg once daily in patients with significant renal impairment. The dosage for *children 1 year old through 12 years old* is based on body weight as follows: under 15 kg, 30 mg twice daily; 15 to 23 kg, 45 mg twice daily; 23 to 40 kg, 60 mg twice daily; and over 40 kg, 75 mg twice daily.

For *prevention* of influenza in patients *age 13 years and older*, the dosage is 75 mg once a day—one-half the dosage used for treatment. (Oseltamivir is not approved for prophylaxis in patients younger than 13.) Candidates for prophylactic therapy include family members of someone with flu and residents of nursing homes. To protect family members, dosing should begin within 48 hours of exposure and should continue for 7 days. To protect residents of

nursing homes or high-risk members of the community at large, dosing can be done continuously for up to 42 days.

93.4.2.2 Zanamivir

93.4.2.2.1 Actions and Uses.

Zanamivir [Relenza], administered by oral inhalation, is approved for *treatment* of acute uncomplicated influenza in patients at least 7 years old, and for *prophylaxis* of influenza in people at least 5 years old. As with oseltamivir, benefits derive from inhibiting viral neuraminidase, an enzyme required for viral replication. Like oseltamivir, zanamivir is well tolerated, although benefits appear to be limited.

In animal studies, zanamivir has been effective against some avian strains of influenza. Although human data are lacking, the drug should be effective for prophylaxis and treatment of H5N1 disease.

93.4.2.2.2 Clinical Trials.

Zanamivir is moderately effective at shortening the duration of influenza symptoms. In Phase III clinical trials, improvement in symptoms was defined as (1) the absence of fever and (2) mild or no headache, myalgia, cough, or sore throat. In patients taking zanamivir (10 mg twice daily for 5 days, beginning no later than 36 hours after the onset of symptoms), the average duration of symptoms was 5 days, compared with 6.5 days for patients taking placebo. In addition, zanamivir reduced the incidence of complications (sinusitis, bronchitis) requiring antibacterial drugs.

In a 4-week trial conducted during the influenza season, once-daily treatment with 10 mg of inhaled zanamivir was 84% effective at preventing febrile illness.

93.4.2.2.3 Pharmacokinetics.

Zanamivir is formulated as a dry powder for oral inhalation. The drug is poorly absorbed from the GI tract, and hence cannot be administered by mouth. Most (70% to 90%) of an inhaled dose is deposited in the oropharynx and throat. About 10% to 20% reaches the tracheobronchial tree and lungs. Between 4% and 17% of each dose undergoes absorption into the systemic circulation. Zanamivir has a plasma half-life of 2.5 to 5 hours and is eliminated unchanged in the urine. No metabolites have been detected.

93.4.2.2.4 Adverse Effects and Interactions.

In patients with healthy lung function, adverse effects are rare. Because zanamivir is administered as an inhaled powder, patients may experience cough or throat irritation. Zanamivir appears devoid of drug interactions.

In patients with pre-existing lung disorders (eg, asthma, chronic obstructive pulmonary disease), zanamivir may cause severe bronchospasm and respiratory decline. Some patients have required immediate treatment or hospitalization. Deaths have occurred—however, given the impact of flu itself on lung function, it's not clear that zanamivir was the cause. Nonetheless, owing to the potential risk, zanamivir is not generally recommended for patients with underlying airway disease.

93.4.2.2.5 Preparations, Dosage, and Administration.

Zanamivir [Relenza] is supplied in blister packs that contain 5 mg of powdered drug. Administration is by oral inhalation using the *Diskhaler* provided by the manufacturer. The dosage is 10 mg (two 5-mg inhalations) twice daily for 5 days. Each 10-mg dose should be separated by 12 hours. However, on the first day of treatment, less separation (as little as 2 hours) is permitted if the first dose cannot be taken early enough in the day to allow 12 hours between doses. Patients who are using an inhaled bronchodilator (eg, albuterol) should administer the bronchodilator before inhaling zanamivir.

93.4.3 Adamantanes

The adamantanes—amantadine and rimantadine—were the first influenza drugs available. These agents have moderate activity against influenza A, and none against influenza B. With amantadine, adverse CNS effects are common, and with both drugs, resistance can develop rapidly. In the United States, resistance among influenza A isolates has risen sharply, from just 2% in 2003 to 91% by 2005, causing the CDC to recommend against using these drugs for the 2005–2006 flu season. To date, resistance to neuraminidase inhibitors remains low.

93.4.3.1 Amantadine

Amantadine [Symmetrel] is employed for prophylaxis and treatment of infections caused by type A influenza virus. As discussed in [Chapter 21](#), the drug is also used to treat Parkinson's disease.

93.4.3.1.1 Mechanism of Antiviral Action.

Just how amantadine suppresses viral growth is not completely understood. The drug can prevent penetration of influenza A virus into host cells and can inhibit viral uncoating. In addition, it inhibits an early step in replication of viral components.

93.4.3.1.2 Therapeutic Use.

Antiviral applications of amantadine are limited to prophylaxis and treatment of respiratory tract infections caused by type A influenza virus strains. The drug is not active against type B influenza.

Prophylaxis should be instituted only in the presence of a documented influenza A epidemic. Candidates for prophylaxis include (1) individuals at high risk of developing complications from influenza (eg, elderly patients and those with cardiopulmonary disease) and (2) healthcare workers and family members who have extensive contact with patients at risk. Prophylaxis is continued until the epidemic abates (usually in 5 to 6 weeks). It should be noted that immunization against influenza A is preferred to prophylaxis with amantadine. Because amantadine does not impede the immune response to influenza A vaccine, individuals at risk can be vaccinated while receiving amantadine for prophylaxis. Amantadine can be discontinued 2 weeks after vaccination.

For treatment of active influenza A infection, amantadine is most effective when therapy is instituted early (within 48 hours of the onset of symptoms).

93.4.3.1.3 Pharmacokinetics.

Amantadine is well absorbed following oral administration and is distributed widely to body fluids and tissues. The drug crosses the blood-brain barrier and placenta. It also appears in saliva, nasal secretions, and breast milk. Amantadine is not metabolized. Excretion is renal. In patients with renal impairment, amantadine will accumulate to high levels if the dosage is not reduced.

93.4.3.1.4 Adverse Effects.

Amantadine is generally well tolerated at the doses employed for prophylaxis and treatment of influenza.

93.4.3.1.4.1 CNS Effects.

CNS effects occur in 10% to 30% of patients. Reactions include dizziness, nervousness, insomnia, and difficulty concentrating. Individuals involved in hazardous activities should exercise appropriate caution. More serious CNS effects (depression, hallucinations, seizures) have occurred. Accordingly, care should be exercised in patients with a history of epilepsy or psychosis.

93.4.3.1.4.2 Cardiovascular Effects.

Rarely, amantadine has caused heart failure (HF). The drug should be used with caution in patients with HF or peripheral edema. Patients should be instructed to contact their physician if they experience shortness of breath or swelling of the extremities.

Orthostatic hypotension has occurred. Patients should be advised to move slowly when assuming an upright position. Also, they should be advised to sit or lie down if dizziness or lightheadedness occurs.

93.4.3.1.4.3 Use in Pregnancy and Lactation.

Amantadine is teratogenic and embryotoxic in rats. Adequate studies during human pregnancy have not been performed. The drug crosses the placenta and is classified in *FDA Pregnancy Risk Category C*. It should be avoided by pregnant women unless the benefits of treatment are deemed to outweigh the potential risks to the fetus. Amantadine is secreted in breast milk and should not be used by nursing mothers.

93.4.3.1.5 Drug Interactions.

Amantadine can intensify the peripheral and CNS effects of anticholinergic drugs. When amantadine has been combined with anticholinergic drugs, psychotic reactions resembling those associated with atropine poisoning have occurred. These responses can be reduced by lowering the dosage of either amantadine or the anticholinergic agent.

93.4.3.1.6 Preparations, Dosage, and Administration.

Amantadine [Symmetrel] is supplied in a syrup (10 mg/mL) and in 100-mg tablets and capsules. For treatment or prophylaxis of influenza A, the dosage for patients older than 9 years is 100 mg twice daily. For children ages 1 to 9 years, the dosage is 4.4 to 8.8 mg/kg/day in two or three divided doses. The dosage must be reduced in patients with kidney

dysfunction. Prophylactic administration should commence prior to anticipated viral exposure and should continue for as long as the influenza A epidemic lasts. For treatment of active influenza A infection, therapy should begin within 48 hours of symptom onset and should continue for 4 to 5 days.

93.4.3.2 Rimantadine

Rimantadine [Flumadine] is very similar to amantadine in structure, actions, and uses. Like amantadine, rimantadine is indicated only for prophylaxis and treatment of influenza A virus infections. During the 2005–2006 flu season, the CDC recommended against use of rimantadine (and amantadine) owing to widespread resistance. Rimantadine is administered by mouth, and bioavailability appears to be high (greater than 90%). In contrast to amantadine, which is not metabolized, rimantadine undergoes extensive metabolism prior to excretion in the urine. Primary adverse effects are nervousness, lightheadedness, difficulty in concentration, sleep disturbances, and fatigue. However, these occur less frequently than with amantadine (3% vs. up to 30%). The *adult* dosage for treatment or prophylaxis is 100 mg twice a day. The duration of therapy is 5 days for treatment of active infection and up to 6 weeks for prophylaxis. The dosage for *prophylaxis* in *children* is 5 mg/kg/day. Rimantadine is not approved for treating active infection in children. Rimantadine is available in 100-mg capsules.

1084

93.5 DRUGS FOR RESPIRATORY SYNCYTIAL VIRUS INFECTION

Respiratory syncytial virus (RSV) infection is a major cause of lower respiratory tract disease. Symptomatic infection with RSV is most likely in the very young, the elderly, and persons with disorders of the respiratory, cardiac, or immune systems. In the United States, RSV infection is the most common cause of lower respiratory tract disease in infants and young children, leading to between 51,000 and 82,000 hospitalizations each year. Among children 5 years old and younger, RSV is the leading cause of viral death. The death rate from RSV in the elderly is also high. Like influenza, infection with RSV is seasonal, with most cases occurring in the winter (December through March). Only two antiviral drugs—ribavirin and palivizumab—are approved for treating RSV. Unfortunately, neither drug is very effective.

93.5.1 Ribavirin (Inhaled)

Ribavirin, a broad-spectrum antiviral drug, is available in two formulations: aerosol and oral. The aerosol formulation, marketed as Virazole, is used for infection with RSV. The oral formulation, marketed as Rebetol, is used for chronic hepatitis C. Discussion here focuses on RSV. Use against hepatitis C is discussed above.

93.5.1.1 Antiviral Actions.

Ribavirin [Virazole] is virustatic. The drug is active against RSV, HCV, influenza virus (types A and B), and HSV. Although several biochemical actions of the drug have been described, it is not known which (if any) is responsible for antiviral effects.

93.5.1.2 Use in RSV Infection.

Ribavirin is labeled only for severe viral pneumonia caused by RSV in carefully selected, hospitalized infants and young children. Unfortunately, benefits of treatment are usually minimal—and the cost is high (over \$1300/day). Ribavirin should not be used for mild RSV infections.

93.5.1.3 Pharmacokinetics.

For treatment of RSV, ribavirin is administered by oral inhalation. The drug is absorbed from the lungs and achieves high concentrations in respiratory tract secretions and erythrocytes. Concentrations in plasma remain low. The drug is metabolized to active and inactive products. Excretion is via the urine (30% to 55%) and feces (15%). Ribavirin that is sequestered in erythrocytes remains in the body for weeks.

93.5.1.4 Adverse Effects.

Inhalation of ribavirin produces little or no systemic toxicity. However, although generally safe, inhaled ribavirin does pose a hazard to infants undergoing mechanical assistance of ventilation: The drug can precipitate in the respiratory apparatus, thereby interfering with safe and effective respiratory support. Consequently, ribavirin should not be administered to infants who need respiratory assistance. In some infants, and in adults who have asthma or chronic obstructive lung disease, ribavirin has caused deterioration of pulmonary function. Accordingly, respiratory function should be carefully monitored. If deterioration occurs, ribavirin should be discontinued. When administered systemically (PO or IV), ribavirin frequently causes anemia. This has not been reported with inhalational therapy.

93.5.1.5 Use in Pregnancy.

Ribavirin is *contraindicated for use during pregnancy*. Although studies in primates indicate no effect on the developing fetus, ribavirin has proved either teratogenic or embryolethal in nearly all other species tested. No studies in humans have been performed. *Ribavirin is classified under FDA Pregnancy Risk Category X:* The risk of use during pregnancy clearly

outweighs any potential benefits. Because of the risk of significant drug exposure, pregnant women should not directly care for patients undergoing ribavirin aerosol therapy.

93.5.1.6 Preparations, Dosage, and Administration.

For treatment of RSV, ribavirin [Virazole] is supplied as a powder (6 gm/100-mL vial) to be reconstituted for aerosol administration. According to the manufacturer, only one device—the Viratek Small Particle Aerosol Generator (SPAG) model SPAG-2—should be employed for ribavirin administration. The SPAG-2 is used to deliver ribavirin to an infant oxygen hood. Treatment is given 12 to 18 hours a day for no less than 3 days and no more than 1 week. The drug should not be administered to patients who require ventilatory assistance. To reconstitute powdered ribavirin, dissolve 6 gm of the drug in sterile water for injection or inhalation, transfer this concentrated solution to the SPAG-2 reservoir, and dilute to a final volume of 300 mL using sterile water for injection or inhalation. The final concentration of ribavirin is 20 mg/mL. This solution is aerosolized and inhaled by the patient.

93.5.2 Palivizumab

93.5.2.1 Actions and Uses.

Palivizumab [Synagis] is a monoclonal antibody indicated for preventing RSV infection in premature infants and in young children with chronic lung diseases. The antibody binds to a surface protein on RSV and thereby prevents replication. In clinical trials, the rate of hospitalization was 1.8% for premature infants treated with palivizumab, compared with 8.1% for those receiving placebo. In young children with chronic lung disease, the hospitalization rate was 7.9% for those receiving the antibody, versus 12.8% for those receiving placebo.

93.5.2.2 Adverse Effects.

Except for *hypersensitivity reactions*, which are rare, palivizumab appears devoid of significant adverse effects. Acute hypersensitivity reactions have occurred with initial drug use and with subsequent use. Very rarely (less than 1 in 100,000 cases), palivizumab has caused anaphylaxis, but only with re-exposure, not with the initial dose. If a *mild* hypersensitivity reaction occurs, cautious use of palivizumab can continue. However, if a *severe* reaction occurs, the drug should be stopped and never used again. Severe reactions are managed with parenteral epinephrine and supportive care.

93.5.2.3 Preparations, Dosage, and Administration.

Palivizumab [Synagis] is supplied in solution (50 and 100 mg/mL). The dosage is 15 mg/kg once a month, injected IM into the anterolateral aspect of the thigh. Dosing should commence before the RSV season (December through March in the United States) and continue until the season ends. The cost for a full season of treatment is about \$7000. However, although this seems high, it could save more than \$50,000 by avoiding hospitalization.

93.5.2.3.1

KEY POINTS

- Because viruses use host-cell enzymes and substrates to reproduce, it is difficult to suppress viral reproduction without also harming cells of the host.
 - Acyclovir is the drug of choice for most infections caused by herpes simplex viruses and varicella-zoster virus.
 - Following conversion to its active form, acyclovir suppresses viral reproduction by inhibiting viral DNA polymerase and by causing premature termination of viral DNA strand growth. Because the active form of acyclovir is not a good inhibitor of human DNA polymerase, cells of the host are spared.
 - In patients with genital herpes infections, oral acyclovir can decrease the duration and severity of the initial episode and the frequency of lesion recurrence.
 - Although acyclovir reduces symptoms of genital herpes, the drug does not produce cure (ie, it does not eliminate the virus) and does not prevent transmission to sexual partners.
 - Acyclovir is eliminated unchanged by the kidneys. Accordingly, dosage must be reduced in patients with renal impairment.
 - Intravenous acyclovir can injure the kidneys. Renal damage can be minimized by infusing acyclovir slowly and by ensuring adequate hydration during and after the infusion.
-
- Ganciclovir is the drug of choice for prophylaxis and treatment of CMV infection in immunocompromised patients, including those with AIDS.
 - Ganciclovir does not cure CMV retinitis in patients with AIDS, and hence, in most cases, treatment must continue for life.

1084

1085

- Like acyclovir, ganciclovir becomes activated within infected cells, after which it inhibits viral DNA polymerase and causes premature termination of viral DNA strand growth.
- Like acyclovir, ganciclovir is excreted unchanged in the urine. Hence, dosage must be reduced in patients with renal impairment.
- The major adverse effects of ganciclovir are granulocytopenia and thrombocytopenia.
- Chronic hepatitis is caused primarily by HBV and HCV.
- Hepatitis B can be prevented by vaccination. There is no vaccine for hepatitis C.
- The treatment of choice for chronic hepatitis C is peginterferon alfa plus ribavirin.
- The principal adverse effects of interferon alfa are a flu-like syndrome and severe depression.
- Ribavirin is teratogenic and embryolethal, and can cause sperm abnormalities. Accordingly, the drug is contraindicated for use during pregnancy. Pregnancy must be avoided by women taking ribavirin, and by female partners of men taking the drug.
- Hepatitis B can be treated with interferon alfa or a nucleoside analog, such as lamivudine.
- Rarely, lamivudine causes lactic acidosis and severe hepatomegaly.
- Vaccination is the best way to prevent influenza.
- Because influenza viruses evolve rapidly, influenza vaccines must be reformulated each year, and persons wanting protection must receive the new vaccine each year.
- Two types of influenza vaccine are available: inactivated influenza vaccine (administered by IM injection) and live, attenuated influenza vaccine (administered by nasal spray).
- Amantadine, a member of the adamantane family, is used for prophylaxis and treatment of influenza A infections, but not influenza B infections.
- Resistance to amantadine can develop rapidly.

- In contrast to amantadine, the neuraminidase inhibitors—oseltamivir and zanamivir—are active against influenza A *and* influenza B.
- Resistance to neuraminidase inhibitors is rare.

93.5.2.3.2

Summary of Major Nursing Implications*

93.5.2.3.2.1

ACYCLOVIR

93.5.2.3.2....

Preadministration Assessment

93.5.2.3.2....

Therapeutic Goal

Treatment of infections caused by herpes simplex viruses and varicella-zoster virus.

93.5.2.3.2....

Identifying High-Risk Patients

Use with *caution* in patients with dehydration or renal impairment and in those taking other nephrotoxic drugs.

93.5.2.3.2....

Implementation: Administration

93.5.2.3.2....

Routes

Topical, oral, IV.

93.5.2.3.2....

Dosage

Oral and IV dosages must be reduced in patients with renal impairment.

93.5.2.3.2....

Administration

93.5.2.3.2....

Topical.

Advise patients to apply the drug with a finger cot or rubber glove to avoid viral transfer to other body sites or other people.

93.5.2.3.2....

Oral.

Dosages vary widely for different indications (see [Table 92-2](#)).

93.5.2.3.2....	Intravenous. Give by slow IV infusion (over 1 hour or more). Never administer by IV bolus.	
93.5.2.3.2....	Implementation: Measures to Enhance Therapeutic Effects Inform patients with herpes simplex genitalis that acyclovir only decreases symptoms; it does not eliminate the virus and does not produce cure. Advise patients to cleanse the affected area with soap and water 3 to 4 times a day, drying thoroughly after each wash. Advise patients to avoid all sexual contact while lesions are present, and to use a condom even when lesions are absent.	
93.5.2.3.2....	Ongoing Evaluation and Interventions	
93.5.2.3.2....	Evaluating Therapeutic Effects Observe for decreased clinical manifestations of herpes simplex and varicella-zoster infections. Virologic testing may also be performed.	
93.5.2.3.2....	Minimizing Adverse Effects	
93.5.2.3.2....	Nephrotoxicity. Intravenous acyclovir can precipitate in renal tubules, causing reversible kidney damage. To minimize risk, infuse acyclovir slowly and ensure adequate hydration during the infusion and for 2 hours after. Exercise caution in patients with pre-existing renal impairment and in those who are dehydrated or taking other nephrotoxic drugs.	1085 1086
93.5.2.3.2.2	GANCICLOVIR	
93.5.2.3.2....	Preadministration Assessment	
93.5.2.3.2....	Therapeutic Goal Treatment and prevention of CMV infection in immunocompromised patients, including those with AIDS and those taking immunosuppressive drugs following an organ transplant.	

93.5.2.3.2....

Baseline Data

Obtain a complete blood count and platelet count.

93.5.2.3.2....

Identifying High-Risk Patients

Ganciclovir is *contraindicated* during pregnancy and for patients with neutrophil counts below 500/mm³ or platelet counts below 25,000/mm³.

Use with *caution* in patients taking zidovudine or nephrotoxic drugs (eg, amphotericin B, cyclosporine) and in patients with a history of cytopenic reactions to other drugs.

93.5.2.3.2....

Implementation: Administration

93.5.2.3.2....

Routes

Oral, IV, intraocular.

93.5.2.3.2....

Dosage

Oral and IV dosages must be reduced in patients with renal impairment. AIDS patients with CMV retinitis must take ganciclovir for life.

93.5.2.3.2....

Administration

93.5.2.3.2....

Intravenous.

Give by slow IV infusion (over 1 hour or more). Ensure adequate hydration to promote renal excretion.

93.5.2.3.2....

Oral.

Advise patients to take oral ganciclovir with food.

93.5.2.3.2....

Intraocular Implants.

Surgical implants are replaced every 5 to 8 months.

93.5.2.3.2....

Ongoing Evaluation and Interventions

93.5.2.3.2....

Minimizing Adverse Effects

93.5.2.3.2....

Granulocytopenia and Thrombocytopenia.

Ganciclovir suppresses bone marrow function when given IV or PO. Obtain complete blood counts and platelet counts frequently. Discontinue ganciclovir if the neutrophil count falls below $500/\text{mm}^3$ or the platelet count falls below $25,000/\text{mm}^3$. The risk of granulocytopenia can be reduced by giving granulocyte colony-stimulating factors. The risk of granulocytopenia is increased by concurrent therapy with zidovudine (a drug for AIDS).

93.5.2.3.2....

Reproductive Toxicity.

In animals, ganciclovir is teratogenic and embryotoxic and suppresses spermatogenesis. Warn patients against becoming pregnant. Inform male patients about possible sterility.

* Patient education information is highlighted as blue text.

⁹⁴CHAPTER 93 Antiviral Agents II: Drugs for HIV Infection and Related Opportunistic Infections

JACK LE FROCK

RICH LEHNE

In this chapter we discuss drug therapy of infection with the *human immunodeficiency virus* (HIV), the microbe that causes *acquired immunodeficiency syndrome* (AIDS). HIV promotes immunodeficiency by killing CD4 T lymphocytes (CD4 T cells), which are key components of the immune system (see [Chapter 66](#)). As a result of HIV-induced immunodeficiency, patients are at risk of opportunistic infections and certain neoplasms.

It is important to appreciate that HIV infection is not synonymous with AIDS, which develops years after HIV infection is acquired. The definition of AIDS, established by the Centers for Disease Control and Prevention (CDC) in 1993, is a syndrome in which the individual is HIV positive and has either (1) CD4 T-cell counts below 200 cells/mL or (2) an AIDS-defining illness. Included in the CDC's long list of AIDS-defining illnesses are *Pneumocystis pneumonia*, cytomegalovirus retinitis, disseminated histoplasmosis, tuberculosis, and Kaposi's sarcoma.

Since being identified as a new disease in 1981, AIDS has become a global epidemic. In the United States, over 1 million people are now infected, and more than 560,000 have died. Worldwide, an estimated 33 million people are living with HIV and approximately 2.1 million have died, including 260,000 children in 2007. The economic costs of AIDS are staggering, and the personal and societal costs are incalculable.

Therapy of HIV infection has made dramatic advances. Today, standard *antiretroviral therapy* (ART) consists of three or four drugs. These combinations, often referred to as *HAART* (for *highly active antiretroviral therapy*), can decrease plasma HIV to levels that are undetectable with current technology, and can thereby delay or reverse loss of immune function, decrease certain AIDS-related complications, preserve health, and prolong life. In the United States, ART has reduced AIDS-related deaths by 72%—from a peak of 50,000 in 1995 to 14,000 in 2006. However, these benefits have not come without a price: ART is expensive, is often complex, poses a risk of long-term side effects and serious drug interactions, and, in most cases, must continue lifelong. Accordingly, if treatment is to succeed, patients must be highly motivated and well informed about all aspects of the treatment program. A strong support network is extremely valuable too.

ART cannot cure HIV infection. Although treatment can greatly reduce HIV levels—often rendering the virus undetectable—discontinuation has consistently been followed by a rebound in HIV replication. Because ART does not eliminate HIV, patients continue to be infectious and must be warned to avoid behaviors that can transmit the virus to others.

1087

Understanding this chapter requires a basic understanding of the immune system. Accordingly, you may find it helpful to read [Chapter 66](#) (Review of the Immune System) before proceeding.

1088

94.1 PATHOPHYSIOLOGY

94.1.1 Characteristics of HIV

HIV is a *retrovirus*. Like all other viruses, retroviruses lack the machinery needed for self-replication, and hence are obligate intracellular parasites. However, in contrast to other viruses, retroviruses have positive-sense, single-stranded RNA as their genetic material. Accordingly, in order to replicate, retroviruses must first transcribe their RNA into DNA. The enzyme employed for this process is viral *RNA-dependent DNA polymerase*, commonly known as *reverse transcriptase*. (The enzyme is called reverse transcriptase to distinguish it from DNA-dependent RNA polymerase, the host enzyme that transcribes DNA into RNA, which is the usual [“forward”] transcription process.) The name *retrovirus* is derived from the first two letters of *reverse* and *transcriptase*.

There are two types of HIV, referred to as HIV-1 and HIV-2. HIV-1 is found worldwide, whereas HIV-2 is found mainly in West Africa. Although HIV-1 and HIV-2 differ with respect to genetic makeup and antigenicity, they both cause similar disease syndromes. Not all drugs that are effective against HIV-1 are also effective against HIV-2.

94.1.1.1 Target Cells

The principal cells attacked by HIV are *CD4 T cells* (helper T lymphocytes). As discussed in [Chapter 66](#), these cells are essential components of the immune system. They are required for production of antibodies by B lymphocytes and for activation of cytolytic T lymphocytes. Accordingly, as HIV kills CD4 T cells, the immune system undergoes progressive decline. As a result, infected individuals become increasingly vulnerable to opportunistic infections, the major cause of death among people with AIDS. HIV targets CD4 T cells because the CD4 proteins on the surface of these cells provide points of attachment for HIV (see below). Without such a receptor, HIV would be unable to connect with and penetrate these cells. Once HIV has infected a CD4 T cell, the cell dies in about 1.25 days. It is important to appreciate

that only a few percent of CD4 T cells circulate in the blood; the vast majority reside in lymph nodes and other lymphoid tissues.
